EMFW software provides the calculated field values in a 3-D volume around the transmission line space. Fig. 2 shows the 3-D calculated electric field around the transmission line between the mid-span point and the tower location.

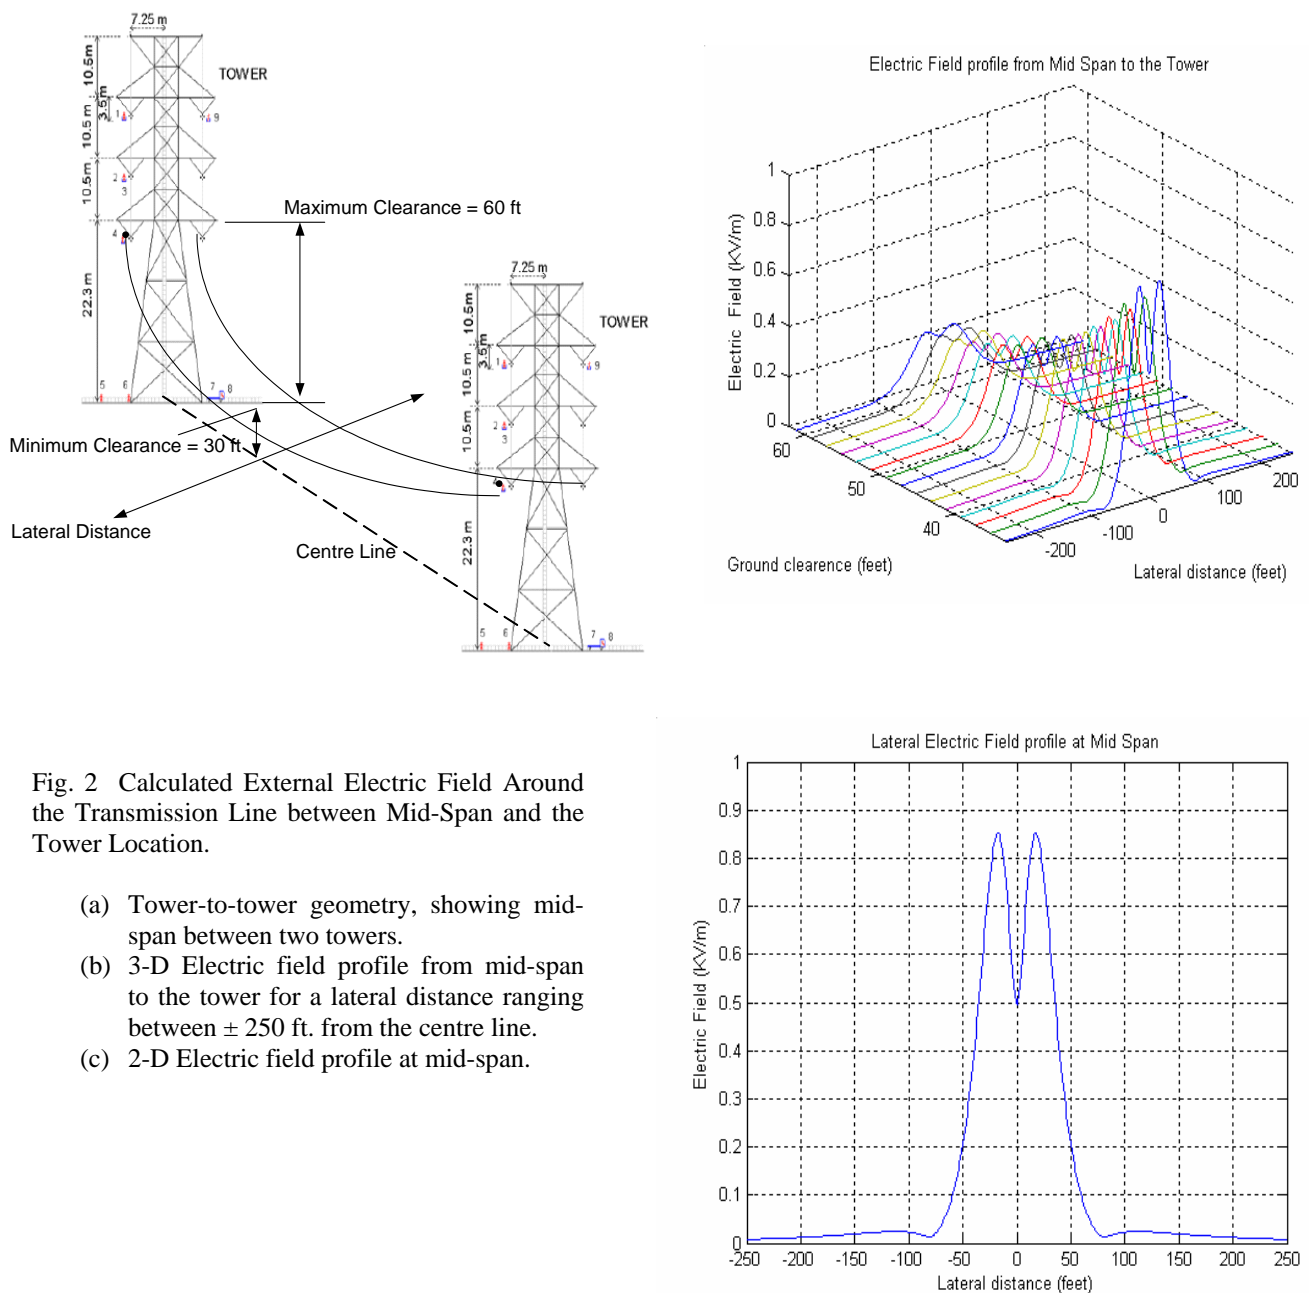

Fig. 2 Calculated External Electric Field Around the Transmission Line between Mid-Span and the Tower Location.

- Tower-to-tower geometry, showing mid-span between two towers.
- 3-D Electric field profile from mid-span to the tower for a lateral distance ranging between ± 250 ft. from the centre line.
- 2-D Electric field profile at mid-span.

The 2-D electric field profile shows that the calculated E field at the right of way is 0.165 kV/m. The E field decreases with increased distance from the centre line of the transmission line.

Similar behaviour is observed for the calculated magnetic field. This is shown in Fig. 3 (a and b).

Fig. 3 (a) 3-D Magnetic field profile from mid-span to the tower for a lateral distance between ± 250 ft.
(b) 2-D Magnetic field profile at mid-span.

The results shown in the 2-D profile indicate that the magnetic field value at the right of way is 10 mG, which is far below the standards set by the IEEE, ICNIRP and NRPB. The maximum calculated magnetic field at the right of way is 21.4 mG, which is still far lower than all the standards set for the general public exposure.

Comparison to the International Standards

The calculated electric and magnetic field exposure levels are compared to the universal standards such as IEEE Standard C95.6 [2], ICNIRP guidelines [3], and NRPB [4]. The comparison is given in table 3. The IEEE Standard C95.6 recommends limits on exposures to electric and magnetic fields in the frequency range of 0 to 3000 hertz (Hz).

TABLE 3
COMPARISON OF THE CALCULATED FIELDS AT THE RIGHT OF WAY TO THE INTERNATIONAL STANDARDS

Organization	E (kV/m)	$B \times 10^4$ (mG)
IEEE	5	0.833
ICNIRP	4.2	0.1
NRPB	12	1.3
ACGIH	No specific standard for general public.	
At ground level(ROW)	0.165	0.00214

The highest electric field exposure level computed at the right of way (ROW) is 0.165 kV/m. However, the Maximum Permissible Exposure (MPE) for the power frequency electric field as per the IEEE Standard C95.6 is 5 kV/m for a controlled (occupational) environment. The maximum permissible level according to the ICNIRP guidelines for occupational exposure is 4.2 kV/m. The limit according to the NRPB Guidelines for Exposure to 60 Hz EMF is 12 kV/m.

The maximum magnetic field computed at the right of way is 21.4 mG. However, the Maximum Permissible Exposure for the power frequency magnetic field by the general public as per the IEEE Standard is 0.833×10^4 mG. The maximum permissible level according to the conservative standard ICNIRP guidelines is 0.1×10^4 mG. The limit according to the NRPB for Exposure to 60 Hz EMF is 1.3×10^4 mG. There are no limits set by the ACGIH for the general public.

The highest electric and magnetic fields exposure level for the SEC 132 kV transmission line, therefore, is well below the limits set by the different standards for general public exposure.

Conclusion

The exposure of the general public to the electric and magnetic fields associated with a 132 kV HV transmission line has been evaluated. The EPRI's EMF Workstation software has been used to calculate the external electric and magnetic fields due to the 132 kV high voltage transmission line at ground level and for distances starting from the right of way of the transmission line. Comparison of the values of external electric and magnetic fields, with the allowable limits set by international standards reveals that the level of exposure of the general public to extremely low frequency electric and magnetic fields are well below the limits recommended by these international standards.

Abstract

Background: Recent studies suggest that about 10-15% of the adult population experiences tinnitus. As there are indications that mobile phone use could be a risk factor for the occurrence of tinnitus, we performed a case-control study on this issue.

Methods: One hundred patients presenting with tinnitus at the Ear-Nose-Throat (ENT) Department of the Medical University of Vienna were enrolled into the study. For each case a control subject was randomly selected matched for sex and age with various diagnoses not related to tinnitus. A standardized questionnaire (based on the protocol of the Interphone study) was answered by study participants. Patients' history was obtained and clinical examinations were conducted to exclude known underlying causes of tinnitus. Only patients were included that were negative in this respect and therefore suffered from "idiopathic" tinnitus. Odds ratios were computed based on conditional logistic regression with age, sex, years of education, and living in an urban area as covariates.

Results: Mobile phone use was highly prevalent in cases as well as controls (>90%). Concerning mobile phone use up to the index date (onset of tinnitus) neither regular use nor intensity or cumulative hours of use had a significant effect. However, prolonged use (four years or more) of a mobile phone was associated with a significant odds ratio of 1.95 (CI 1.003-3.80).

Conclusions: There could be an association between mobile phone use and the occurrence of tinnitus with a latency of several years.

Introduction

Subjective tinnitus (tinnitus aurium) is defined as a sound sensation that cannot be attributed to an external sound source. It is a symptom of different underlying diseases, not a disease itself. The numerous mechanisms that produce tinnitus are not fully known and associated with nearly all diseases and disorders of the ear (middle ear, inner ear) and retrocochlear disease also causing hearing loss. Different hypotheses explain the various pathophysiological aspects of tinnitus [1]. Tinnitus seems to be generated predominantly in the primary afferent synapses of the cochlea [2,3], but leads to a cortical reorganisation [3]. Tinnitus is experienced by the patients either uni- or bilateral as a sound in the ear/head of varying quality (e.g. roaring, hissing, ringing); it may occur of non-pulsatile or pulsatile character, the latter may be due to vascular pathology.

Most often tinnitus sensation is intermittent and sometimes associated with specific conditions - such as listening to loud music, fever, use of aspirin or quinine, or transient perturbations of the middle ear - and subsides over a period of time ranging from a few seconds to a few days. Studies indicate that the prevalence of tinnitus in adults falls in the range of 10-15% [4-6].

At least in 1-3% of the general population tinnitus affects the quality of life, involving sleep disturbance, work impairment and psychic distress [7].

Tinnitus is more common in the elderly but may also occur in children. It could become more common in the future as a direct consequence of the rise in recreational-noise-induced hearing loss (i.e. from overly loud music) combined with an increased life span. Due to the various pathophysiological mechanisms of tinnitus, therapy is problematic, and evidence-based therapeutic interventions are rare. There currently are very few interventions available that reduce tinnitus loudness and annoyance effectively [8]. Therefore it is important to focus research on possible (environmental) risk factors.

During the last years the habit to extensively use mobile telephones has emerged, such that the majority of the population of Western and Middle-European countries are regularly using these phones. There are concerns that mobile telecommunication could be a possible risk factor for the occurrence of tinnitus (complaints of patients to environmental out-patient departments, neighbours of basestations [e.g.9]). However, up to now there have been no systematic investigations of this problem.

Our study should provide first answers to the question whether or not intensive use of mobile phones increases the risk of tinnitus occurrence.

Methods

Study design and participants

The study was carried out as a hospital-based case-control study at the Ear-Nose-Throat (ENT) Department Medical University of Vienna, Austria. Cases were enrolled consecutively as they presented at the out-patient unit. For each case a control was selected from the same department, of the same age group ($\pm 2,5$ years < 55 years; ± 5 years > 55 years), the same sex and ethnic group. Exclusion criteria were diseases of the middle ear, status post middle ear surgery, retrocochlear disease, severe psychiatric and systemic diseases and medication with drugs that can influence tinnitus (ototoxic or psychopharmacological drugs). Patients with acute and chronic tinnitus who attended the ENT department (age 16 to 80 years) were included.

Controls were patients without any concomitant condition that is related to tinnitus (except for unspecific causes such as hypertension).

Diagnostics/investigation procedure

For the selection of patients, the diagnostic test battery contained the following procedures

- careful history with special regard to tinnitus and its risk factors
- clinical ENT examination with otomicroscopy
- pure-tone and speech audiogram
- tympanogram and testing of the stapedius reflex
- subjective rating of the tinnitus
- tinnitus matching
- MRI (if indicated, to exclude retrocochlear pathology)

Each case that was enrolled received a standardized questionnaire (Structured Tinnitus Interview, STI [8]). Items refer to central characteristics of tinnitus history, etiological factors and tinnitus-related psychological complaints. In addition, a medical interview was conducted. Patients' history and clinical examination concerning possible underlying causes of tinnitus were obtained by usual clinical procedures. For each patient a CRF (Case Report Form) was compiled that was maintained according to GCP (Good Clinical Practice) guidelines.

Pure-tone and speech audiometry (Clinical Audiometer AC 40, Interacoustics©) were applied in order to exclude tinnitus related to sudden deafness and Morbus Menière. Tympanometry and stapedius reflex measurements (Impedanz Audiometer AZ 26, Interacoustics©) were carried out in order to exclude tinnitus related to conductive hearing loss. If retrocochlear hearing loss was suspected, cranial MRI was applied.

For the evaluation of tinnitus, both a subjective rating of the tinnitus on a five-point scale (0 = no tinnitus; 1 = slight; 2 = moderate; 3 = severe; 4 = tormenting tinnitus) and a tinnitus matching as a psychoacoustic measurement of tinnitus were carried out.

The audiometric tinnitus simulation test (= tinnitus matching) (Clinical Audiometer AC 40, Interacoustics©) determined character (pure-tone, narrow and wide band), frequency and intensity of the tinnitus. Tinnitus matching was performed contralaterally.

With the help of this procedure tinnitus subtypes (esp. temporo-mandibular joint dysfunction related tinnitus, cervical tinnitus, acute tinnitus/sudden deafness/noise trauma, suspected cochlear-synaptic tinnitus) could be identified. This information was used to exclude patients with known underlying pathophysiology.

For the exploration of the mobile phone habits we used a standardized questionnaire (based on the protocol of the Interphone Study of the WHO). In short, for each mobile phone the subject used or has used, the type of phone, duration and intensity of use, side of the head the phone was predominantly held, use of head sets, use in urban/rural areas and in cars was assessed. In addition, to assess individual microwave exposure for future investigations we took two photos of the participants while using a mobile phone in typical position. Furthermore, somatometry of the head was performed on specific anthropogenic diameters (e.g. tragus - tragus, binauricular diameter) with a calliper.

Statistical Methods

Data on mobile phone use were censored at the date of first occurrence of tinnitus. Index date of controls was the occurrence of tinnitus in the matched case. Intensity of use, cumulative number and duration of calls were categorized based on the distribution of these variables in controls: The median (excluding never users) was chosen as cut-off. Reference category was never use of a mobile phone (prior to index date). In all cases data on mobile phone use were adjusted for the use of hands-free devices. Further adjustments were applied for the side of the head of predominant use. Mobile phone use was only counted if it occurred on the same side of the head as the tinnitus (controls were assigned the side of the matched case). Duration of mobile phone use was categorized into three groups: never use or use for less than one year (reference), 1 to 4 years, and longer than 4 years.

Conditional logistic regression analyses for individually-matched data were used to estimate odds ratios and 95% confidence intervals. All analyses were adjusted for gender, age, years of education (less than and 12 years or more) and living in an urban area.

Results

Subjects' characteristics were comparable in cases and controls (table 1). Due to matching for gender and age these variables were in agreement, but also other personal characteristics did not differ significantly between cases and controls. There was a slight tendency for a somewhat higher socio-economic status (SES) implied by the higher education, higher rate of white collar workers and urban residents in controls.

Table 1. Demographic characteristics of cases and controls⁺⁾ . p-value for comparison of non-matching variables.

	Cases	Controls	p-value

no	23	18	

⁺⁾ Percentages not summing up to 100 due to missing values

Almost all subjects at time of inquiry used a mobile phone (92% and 93% for cases and controls, respectively), however, at the time of first occurrence of tinnitus (and the respective index date in controls) only 73% of cases and 67% of controls were using a mobile. Another 7% of cases and 8% of controls used the mobile at that time for less than one year. For ever users prior to occurrence of tinnitus there was a slightly but not significantly increased odds-ratio of 1.37 (95% CI: 0.73-2.57). Moderate increases of odds-ratios were noted for all variables of intensity of use: average daily duration of use for 10 minutes or more was associated with an odds-ratio of 1.71 (95% CI: 0.85-3.45), cumulative hours of use of 160 or more gave an odds ratio of 1.57 (95% CI: 0.78-3.19), cumulative number of calls in excess of 4000 an odds-ratio of 1.28 that was less than for lower number of calls (odds-ratio 1.46) possibly indicating greater importance of duration as compared to number of calls. A borderline significant result was obtained for duration of use of 4 or more years: odds-ratio 1.95 (95% CI: 1.003-3.80). Test of trend for duration of use was also significant ($p=0.046$).

Discussion

The prevalence of tinnitus has increased over the past decade and is currently 10-15% in industrialized countries [7]. Increase in incidence may be due to better diagnostic tools and increased awareness of the disease; however, a number of environmental factors have been implicated to increase the risk of tinnitus. The suspected factors include electromagnetic fields emitted by hand-held cellular telephones.

Since the majority of the population is using mobile phones more or less intensively people were concerned about effects on wellbeing [11,12]. Practitioners are confronted with reports of sensation of tinnitus related to mobile phone use by their patients [13].

In our study slight increases in risk were noted for all variables of intensity of use. The study was designed to detect a twofold increase of risk with 80 percent power. Further investigations esp. multicenter designs will be more efficient to detect these moderately increased risks. Because of the high prevalence of tinnitus and the widespread use of mobile phones even a small enhancement of the risk could be of public health importance.

From a theoretical point of view this possible association of mobile phone use and occurrence of tinnitus has some plausibility, because the cochlea is located in an anatomic region where a considerable amount of the power emitted by cell phones is absorbed [14]. One etiologic factor for tinnitus is calcium imbalance in the neural acoustic pathway. It is well known that exposure to modulated high-frequency electromagnetic fields (HF-EMF) has the potential to affect calcium homeostasis especially in neural tissue [15].

Because some mobile telephones (especially newer types) cause rather high exposure of the cochlea [14] and along the acoustic pathway it is possible that tinnitus could be caused by calcium efflux. Effects of exposure on calcium homeostasis was also implied as one factors in the development of acoustic neuroma. Ten studies [16-25] investigating the association between mobile phone use and acoustic neuroma have been published so far.

Half of these studies found indications of an association [21-25], the other 5 were those with shorter duration of mobile phone use and/or smaller number of long-term users of a mobile [16-20].

Tinnitus strongly interferes with the daily lives of people. In industrialized countries, 10-15% of the adult population currently experience tinnitus. There are very few interventions available that effectively reduce tinnitus loudness and annoyance. Therefore, all measures should be taken to avoid further increase of tinnitus prevalence.

Results indicate that high intensity and long duration of mobile phone use might be associated with occurrence of tinnitus. As more persons start using mobile phones at younger age, this indeed may become a public health problem.

HIROSAKI UNIVERSITY, HIROSAKI, AOMORI, 036-8564, JAPAN

Abstract

High-frequency electromagnetic fields (HFEMF) used for mobile phones may be of great concern for human health. In order to investigate the properties of HFEMF, we have examined the genotoxic effects of 2.45 GHz EMF on micronucleus (MN) formation, DNA strand breaks, and chromosomal aberrations in cultured cells. Chinese hamster ovary (CHO)-K1, human glioma MO54, and mouse m5S cells, respectively, were used in these experiments for MN formation, DNA strand breaks, and chromosomal aberration. The DNA strand breaks were detected using an alkaline comet assay. Cells were exposed to HFEMF for 2 h at average specific absorption rates (SARs) from 5 to 200 W/kg, and the effects on these cells were compared with those in sham-exposed cells. Heat treatment as a heat control was performed at temperatures of 37 to 44°C. MN frequency at SAR of lower than 50 W/kg did not differ from the sham-exposed controls, while MN frequency at SARs of 100 and 200 W/kg was significantly higher. No significant differences in the DNA strand breaks and the chromosomal aberrations were observed following exposure to HFEMF from 5 to 200 W/kg, compared with sham-exposed control. In summary, HFEMF exposure at 2.45 GHz for 2 h up to SAR of 50 W/kg does not induce MN formation, DNA strand breaks and chromosomal aberrations.

Introduction

In recent years there has been a rapid increase in the use of devices and systems employing high-frequency electromagnetic fields (HFEMF) in our lives, including radio and TV transmitters, microwave ovens, telecommunication links, and satellite communications, as well as mobile phones and their supporting transmitters (base stations). Thus exposure to HFEMF in the environment is greater than any of the former ages of human. A consequent result of this has been increased concern about the association between environmental exposure to HFEMF and cancer. Although several theoretical models have been proposed [1-3], the association between HFEMF and cancer remains unclear.

General concerns regarding the potential hazards of exposure to HFEMF have led to many epidemiological investigations [4-6]. Several studies have suggested that exposure to HFEMF can interact with behavior [7, 8]. *In vitro* studies have reported the effects of HFEMF on several end-points, including effects on DNA damage [9], chromosome aberrations [10], mutation [11], cell transformation [12] and gene expression [13]. In these studies, cells were typically subjected to exposures as low as specific absorption rates (SARs) of 10 W/kg to estimate the

Effects of 2.45 GHz Electromagnetic Fields with a Wide Range of SAR on Cellular Genotoxicity in Cultured Cells

Junji Miyakoshi, Shin Koyama, Yoshiki Komatsubara, Jin Wang, Tomonori Sakurai

risk of weak HFEMF that we are actually exposed to daily, since this is the final goal of these studies. However, exposures to a higher intensity are also necessary to explore the effects of HFEMF for safety evaluation. We have previously reported that exposure to 2.45 GHz electromagnetic fields for 2-16 h induced Hsp70 in human glioma MO54 cells [14], and exposure to HFEMF at 100 W/kg did not cause any DNA damage according to the comet assay system [15]. HFEMF at high SAR mainly results in heating of the cells. Heat is known to cause many biological changes and the heating effect of HFEMF is well established [16]. However, there have been claims that HFEMF could exert non-thermal effects on biological systems. Hence, with exposure conditions used in these experiments it becomes very important to establish the differences between thermal and non-thermal effects.

Considering these previous data, we have examined the frequency of micronucleus (MN) formation in Chinese hamster ovary (CHO)-K1 cells following HFEMF exposure. MN formation is derived from clastogenic activity arising from chromosomal fragments that are not incorporated into daughter nuclei at mitosis. This occurs because of the lack of a kinetochore. MN formation is also derived from an aneuploid process when the whole chromosome is not correctly integrated into the two daughter nuclei at the time of cell division [17-20]. In the present study, we also examined the presence or absence of single-strand DNA breaks and chromosomal aberrations in mammalian cells exposed to 2.45 GHz HFEMFs with a wide range of SAR (5 W/kg to 200 W/kg) in human glioma MO54 and mouse m5S cells, respectively.

Materials and methods

1. Exposure system

The exposure system of HFEMF was described elsewhere [21-23]. In brief, the applicator is based on a rectangular waveguide, with its size determined to be 110 mm (wide) × 55 mm (high) × 310 mm (deep). The electromagnetic waves are propagated along the waveguide in TE₁₀ mode. One end of the applicator is terminated with a short-circuiting plate to generate standing waves in the waveguide.

A rectangular culture dish is placed on two slits, which were bored into the wider wall of the waveguide. The cells in the dish are exposed to the HFEMF through these slits. The two slits are pinch shaped, which enhances the coupling of the electromagnetic field to increase the effective exposure area. The culture dish is divided into four compartments. The distribution of the electric field in the medium depends on the thickness of the medium. Therefore, it is preferable to choose a thickness that maximizes the SAR at the bottom of the well, where the cells are present. Numerical analysis indicates that the appropriate thickness is 8 mm, which corresponds to a half wavelength in the medium.

The SAR distribution in the exposure apparatus was calculated using the Finite Difference Time Domain (FDTD) method. In each compartment has a different value of SAR. The maximum SAR appears in compartment 3. The maximum SAR values in compartment 2 and 4 are 80% and 85% of the maximum SAR value in compartment 3. The minimum SAR in compartment 1 is 1% of the maximum value.

2. Cells and culture conditions

CHO-K1 cells were obtained from the Japanese Cancer Research Bank, Tokyo. Cells were maintained in Ham's F-12 medium (Nikken Bio Medical Laboratory, Kyoto, Japan) supplemented with 10% fetal bovine serum (Gibco, BRL) at 37°C in 95% air and 5% CO₂ [21].

MO54 cells, derived from a human malignant glioma, were used in this study. Cells were cultured in Dulbecco's modified Eagle's medium (Nikkenn Bio Medical Laboratory) supplemented with 10% fetal bovine serum (GIBCO, BRL) at 37°C in an atmosphere of 95% air and 5% CO₂ [22].

Mouse m5S cells are a near-diploid cell line established from embryonic skin; they are immortalized but non-tumorigenic [24]. The cells were grown as monolayers in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum (BioWest, Rue de la Caille 49340 Nuail, br, France) at 37°C in an atmosphere of 95% air and 5% CO₂ [23].

3. MN analysis

After a 2 h exposure to HFEMF, the cells were trypsinized and seeded in 10 cm culture dishes in medium containing cytochalasin B at a final concentration of 3 µg/ml for 18 h, in order to prevent cell division. A sham-exposure experiment was performed as a negative control. Cells were treated in the same way to those that underwent HFEMF exposure, except that HFEMF exposure itself was omitted. Instead, the cells were incubated for 2 h in a conventional incubator. In addition, the cells were treated with bleomycin alone as a positive control, using the same conditions as those used for sham exposure.

The cells were collected at a concentration of 2.7×10^4 cells/ml, and samples of 0.2 ml were centrifuged onto slides, using a Cytospin centrifuge (Shandon Southern Ltd.) at $100 \times g$ for 5 min. The cells were then fixed with 80% cold ethanol for 30 min. The slides were washed gently with PBS and soaked in new PBS for 5 min to

completely remove the ethanol.

The cells on the slides were stained with 20 μ l of propidium iodide (PI) diluted in glycerol (to a concentration of 0.2 μ g/ml), and kept in the dark until counting was performed. A total of 1000 binucleated cells were scored for evaluation of the frequency of induction of MN, using fluorescence microscopy (Olympus). Cells were counted as having MN formation when they contained at least one micronucleus. The procedure was performed in a double-blind manner, and followed the method described by Countryman and Heddle [20]. Statistical analysis of the data in the control and experimental groups was conducted using ANOVA (analysis of variance) followed by Fisher's Protected Least Significant Difference (PLSD) test.

4. Comet assay

To detect DNA damage at the single-cell level, an alkaline comet assay was performed. The method of the comet assay has been described previously [25]. In brief, we used a Trevigen Comet Assay system (Trevigen, Inc., Gaithersburg, MD). After the treatments, the cells were rinsed with phosphate-buffered saline (Ca^{++} and Mg^{++} free; PBS) and treated with trypsin. Cell suspension in 1 \times PBS on ice was mixed with low melting agarose at 37 °C (cell suspension : agarose = 1 : 8). The mixture of cell suspension and agarose was kept on a slide in the dark at 4 °C, underwent 5 minutes of fixation, and was then immersed in a lysis solution at 4°C for 40 min. The slide was placed in the alkali buffer for 15 minutes. Electrophoresis was performed as reported previously [26]. After the electrophoresis, the samples were fixed in ethanol for 5min and then dried. DNA in agarose was stained with SYBR Green according to the manufacturer's recommended procedure.

DNA Strand breaks were analyzed by using IDL Comet 6.0 (Adamnet, Tokyo, Japan). Tail length is the distance from the first non-zero element to the last non-zero elements in tail content. Tail content was calculated as the integrated value of the fluorescent brightness of the total comet minus the integrated value of the fluorescent brightness of the comet head. The unit of the parameter is given as "pixels". The tail length is the distance between the first and last non-zero elements in the tail content. The tail moment was calculated according to the following equation:

Tail moment = Differential between means \times % in tail.

For a statistical evaluation of the tail moment, tail length, and tail percent, An analysis of variance (ANOVA) test was used to determine any inter-group differences. When a significant *F* value was found ($p < 0.05$), the Bonferroni/Dunn test was used for a multiple comparison. *P*-value that were less than 0.05 were considered statistically significant.

5. Chromosomal aberrations

After exposure, the cells were removed and cultured in a conventional incubator for 24 h. Colcemid (0.1 μ g/mL, Sigma) was added during the last 4 h. Unexposed control cells were incubated for the same period in a conventional incubator. Chromosome preparations were made according to the standard air-drying method and stained with 3% Giemsa solution (pH 6.4). For each culture, a minimum of 200 cells was assessed for the types and frequencies of chromosomal aberrations; all structural chromatid-type and chromosome-type changes, including gaps, were recorded. The scoring was conducted in a double-blind manner.

The experimental data are presented as the mean \pm S.E.M. *Chi* square tests were performed to determine whether there was a significant difference in the proportion of cells with aberrations between the cells exposed to HFEMF and unexposed cells. The statistics were calculated either including or excluding gaps.

Results

1. MN formation

There was no increase in MN formation in cells exposed to HFEMF at SAR from 5 to 50 W/kg. However, the frequency of MN formation in cells exposed to HFEMF at SAR of 100 and 200 W/kg was statistically significantly different to that observed following sham-exposure (Fig. 1). The frequency of MN formation following treatment with bleomycin alone was statistically higher, compared with the sham-exposed control (Fig. 1). Although there was no increase in MN formation in cells treated with a combination of bleomycin and HFEMF exposure at SAR from 5 to 100 W/kg, there was a statistically significant difference in MN formation between treatment with bleomycin alone and combined treatment with bleomycin and HFEMF exposure at a SAR of 200 W/kg.

The frequency of MN formation with heat treatment increased in a temperature-dependent manner. However, there was no difference between bleomycin-treated cells and cells treated with a combination of heat and bleomycin for temperatures from 38 to 41°C (data not shown).

Figure 1. The frequency of MN formation in CHO-K1 cells exposed to HFEMF with or without bleomycin, compared to that following sham-exposure. The bars show standard deviations, based on three experiments. An asterisk indicates a statistically significant difference between sham-exposure and HFEMF exposure ($p<0.01$). A sharp indicates a statistically significant difference between treatment with bleomycin alone and combined treatment with HFEMF exposure and bleomycin ($p<0.01$).

2. DNA strand breaks

No significant difference in tail moment was seen for each exposure condition at SAR levels from 5 W/kg to 200 W/kg (Table 1).

Table 1 Comparison of Comet Parameters in MO54 Cells Exposed to 2.45GHz Continuous-Wave HFEMF, Sham and 100 μ g/mL bleomycin

Exposure Condition	Sham	5 W/kg	10 W/kg	20 W/kg	50 W/kg	100 W/kg	200 W/kg	Bleomycin
Tail Moment	406.6 \pm 113.2	365.1 \pm 13.9	425.1 \pm 30.5	353.2 \pm 44.0	372.3 \pm 83.7	335.6 \pm 53.9	432.6 \pm 70.4	2071.9 \pm 419.8 *
Tail Length	54.7 \pm 23.6	76.0 \pm 8.5	80.3 \pm 13.8	68.6 \pm 25.4	61.2 \pm 18.5	48.5 \pm 3.9	53.9 \pm 3.6	118.9 \pm 41.1 *
Tail Percent	24.5 \pm 5.1	24.6 \pm 1.1	25.2 \pm 5.2	24.8 \pm 0.8	24.3 \pm 2.6	22.7 \pm 3.2	25.0 \pm 3.2	40.1 \pm 9.7 *

Data are presented as the mean \pm standard deviation, based on three experiment.

The units of each parameter are Tail moment = arbitrary unit, Tail length – pixel, and Tail percent - %.

*Significantly different (at $p<0.01$) from Sham, HFEMF exposure and heat treatment groups.

No significant differences were observed in tail moment for each of the treatment conditions with sham and heating at 39 - 44°C. No cell killing was observed after the HFEMF exposure at the SARs of 5, 10, 20, 50 and 100 W/kg, while cell viability was slightly decreased at 200 W/kg ($83.4 \pm 4.9\%$ (data not shown), No significant difference vs Control). No cell killing was also observed immediately after heat treatment at 39 and 41°C and the treatment with bleomycin. The cell viability at 44°C was decreased ($77.1 \pm 2.5\%$, $p < 0.01$, Significantly different vs Control).

3. Chromosomal aberrations

A summary of chromosomal aberration data is showed in Table 2.

Table 2 Chromosomal aberration in m5S cells after treatment with HFEMF, MMC, or X-rays

Treatment	No. of cells analysed	Chromatid-type				Chromosome type				Aberrations/100 cells		%Aberrant Cells	
		ctg	csg	ctb	cte	Frag	Min	Dic	Ring	Total	Excl	Total	Excl
Sham	200	3	0	0	0	1	1	0	0	2.5	1	2.5	1
5 W/kg	200	2	0	2	0	0	0	0	0	2	1	2	1
10 W/kg	200	0	0	0	0	0	0	1	0	0.5	0.5	0.5	0.5
20 W/kg	200	1	0	0	0	0	0	0	0	0.5	0	0.5	0
50 W/kg	200	1	1	0	2	0	0	0	0	2	0.5	2	1
100 W/kg	200	1	0	1	1	0	2	0	0	2.5	1	2.5	2
MMC (0.1 μ g/mL)	200	4	0	11	78	2	3	1	1	50	43.5	44.5	43.5
X-rays (3 Gy)	200	4	1	5	14	4	18	4	0	25	19	21.5	19

ctb= chromatid breaks, csg= isochromatid gaps, cte= chromatid exchanges.

Isochromatid breaks (csb) were included in acentric fragments (Frag).

Min=minute chromosomes, Dic dicentrics. Excl=excluding gaps.

The rate of incidence of chromosomal aberrations was less than 0.02. No differences were observed between control and HFEMF exposure. The frequency of chromosomal aberration appearance is less than 2.5% between 5 W/kg to 100 W/kg HFEMF exposures. In contrast, X-rays and MMC treatment resulted in chromosomal aberrations in 45% and 20% of the cells, respectively. Results obtained by chromatid and chromosome aberration analysis did not exhibit any statistically significant differences between sham control and HFEMF exposure conditions from 5 W/kg to 100 W/kg. As expected, MMC and X-ray treatment significantly increased ($p < 0.001$) the frequency of chromosomal aberration, chromatid aberration and total chromosomal aberration compared with sham controls.

Conclusions

In conclusion, HFEMF exposure at 2.45 GHz for 2 h up to SAR of 50 W/kg does not induce MN formation. We did not detect the increase in DNA strand breaks and chromosomal aberrations, even at 100 W/kg. For the MN formation, there were statistically significant increases at SARs of 100 and 200 W/kg, compared with the sham-exposed control. However, we also observed that the temperature elevation induced the increased MN formation. Although more research is required, the present study has shown that MN formation at SAR from 5-200 W/kg is connected to temperature raise caused by HFEMF.

In addition, we have reported the effect of HFEMF on cell growth rate, cell cycle distribution, Transformation, and heat-shock protein (hsp) expression. Cell growth rate and cell cycle distribution were not affected by exposure to HFEMF at SAR of lower than 100 W/kg for 2 h [27]. No significant differences were observed in the malignant transformation (Type II + Type III) frequency between the sham-control and the HFEMF at SARs of 5 to 200 W/kg for 2 h [28]. The expression of hsp70 increased in a time and dose-dependent manner at SAR of over 50 W/kg for 1-3 h [29]. However, a similar effect was also observed in corresponding heat controls.

From these results, we considered that HFEMF exposure at 2.45 GHz for 2 h did not affect cell growth, cellular genotoxicity, cell transformation, and hsp70 expression, even at exposure level of 5 to 50 W/kg. Therefore, we can conclude that our investigations have indicate the absence of any relationship between

exposure to the HFEMF at an environmental level and adverse health effect. However, experiments should still be performed to evaluate the safety of the HFEMF exposures.

Acknowledgments

We thank Drs. M. Taki and Y. Suzuki (Tokyo Metropolitan University, Japan) for the supply of HFEMF exposure system. This work was supported in part by the committee to Promote Research on the Possible Biological Effects of Electromagnetic Fields, Ministry of Public Management, Ministry of Internal Affairs and Communications, Japan.

ABSTRACT

We justify the validity of the biexponential Debye relaxation model of the pure water extrapolated until the optical range by means of experiments results obtained on the human skin. The pure water attenuation per wavelength is maximum in the millimeter-wave range. We confirm the measurements which have shown appreciable AC conductivity of DNA due to relaxation losses of their surrounding water dipoles. We extend this property to the UV range showing the action of photons upon free electrons. Excited ions, by means of our external plasma device generator of solitary-waves is the object of photon emissions in the optical range. In particular in UV range the free electron alone is liable to be propelled by a photon with a kinetic energy with a some idea of the size to 10^{-23} Joules. In a large range until millimeter waves, the excited ions can attract electrons showing a kinetic energy of 10^{-21} Joules. They can be used to activate control and explain the division of fibroblasts and the cancer mechanisms of human skin, the main modification of DNA molecules by UV radiation being the formation of pyrimidine dimers. Finally we can conclude that the molecule of DNA has a conducting which is always increasing with the frequency, but can be considered as a real conductor only in the millimeter-wave range with an important absorption per wavelength. The “conduction quality” is the ratio of the conduction to the displacement currents.

INTRODUCTION

PRELIMINARY CLARIFICATION

The electronic conduction in DNA is a polemic subject always going on nowadays. Is DNA conductive or not ? DNA has been reported to be a metal, a semiconductor, an insulator and even a proximity effect induced superconductor. Above all it was advisable to go back to some reminders. In a recent paper [1] it as been shown that appreciable AC conductivity of DNA, measured in the millimeter wave range, is largely ascribed to relaxational losses of the surrounding water dipoles. So it was necessary from the theoretical complex dielectric constant $\tilde{\epsilon}_r = \epsilon_r - j\sigma/\omega\epsilon_0$ of bulk pure water, described by a biexponential Debye relaxation model [2], to calculate its conductivity σ , and the coefficient of absorption A given by the classical expression :

$$A \text{ (Neper } / \lambda_o) = 2\pi \left[-\frac{\epsilon_r}{2} + \frac{1}{2} \sqrt{\epsilon_r^2 + (\sigma / \omega \epsilon_o)^2} \right]^{1/2} = \frac{\lambda_o}{\delta} \quad (1)$$

δ is the thickness penetration and λ_o the free space wavelength.

We introduced the “conduction quality” C_p which is the ratio of the conduction to the displacement currents equal to :

$$C_p = \sigma / 2\pi f \epsilon_o \epsilon_r \quad (2)$$

The **Table I** shows the various parameters in terms of the frequency for the pure water at 20 °C. We can conclude :

- The conductivity σ is increasing with the frequency.
- The absorption coefficient $A(N/\lambda_o)$ has a maximum in the millimeter range (N means Nepers : 1N = 8.69 dB).
- The absorption per unit of length (dB/mm) is increasing with the frequency.
- In the millimeter wave range the water can be considered as a “conductive medium” ($C_p > 1$), and as an insulator medium ($C_p < 1$) when $f < 2.10^{10}$ Hz or $f > 2.10^{11}$ Hz. Nevertheless its conductivity σ is always increasing with the frequency.
- We can justify the values of the conductivity and the absorption in the UV range deduced from the experiments realized on the epidermis. The epidermis is composed, from the skin surface to the depth, by the stratum corneum, the stratum granulosum, the stratum spinosum and the stratum basale. Due to the water content of the cells we can put together the three later layers ; we call them mucus body.

The **Table II** shows the values extracted from measurements upon the human skin which must be compared with these given in **Table I**.

The range UV is separated into two ranges : UVA and UVB. For each of them, and from the measured transmission coefficient [18], we deduced the conductivity σ and the absorption related to the stratum corneum and the mucus body. We note that the bulk water theoretical conductivity is comprised between those of the stratum corneum and mucus body.

CHARGE TRANSPORT IN SYNTHETIC DNA

The denaturation of the DNA is due to the breaking of the hydrogen bonds, which keep in position the two strands (fig. 1).

In the course of the DNA duplication, two complementary strands give birth to two new DNA molecules. The DNA macromolecule structure was introduced in 1953 by Watson and Crick.

Electronic transport along DNA is crucial for the repair mechanism after radiation damage and biosynthesis [3]. In 1989 Peyrard-Bishop study the structure by means of global energies expressed with a Lagrangian.

The various parameters used are :

- the relative displacements of the nucleotidic bases at different sites of each DNA strand,
- the equivalent mass m of a nucleotide pair equal to 300 amu ($m = 5.10^{-25}$ Kg),
- the Morse potential which is the energy of a hydrogen bond between a pair of nucleotides,
- the average of the energy values for the guanine-cytosine basis (G-C) and for the thymine-adenine basis (A-T), which is called the well depth or Morse depth. It corresponds to the dissociation energy of a base pair and is equal do $D = 0.04$ eV let us be $0.64 \cdot 10^{-20}$ J,
- the width of the well equal to : $w = 0.224$ Å,
- the stacking energy between neighboring bonds,
- the energy of the dipole-dipole interaction,
- the dipole parameter expressed in terms of electric charge transfer and of the distance between neighboring base pairs,
- the potential energy between two consecutives bases along a strand $V_o = 0.1\text{eV}$ in an equilibrium state,
- the linear frequency of the isolated oscillator which is equal to :

$$f_o = (1/2\pi) \left(2D/mw^2 \right)^{1/2} = 1.14 \cdot 10^{12} \text{ Hertz} \quad (3)$$

One considers the radial displacement of the base unit and the angular rotation between two adjacent base pairs from their equilibrium state. The lattice oscillations are designed by pulsation Ω_r for the radial displacement and Ω_p for the twist one.

Fig. 1.

The adiabaticity parameter $(\hbar/2\pi)(\Omega_T/V_0)$ (4) equal to : 0.041 proves the adiabatic right hypothesis during a quasi instantaneous displacements. From the fixed parameters at an equilibrium state : $a = 3.4 \text{ Å}$, $\theta_0 = 36^\circ$, $R_0 = 12 \text{ Å}$, we deduced the distance ℓ_0 between two consecutive bases along a strand :

$$\ell_0 = \sqrt{a^2 + 4R_0^2 \sin^2(\theta_0/2)} = 8.16 \text{ Å}$$

The potential energy V_0 is equal to :

$$V_0 = p_0 \cdot q / 4\pi\epsilon_0 \ell_0^2 \quad (5)$$

where p_0 is the moment of the charge. With $V_0 = 0.1 \text{ eV}$ we deduced : $q \cdot p_0 = 1.18 \cdot 10^{-48}$. Taking $p_0 = q \cdot 1 \text{ Å}$, gives : $q = 1.08 \cdot 10^{-19} \text{ C}$ which is approximately the electron charge. The mobility of the charge is possible in the presence of random parametrical and structural disorders inherent to DNA molecules [3].

Recently some authors [4] have considered the charge q when hydrogen bonds stretch using quantum chemical methods taking into account the nucleoside pairs (sugar linked to base). The value of the dipole parameter $J = q^2 / 4\pi\epsilon_0 a^3$ (6) is equal to : $3.3 \cdot 10^{-3} \text{ eV/Å}^2$ let us be 0.053 J/m^2 with $q = -0.095 e$, which is the charge transfer intermediate between the A-T and G-C base pairs [1].

The stacking parameter is given by some authors [5] equal to 0.96 J/m^2 (let us be 0.06 eV/Å^2), and by others [6] comprised between 0.01 and 10 eV/Å^2 . It has been then considered as adjustable parameter [4]. In short we can report according [4] that solitons or “discrete breathers” can be also generated from or exist among random thermal fluctuations. Moving breathers with speed comprised between 4 and 24 m/s , behave as quasiparticles, having an effective mass between 30 and 46 amu and a kinetic energy comprised between $6.5 \cdot 10^{-25} \text{ J}$ and

2.10^{-23} J, which is able to pass over a bending point in function of the strand curvature. For $T = 310^\circ$ K the thermal energy is $KT = 4.3 \cdot 10^{-21}$ J or $2.7 \cdot 10^{-2}$ eV. The conduction mechanism in DNA was recently studied [7], showing the impact of disorder. Evidently the charge motion is influenced by the vibrational modes of the double helix. Results concerning the electron transport in synthetic DNA polymers had been recently published [8]. For many organs we know that beyond a frequency of 2.10^{10} Hertz, the conductivity trends upward very quickly [Gabriel King's College, London, June 1996]. To establish the theory of the cell division Popp [8] supposed a high conductivity for the cell membrane without indication of its value. Albrecht-Buehler [9] thinks that centriolar "blades" have a high conductivity. Centrosome is an intracellular organelle composed of 2 centrioles and pericentriolar material. The centrioles are a pair of cylinder-like structures. ($0.8 \times 0.15 \mu\text{m}$) often disposed in an orthogonal way to each other. Each centriole is composed of 9 separate protofilaments ($0.8 \mu\text{m} \times 40 \text{ nm}$). Electrons of very low energies can induce substantial yields of single and double strand breaks of DNA in near infrared spectrum [10] and [11]. To be in a good agreement with numerous experimental results in near infrared, visible and near ultraviolet spectra we must choose a conductivity of 10^5 S/m for the membrane medium [12].

The figure 2 gives the theoretical velocity v of the moving electron along the DNA chain, as a function of the amplitude E_0 of the periodic field parallel to the double helix axis, for different frequencies in the millimeter wave ranges. It is taken out from [3] but expressed now with more convenient parameters. The normalized frequency given in [4] is related to the frequency f_0 (3), with $D = 0.04 \text{ eV}$, $w = 0.224 \text{ \AA}$ and $m = 5.10^{-25} \text{ Kg}$. Coherent electron transfer can be stimulated when the frequency of the applied field is such that : $10^{11} < f < 3.10^{12} \text{ Hz}$. To be efficient the applied external electric energy $eE_0 \ell_0$ has to be higher than V_0 let us be : $E_0 \ell_0 > 0.1 \text{ V}$ with $\ell_0 = 8.16 \text{ \AA}$ that is $E_0 > 10^8 \text{ V/m}$.

Moreover the electron kinetic energy comprised between 4.10^{-26} and $6 \cdot 10^{-26} \text{ J}$, is very weak compared with the thermal fluctuation kT .

Fig. 2

Fig. 3 : Temporal electronic occupation probability

The figure 3 shows the temporal behavior of the electronic occupation probability of the electron along the DNA axis in the presence of the external field at $f = 10^{11}$ Hz for different amplitudes E_0 and a disorder of 0.02 eV. The position $z(\text{\AA})$ corresponds to the electronic occupation probability after a propagation from a starting one for $t = 0$. When the field amplitude is enlarged the dynamic of the electron and the amplitude of the oscillations become weaker. The oscillation frequencies f_{osc} are higher than the electronic one equal to 10^{11} Hz as indicated in Table III.

E_0 (V/m)	$6 \cdot 10^7$	$1.2 \cdot 10^8$	$1.8 \cdot 10^8$
f_{osc} (Hertz)	$1.25 \cdot 10^{11}$	$2 \cdot 10^{11}$	$2.8 \cdot 10^{11}$

Table III (valid for $f = 10^{11}$ Hz)

Whatever E_0 , the maximum velocity v_M at $f = 10^{11}$ Hz is equal to $2.3 \cdot 10^3$ m/s. All these results, valid for a relative strong disorder ΔE on site electronic energy equal to 0.02 eV, are due to the nonlinear physics applied to DNA.

COMPARISON BETWEEN THEORY AND EXPERIMENTS IN MILLIMETER RANGE

AC conducting DNA in the millimeter range has been measured. Several authors have shown an appreciable conducting which approaches that of a well-doped semiconductor. Nevertheless it has been found that the high AC conductivity of DNA can be attributed largely to relaxational losses of the dipoles of the water molecules in surrounding hydration layers [1]. The total number of water molecules per nucleotide has to be correlated with the relative humidity [13]. For instance the adsorption of water molecules per nucleotide is equal to 13 for a rate of humidity (R.H) equal to 84 % and 4 for a R.H of 60 %. For an R.H of 0 %, there are 2.5-3 water molecules

per nucleotide which cannot be removed from the helix. The table IV shows the AC conductivity of calf thymus DNA measured in terms of the frequency [1].

f(Hz)	10^{11}	$2 \cdot 10^{11}$	$5 \cdot 10^{11}$	10^{12}
RH : 0 % σ (S/m) [1]	1	12	35	100
RH : 84% $\left\{ \begin{array}{l} \sigma(\text{S/m}) \text{ [1]} \\ A(N/\lambda_o) \text{ (1)} \\ C_p \text{ (2)} \end{array} \right.$	25	50	70	110
	4.9	5.4	3.5	3.0
	0.60	0.75	0.40	0.50

Table IV : conductivity σ measurements of calf thymus DNA

The conductivity σ , which is increasing with the frequency and the rate of humidity, can be attributed largely to the water layer surrounding the DNA backbone. In effect, for a R.H equal to 84 % the absorption $A(N/\lambda_o)$ and C_p were calculated with the relations (1) and (2) using the experimental conducting σ [1] and ϵ_r given in **Table I**. The experimental values σ [1] and the deduced absorption $A(N/\lambda_o)$ shown in **Table IV** are normally as should be weaker than these shown in **Table I** valid for the bulk pure water. The measured conductivities of the single and double strands have been found identical [1]. Considering the weak values of C_p we can say that the DNA can be reported to a dielectric medium in spite of its important conductivity. Previously reported conductivity value of 240 S/m was evaluated from the measured loss of highly sensitive resonant cavities operating at 12 and 100 GHz [14].

SOLITARY-WAVE EMISSIONS

The emission are due to solitary-waves or solitons issued from an external confined plasma device [15]. The induced emission lifetime of the ion in vivo medium is given [17] :

$$\tau_B = \frac{78}{\pi^2} \cdot \left(\frac{c}{f_r} \right)^3 \cdot \frac{h^2}{Z^2} \cdot \sqrt{\frac{\epsilon_o}{\mu_o}} \cdot \frac{\epsilon_o}{P_t^2} \left[2\pi e (\Delta n_i) V_p \frac{L}{r} \right]^{-2} \cdot |\tilde{n}|^2 \quad (7)$$

\tilde{n} is the mean complex, index of refraction at f_r in the vivo medium.

The parameters inserted between brackets are related to the plasma device.

P_t is the electric moment of the dipolar transition. Z is the atomic number of the ion. f_r is the square signal modulation frequency of a high RF frequency used to light the discharge inside the plasma tube. The density of the ions at the fundamental state in a strong electrolyte, equivalent to the interstitial liquid, which has been carried is equal to : $N_1 = 1.85 \cdot 10^{26} / \text{m}^3$: [16].

From [17] we deduced in the vivo medium :

$$N_2 = N_1 \cdot 3.7 \cdot 10^{16} \left(\frac{f_r}{v} \right)^3 \cdot \frac{1}{|\tilde{n}|^2} \quad (8)$$

$$\tau_B = 4.10^{20} f_r^{-3} \cdot |\tilde{n}|^2 \quad (9)$$

N_2 is the density of excited ions per unit of volume and v the frequency of their photonic emission. From N_2 we deduced the mean distance between sollicitated ions by the expression : $d = (N_2)^{-1/3}$ (10)

We showed that a low frequency f_r acting upon ion produce an ionizing radiation in the optical range [17].

The **Table V** shows the calculated values related to the ion induced emissions in terms of the free wavelengths for a higher modulation frequency f_r and a weak lifetime.

λ_o	0.25 μm	1 μm	10 μm	100 μm	1 mm	1.78 mm
d	16 μm	4 μm	0.4 μm	400 \AA	40 \AA	22 \AA
$n = N_2 / N_1$	$1.3 \cdot 10^{-12}$	$8.8 \cdot 10^{-11}$	$8.8 \cdot 10^{-8}$	$8.8 \cdot 10^{-5}$	$8.8 \cdot 10^{-2}$	0.5
N_2 / m^3	$2.4 \cdot 10^{14}$	$1.6 \cdot 10^{16}$	$1.6 \cdot 10^{19}$	$1.6 \cdot 10^{22}$	$1.6 \cdot 10^{25}$	$9.2 \cdot 10^{25}$
$\nu(\text{Hz})$	$1.2 \cdot 10^{15}$	$3 \cdot 10^{14}$	$3 \cdot 10^{13}$	$3 \cdot 10^{12}$	$3 \cdot 10^{11}$	$1.69 \cdot 10^{11}$
$W = h\nu$ (J)	$8 \cdot 10^{-19}$	$2 \cdot 10^{-19}$	$2 \cdot 10^{-20}$	$2 \cdot 10^{-21}$	$2 \cdot 10^{-22}$	$1.1 \cdot 10^{-22}$
d/λ_o	64	4	0.04	$4 \cdot 10^{-4}$	$4 \cdot 10^{-6}$	$1.2 \cdot 10^{-6}$

Table V : Ion induced emission

$$\text{valid for } f_r = 4 \cdot 10^6 \text{ Hz, } \tau_B = 6 \cdot 10^3 \text{ s (9), } N_1 = 1.85 \cdot 10^{26} / \text{m}^3, |\vec{n}|^2 = 10^3,$$

When the wavelength is enlarged the mean distance d between the sollicitated ions and the energy of the quantic oscillator W are decreasing, while their density N_2 increases. We have shown in [17] that when $d/\lambda_o < 1/\pi$ two adjacent dipoles have a strong mutual coupling such that the radiation of the array due to the whole excited ions was suppressed. Nevertheless the electric field amplitude E_o due to one ion is given by :

$$E_o = P_t / 4\pi\epsilon_o r^3 \quad (11)$$

P_t is the electric moment of the dipolar transition approximately equal to :

$$P_t = e \cdot 1 \text{ \AA} = 1.6 \cdot 10^{-29} \text{ (C.m)}$$

For $r = 10 \text{ \AA}$, we obtain from (11) : $E_o = 1.4 \cdot 10^8 \text{ V/m}$. Let us consider the electrostatic attraction of an electron by the ion when the viscosity strength is taken into account. We calculate for $r = 10 \text{ \AA}$ a speed of $5.5 \cdot 10^4 \text{ m/s}$, that is a kinetic energy equal to 10^{-2} eV . Let be a free electron motionless knocked by a photon of $W = h\nu$ energy. We suppose a perfectly elastic shock. Before and after the shock the whole impulse is unchanged. If we neglect the Compton effect, that is the frequency variation of the photon, we can write :

$$\frac{2h\nu}{c} = m_e v_e \quad (12),$$

With : $h\nu = 5.1 \text{ eV}$, $m_e = 0.91 \cdot 10^{-30} \text{ Kg}$, we deduced from (12) the electron speed : $v_e = 6 \cdot 10^3 \text{ m/s}$. So the electron kinetic energy is equal to : $1.6 \cdot 10^{-23} \text{ J}$, that is 10^{-4} eV . The photon which is associated with an electromagnetic wave is moving along the DNA with a speed equal to : $v_p = 1.65 \cdot 10^8 \text{ m/s}$ (see Table I). The photon can be also absorbed by the particle. Then the photo-ionization principle may give birth to an electron, with an energy higher than 10^{-4} eV .

SUMMARY

a) We introduced the ratio of the conduction to the displacement currents to express the conduction quality C_p (2) of a medium. Thus the pure water has a conduction σ which is always increasing all along the frequency range, while the conduction quality C_p is the highest in the millimeter wave range (**Table I**).

b) We justify the validity of the biexponential Debye relaxation model of the pure water extrapolated until the U.V range, by means of experimental results obtained on the human skin.

c) **Table I** shows the attenuation per wavelength which is maximum in the millimeter-wave range. Recent measurements in that range have shown appreciable AC conductivity of DNA which is largely ascribed to relaxational losses of the surrounding water dipoles [1]. We have extended this property to the UV range (**Table II**), showing further the action of photons upon free electrons.

d) Excited ions, by means of our external plasma device generator of solitary waves, is the object of photon emissions where an example is given in the Table V. An electron can be shocked by a photon in UV, showing a kinetic energy equal to 10^{-4} eV. What's more by means of the electrostatic attraction of one ion, an electron can show a kinetic energy equal to 10^{-2} eV. They can be used to activate, control and explain the division of fibroblasts and the cancer mechanisms of human skin, the main modification of DNA molecules by U.V radiation being the formation of pyrimidine dimers [11].

Abstract

Simple parametric equations are presented in terms of Jacobi elliptic functions that provide a realistic model of abnormal variations in size which maintain the biconcave shape of a normal erythrocyte (anisocytosis), and abnormal variations in shape which maintain the original volume of the erythrocyte (poikilocytosis), as well as continuous deformations from the normal to the altered shapes. We illustrate our results with parameterizations of spherocytes, ellipsoids, microcytes, macrocytes and stomatocytes, and apply these parameterizations to the numerical calculation of the induced transmembrane potential in stomatocytes and the induced electric stress on the membrane of erythrocytes when both cells are exposed to an external electromagnetic field of 1800 MHz.

Introduction

Erythrocytes are the most numerous cells in the blood and their complete characterization has attracted much effort. In particular it has been known experimentally for more than fifty years that a variety of agents can modify systematically and reversibly the normal erythrocyte shape and size [Ponder 1948]. From a biophysical point of view changes in shape have been related to different mechanisms, such as variations of the membrane potential and temperature [Glaser 1979], to anion-exchange protein band 3 [Wong 1994, Gimsa 1998] or to the influence of the cytoplasmatic pH [Gedde et al. 1995]. From a complementary point of view, the increasing use of numerical techniques in the calculation of multiple-cell phenomena has prompted the development of realistic mathematical models for the shape of normal erythrocytes [Gray 1998, Bloor and Wilson 2000, Oroz 2004]. In fact, we have shown in previous work the crucial role played by an accurate geometry of the cell in the study of the response of normal erythrocytes to electromagnetic fields [Sebastian et al. 2001, 2004, Muñoz et al. 2003]. However, we are not aware of any simple geometrical model for altered erythrocyte shapes.

In this paper we address the modeling of abnormal variations in size which maintain the basic biconcave shape of the normal erythrocyte (anisocytosis), and abnormal variations in shape which maintain the original volume of the erythrocyte (poikilocytosis).

Anisocytosis is the generic term used to describe an abnormally wide distribution of the sizes of the erythrocytes in the blood, be it due to the presence of young red blood cells such as macrocytes which are larger than mature normal red blood cells, or to the presence of smaller red blood cells such as microcytes. Although anisocytosis by itself is not diagnostic, an improved anemia classification might be available by combining measures of red blood cell size variability with mean corpuscular volume [Simel et al. 1988]. Microcytic cells occur in immune-

mediated hemolytic anemia, microvascular constriction, early Heinz-body anemia and iron-deficiency anemia. Macrocytic cells occur with regenerative anemia and rarely with erythrocytic leukemia.

The rather non-specific term poikilocytosis is used to describe an unusually high (greater than 10%) population of abnormally shaped erythrocytes in peripheral blood [Harvey 2001]. These morphologically abnormal erythrocytes (poikilocytes) may be caused by a variety of conditions, including fragmentation of erythrocytes, oxidative injury, immune-mediated damage, and congenital abnormalities [Cowell et al. 1999]. Among these morphologically abnormal cells are the spherocytes and stomatocytes. Spherocytes are red blood cells that are almost spherical in shape. They have no area of central pallor like a normal red blood cell. Large spherocytes (macrocytes) are seen in hemolytic anemia, whereas small spherocytes (microcytes) are sometimes seen in severe burn cases. Stomatocytes are characterized by a slit-like zone of central pallor. Stomatocytes are usually the result of a water content increase, an alteration of cation content and flux or and amphipathic drug use [Lim et al. 2002, Fujii et al. 1979, Elgsaeter and Mikkelsen 1991, Isomaa et al. 1987]. This altered erythrocyte shape is particularly interesting because of its abnormal increase in osmotic fragility which could lead to mechanical damage in turbulent blood flow circulation.

Considering the essential role played by the shape and size of the red blood cells in all the processes mentioned above, realistic cell models for spherocytes, macrocytes, microcytes and stomatocytes (as typical representatives of poikilocytes) must be used in any morphological cell analysis. In particular, the variation of the transmembrane potential when the cell is exposed to an electromagnetic (EM) field is a good probe of the interaction mechanism between biological cells and external radiation.

The layout of this paper is as follows: in the next section we briefly review existing mathematical models for the normal erythrocyte shape, and then present a new set of simple parametric equations that by means of free parameters model accurately continuous deformations from a simple sphere to the final erythrocyte altered shapes; then, as applications of these equations, we determine the transmembrane potential and the electric stress forces induced in the membrane of different cell shapes when they are exposed to an external EM field; the paper ends with a brief summary.

Parameterizations of erythrocyte shape abnormalities

Among the methods frequently used to model the erythrocyte normal shape [Sebastian et al. 2004, Moon and Spencer 1998] we mention the surface of revolution generated by a Cassini curve [Gray 1998]. Its main advantage is that Cassini curves have simple parametric representations in terms of trigonometric functions; its main limitations are that Cassini curves are determined by only two parameters (which can be used to fix only the length and the height of a real erythrocyte), and that the implementation of anisotropic deformations is not straightforward (in particular poikilocytosis and the changes in the shape of membranes which occur spontaneously when the cells are immersed in an aqueous environment under appropriate conditions [Jie et al. 1998]).

At the other end in complexity is the approach proposed by [Bloor and Wilson 2000], who use an elliptic partial differential equation in combination with an expression for the membrane surface energy to give a most realistic representation of the shape of the membrane surface. This approach, however, lacks the advantages of a simple parametric representation.

To find a reasonably simple parametric representation that allows for the modeling of the deformations we finally recall the parametric representation of the normal biconcave erythrocyte in terms of the $\text{sn}(u|m)$, $\text{cn}(u|m)$ and $\text{dn}(u|m)$ Jacobi elliptic functions with three free parameters [Kuchel and Fackerell 1999], which we prefer to write directly in terms of as many physically measurable parameters as possible:

$$\mathbf{r}(u, \phi) = \left(\frac{\ell}{2} \text{cn}(u|m) \cos \phi, \frac{\ell}{2} \text{cn}(u|m) \sin \phi, \pm h_0 \text{sn}(u|m) \frac{\text{dn}(u|m)}{\text{dn}(U|m)} \right), \quad (1)$$

where ℓ is the diameter of the erythrocyte, $2h_0$ is the height of the erythrocyte at its center, $U = K(m)$ is the corresponding complete elliptic integral of the first kind (which satisfies $\text{cn}(U|m) = 0$, $\text{sn}(U|m) = 1$ and

ERYTHROCYTE PARAMETERIZATION

$\text{dn}(U|m) = \sqrt{1-m}$, although for clarity we keep the functional form of this last expression in the parametric equations), $u \in [0, U]$, $\phi \in [0, 2\pi]$, and the plus and minus signs correspond to the upper and lower half of the cell respectively. The only remaining parameter is $m \in [0, 1]$, which can be used to fix for example $2h_{\max}$, the maximum height of the erythrocyte. Equation (1) is obviously suitable to model not only normal erythrocytes but also macrocytes and microcytes, because they essentially keep the normal erythrocyte shape and only differ in that they have different values for the diameter and height of the cell (and therefore different volumes).

To discuss the parameterization of altered shapes we first proceed by example: our model of the stomatocyte is generated by the equations

$$\mathbf{r}_+(u, \phi) = \left(\frac{\ell}{2} \text{cn}(u|m_+) \cos \phi, \frac{\ell}{2} \text{cn}(u|m_+) \sin \phi, h_+ \text{sn}(u|m_+) \left(\frac{\text{dn}(u|m_+)}{\text{dn}(U_+|m_+)} \right)^3 \right), \quad (2a)$$

$$\mathbf{r}_-(u, \phi) = \left(\frac{\ell}{2} \text{cn}(u|m_-) \cos \phi, \frac{\ell}{2} \text{cn}(u|m_-) \sin \phi, -h_- \text{sn}(u|m_-) \left(\frac{\text{dn}(u|m_-)}{\text{dn}(U_-|m_-)} \right)^2 \right), \quad (2b)$$

for the upper and lower parts of the cell respectively. Note that in addition to the different powers (cube and square respectively) of the Jacobi $\text{dn}(u|m)$ function in the third component of $\mathbf{r}_{\pm}(u, \phi)$, we also use independent values of the parameters h_{\pm} and m_{\pm} (and the ensuing $U_{\pm} = K(m_{\pm})$) for the upper and lower part of the cell.

Figure 1 shows the parameters and 2D generating curves for the sphere, ellipsoid, basic discocyte and a stomatocyte of the same volume obtained from Eqs. 1 and 2 respectively. Similarly, Figure 2 shows the 3D

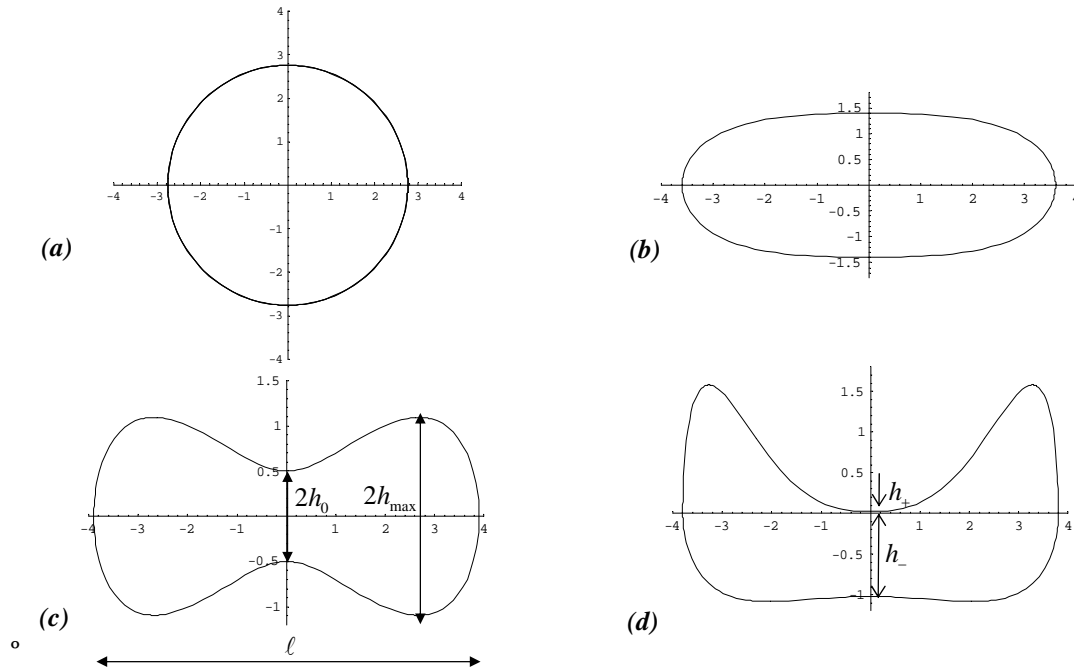

Fig. 1 2D generating curves obtained from equations 1 and 2 for a) spherocyte b) ellipsoid c) normal biconcave erythrocyte and d) Stomatocyte. The different modeling parameters used in the equations are shown in Table 1.

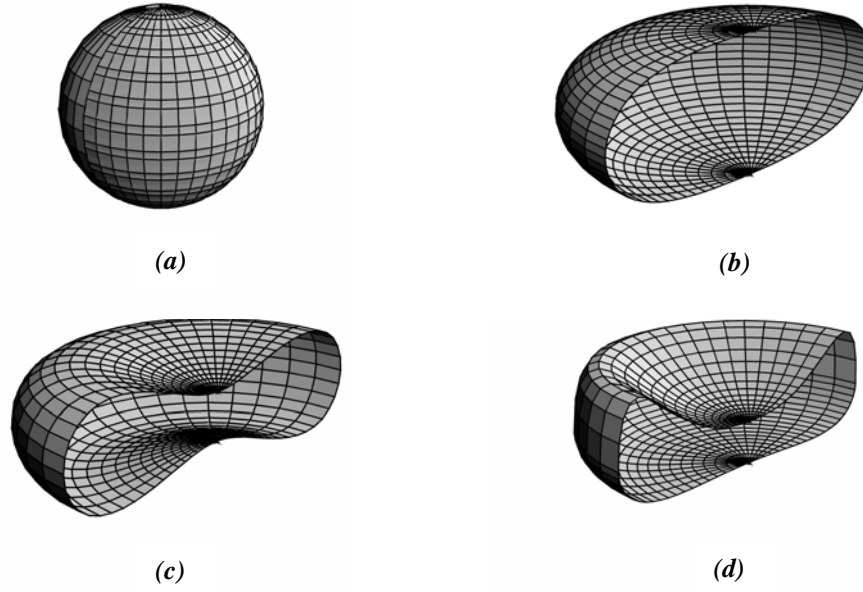

Fig. 2 3D view of the spherocyte, ellipsoid, erythrocyte and stomatocyte models generated using *Mathematica*.

cell geometries generated in *Mathematica* [Wolfram 2003] by rotation of these curves around the vertical axis. As it can be easily seen in both the 2D and the 3D figures, our stomatocyte model has a deep dimple. This degree of severity of the invagination determines that it belongs to subclass II [Bessis 1977] and is perfectly modeled by the modified Eq. 2. In Table 1 we present the numerical values of the parameters of these cells as well as of the parameters of the macrocyte and microcyte. Note that the maximum height of the stomatocyte has to be determined by using the inverse functions $u_{\pm} = \text{sn}^{-1}(x, m_{\pm})$, and that the volumes of the upper and lower parts of the cells can be readily calculated thanks again to the parametric equations:

$$V_{\pm} = -2\pi \int_0^{u_{\pm}} x'(u, m_{\pm}) x(u, m_{\pm}) z(u, m_{\pm}) du, \quad (3)$$

where the prime denotes derivation with respect to u .

Cell	ℓ (μm)	h (μm)	m	V (μm^3)	$2h_{\text{max}}$ (μm)	δ (nm)
Spherocyte	5.46	2.73	0	85.29	5.46	8
Ellipsoid	7.2	1.4	0.3954	85.17	2.8	8
Normal erythrocyte	7.8	0.5	0.9447	85.1	2.19	8
Microcyte	5	0.4	0.9520	29.8	1.87	8
Macrocyte	10	0.65	0.8446	118.1	1.79	8
Stomatocyte II (+, -)	7.6	(0.1242, 1.4037)	(0.9741, 0.4720)	85.02	2.19	8

Table 1. Parameters used in Eqs. 1 and 2 to model the different cell shapes: ℓ is the diameter of the cell, $2h$ ($h_+ + h_-$ for the stomatocyte) is the height at the centre, m (m_+ and m_- for the stomatocyte) is the parameter in the Jacobi elliptic functions, V is the volume, $2h_{\text{max}}$ the maximum height and δ the thickness of the membrane.

We now proceed to discuss the rationale behind and the generalization of the parameterization given by Eq. 2. Note that the common structure of Eqs. 2a and 2b is

$$\mathbf{r}(u, \phi) = \left(\frac{\ell}{2} \operatorname{cn}(u|m) \cos \phi, \frac{\ell}{2} \operatorname{cn}(u|m) \sin \phi, h \operatorname{sn}(u|m) \left(\frac{\operatorname{dn}(u|m)}{\operatorname{dn}(U|m)} \right)^p \right) \quad (4)$$

where the exponent p (here equal to 3 and 2 respectively) is a new parameter which in effect controls the gross features of the shape. Note also that the original parameterization of the normal erythrocyte shape of Kuchel and Fackereil is the particular case $p = 1$ of our Eq. 4. In fact, taking into account that the Jacobi elliptic functions can be considered as deformations of the familiar trigonometric functions to which they reduce for $m = 0$ ($\operatorname{sn}(u|0) = \sin u$, $\operatorname{cn}(u|0) = \cos u$ and $\operatorname{dn}(u|0) = 1$, in which case the parametric Eq. 4 represents a revolution ellipsoid) and taking into account also the elementary properties of these Jacobi functions [Abramowitz and Stegun 1972], it can be seen that the essential features of the parameterization (4) are maintained for positive (not necessarily integer) values of p . This new, continuous parameter can be used to advantage in the modeling not only of altered shapes, but of continuous deformations of the normal erythrocyte into these deformed shapes.

Finally, we have insisted on the advantages of an explicit parametric representation: in particular we can easily generate the uniform shell representing the membrane by shifting any parametric surface given by Eq. 4 by a constant distance δ along the outer normal at each point, i.e., the outer layer of the membrane is given by

$$\mathbf{r}_\delta(u, \phi) = \mathbf{r}(u, \phi) + \delta \mathbf{n}(u, \phi) \quad (5)$$

where

$$\mathbf{n}(u, \phi) = \frac{(\partial \mathbf{r} / \partial \phi) \times (\partial \mathbf{r} / \partial u)}{\|(\partial \mathbf{r} / \partial \phi) \times (\partial \mathbf{r} / \partial u)\|}. \quad (6)$$

Eqs. 4, 5 and 6 summarize our rather general model of normal or altered erythrocytes.

Applications

To illustrate the practical use of these parameterizations, we present (1) the numerical calculation of the induced transmembrane potential in stomatocytes and (2) the induced electric force (electrical stress tensor) on the interface between the realistic curved membrane and the external medium in normal erythrocytes. Both cells are exposed to an 1800 MHz plane wave, a typical carrier frequency in cellular phones and in wireless surveillance systems.

The resting transmembrane potential is a basic magnitude to the physiological state of the cell [Gedde and Huestis 1997, Glaser 1998, Bifano et al. 1984], and therefore the determination of induced field strengths and transmembrane potentials can provide a good insight on the relation between the exposition to radiofrequency fields and subsequent cell changes. The relevance of the induced transmembrane potential can be inferred from the numerous papers previously published by different authors [Grosse and Schwan 1992, Kotnik and Miklavcic 2000a, 2000b and therein]. However, these former studies have generally used simplified spherical or spheroidal cell geometries (also a particular case of Eq. 4), or at most the more realistic parameterization of the normal erythrocyte by a Cassini curve. Given the numerical precision that can be attained in these calculations we do not expect a significant difference between the results for a normal erythrocyte parameterized by a Cassini curve and a normal erythrocyte parameterized by Eq. 1. However, Eqs. 4-6 permit us to perform the corresponding calculations for abnormal erythrocytes, which to our knowledge has not been carried out before.

Our model of cell (stomatocyte and erythrocyte) is formed by two media: the membrane and the cytoplasm. The cytoplasm is a physiological saline solution with a protein volume fraction of 0.26. The membrane will be represented by a shell of constant thickness $\delta = 8\text{nm}$ that has a very low conductivity and a frequency-independent relative permittivity [Gimsa et al. 2001]. The cell is immersed in an external continuous medium – the radiation region – formed by an electrolyte with the dielectric properties of physiological saline. Table 2 shows the electrical parameters for the membrane, cytoplasm and external medium. These values are typical for the erythrocyte structure and have been extensively used in the literature [Simeonova et al. 2002].

As the cell dimensions ($\approx 8 \mu\text{m}$) are much smaller than the wavelength at the working frequency ($\approx 2 \text{ cm}$), we can assume that the cell is exposed to a uniform field. Therefore a quasistatic approximation holds and we can calculate the field distribution by solving directly the full Maxwell equations using a discretization of the cell model geometry into tetrahedral elements with an adaptive mesh.

Cell	$\varepsilon/\varepsilon_0$	$\sigma \text{ (S/m)}$	Loss tangent
Cytoplasm	50	0.53	0.10590
Membrane	9.04	1×10^{-6}	1.1052×10^{-6}
External medium	80	0.12	0.014986

Table 2. Relative permittivity $\varepsilon/\varepsilon_0$, conductivity $\sigma \text{ (S/m)}$, and loss tangent for the cytoplasm, membrane and external continuous medium at 1.8 GHz.

In this paper we use a finite element (FE) technique [Jin 1993, Douglas et al. 2000] with a variable density mesh to determine the electric field intensity within the different layers of the cell. The cells are exposed to a linearly polarized EM plane wave of frequency 1.8 GHz propagating along the y axis, with the \mathbf{E} and \mathbf{H} field vectors parallel to the z and x axes. The radiation region is taken to be a cube in which the cells are immersed. This region is filled with the external medium and surrounded by perfectly matched layers (PML). This setup provides a reflectionless interface between the region of interest and the PML layers at all incident angles [Becache and Joly 2001]. We achieve a good compromise between accuracy and computing resources by extending the dimensions of the radiation region to the order of four wavelengths in the external medium. This FE numerical technique has already been validated by the authors in previous works with simpler [Sebastian et al. 2001, Muñoz et al. 2003] and more complex geometries [Muñoz et al. 2004, Sebastian et al. 2005]. For normalizing purposes the electric field intensity is set to 1 V/m.

a) Determination of the induced transmembrane voltage in stomatocytes

In contrast to the symmetrical erythrocyte shapes, the asymmetry of the stomatocyte around the major axis leads to different values of the induced transmembrane potential in the upper and in the lower parts of the cell. Figure 3 shows this induced transmembrane potential both in the upper and in the lower parts of a stomatocyte as a

Fig. 3 Induced transmembrane potential in the upper and lower parts of a stomatocyte as a function of the distance x along the major axis of the cell. The cells are exposed to an RF field of frequency 1800 MHz. The electric field has an intensity of 1 V/m and is linearly polarized parallel to the vertical axis.

function of the distance x along the major axis. Again, the incident external electric field is parallel to the vertical axis. Note that in the flattest regions of the lower and upper parts of the stomatocyte the applied external field is perpendicular to the membrane surface. As the values of the conductivities of both the external medium and the

membrane are very low, the induced transmembrane voltage in these regions is, as expected, mainly governed by the ratio of the respective permittivities.

b) Determination of the induced electric stress forces on the membrane of erythrocytes

An obvious assumption concerning the field \mathbf{E} in the membrane is that it generates a Maxwell stress which will compress the membrane. This electrical stress plays a fundamental role in electroporation processes. In the quasistatic case, the forces exerted on a finite volume of material by the electric field can then be expressed as a result of forces acting on the surface limiting this volume by (Giner *et al* 1995)

$$f_i = \int_S T_{ij} dS_j \quad (7)$$

with the stress tensor for the electric field in a material medium defined by

$$T_{ij} = \varepsilon E_i E_j - \frac{1}{2} \delta_{ij} E^2 \left(\varepsilon - \eta \frac{d\varepsilon}{d\eta} \right) \quad (8)$$

In this work, we have not considered any variations of the electric permittivity of both media with their respective mass densities, i.e. $d\varepsilon_i/d\eta_i = 0$, and therefore Eq. 8 is greatly simplified.

Figure 4 Stress force density (T_{zz}) exerted on the centre of the curved erythrocyte membrane (solid line) and on a flat membrane (dashed line). The force density is directed inward the membrane (along the negative z axis as shown in the inset) and is normalized with respect to the external field ($\varepsilon_0 E^2$).

Although our analysis has only been limited to electrical stress and to a very short radius around the z axis of the erythrocyte (as it would be the case of a pore), the results clearly show that the electrical forces favour deforming of the membrane. The shape and size evolution of the cell will eventually be determined by a combination of electrical and mechanical forces. A comparison of the force densities obtained for an unstretched flat membrane and for the realistic erythrocyte model shows that the curvature of the membrane cannot be neglected.

Summary

We have given a simple parameterization of erythrocyte shapes which includes as a special case the normal biconcave erythrocyte of Kuchel and Facherell (and consequently spherical or ellipsoidal models), but allows for continuous deformations from this normal shape to rather general altered shapes (like stomatocytes). As an

added advantage of having a simple, explicit parameterization, we can generate a realistic three dimensional model of these erythrocytes by shifting the inner surface a constant distance along the outer normal.

As an application of this parameterization we have performed numerical calculations of the transmembrane potential induced by an electromagnetic field of 1800 MHz and 1 V/m in stomatocytes and normal erythrocytes. The results for the unsymmetrical stomatocyte depend essentially on the new parameterization, and have to be given separately for the upper and the lower parts of the cell.

Our calculations give insight into electrical stresses on realistic curve membranes of cells immersed in an electric field. This work can be applied to different cell shapes and the refinements thereof may be of potential value in understanding the kinetics of the rupture of membranes and related phenomena such as electrorotation and dielectrophoresis.

Finally, we point out that this analysis is purely theoretical and has been performed for a particular orientation of the external RF field, and as such necessarily calls for further investigations.

Abstract.

We report the results of a study on the influence of extremely-weak power frequency (60 Hz) magnetic field on the rate of regeneration in planarians *Girardia tigrina* and on the rate of gravitropic curvature development in the segments of the line stems. The data presented here demonstrate that the dependence of biological effects on the field's amplitude in the range from 0.5 to 8 μT is polyextremal. In particular, the maxima of effects (activation of regeneration) is observed at $B_{AC} = 1.3$ and 3.9 μT , while at $B_{AC} = 2.5$ and 5.4 μT the value of bioeffects are close to zero. The experimentally observed dependence of bioeffects on the field's amplitude can be reasonably well approximated by the theoretical expression, which we obtained earlier. At the values of $B_{AC} > 8$ -10 μT the bioeffect changes its sign – activation of planarian's regeneration starts to be replaced by its inhibition. The inhibition takes place for the range of the amplitudes from 10 to 140 μT . Simple theoretical estimates indicate, that the observed change in the sign of the effect may result due to the prevalence of the effects caused by the induction of the alternating currents in the test-system at relatively high B_{AC} – amplitudes. These results provide additional evidences for the model, explaining the interaction of weak and extremely weak alternating magnetic fields with biosystems, suggested earlier and provide the basis for planning of the epidemiological studies and interpretation of the corresponding results.

1. Introduction.

At present time it is generally accepted, that low-frequency alternating magnetic fields (AMF) with amplitudes (magnetic induction values, B_{AC}) equal or exceeding 10 μT are capable to induce the biological effects in a number of biosystems. This kind of magnetic fields are widely used in medicine, in particular, to stimulate regeneration of bones and soft tissues. However, humans in living and working places are exposed to the influence of rather weak or extremely weak alternating magnetic fields (EW AMF), originating from technogenic and natural sources. The amplitudes of the power-frequency magnetic fields in most of the living places range from 0.01 to 1-2 μT , while at some working places it may reach 5-6 μT [1]. Some experimental studies indicate that EW AMF may substantially influence some biological systems [1-16]. It should be noted, that in most cases the experiments with AMF are usually performed on the background of the static Earth's magnetic field, B_{DC} , with the value of magnetic induction of about 50 μT . Correspondingly, in a general case the term EW AMF means, that one is using the combined magnetic field, which contains both static and extremely weak alternating components. This circumstance is important for understanding of the physical mechanism the of influence of EW AMF on biological systems. Nevertheless, the term " bioeffects of EW AMF " is often used for brevity and also to emphasize the specificity of the mechanism of action of such fields.

It is necessary to note, that reports on the bioeffects of AMF with the amplitudes higher than 10 μT , as a rule, do not cause any doubts. At the same time some authors deny even a mere possibility of bioeffects of AMF with the amplitudes less than 10 μT . Contrary to the claims denying the possible existence of biological effects of low-frequency magnetic fields with the amplitudes ≤ 2 μT in the frame of traditional physics and biology [8, 17], there is a considerable number of experimental evidence confirming this kind of effects. It is remarkable, that the

important data demonstrating the inhibiting influence of sinusoidal magnetic field ($B_{AC}=1.7 \mu\text{T}$, $f_{AC}=60 \text{ Hz}$) on the oncostatic action of melatonin in a culture of human breast cancer cells have been obtained independently by several laboratories [5, 6, 7, 14, 15].

Despite of a certain, although quite slow, progress in the experimental proof of biological efficiency of some types of EW AMF, there is still no clear understanding of the corresponding mechanisms. In order to develop the possible theoretical models for the interaction of EW AMF with biosystems it is necessary to have the thorough experimental data on the dependence of bioeffect's value on the parameters of the magnetic field.

We have shown recently, that EW AMF with the values of amplitudes in the microtesla, nanotesla and even picotesla range substantially influence the properties of biological test-systems prepared from animal and plant sources [18, 19]. In particular, such fields were found to affect the rate of regeneration in planarians (*Girardia tigrina*) and also the rate of gravitropic response in the stem segments of flax (*Linum bienne*). We have found that the maximal and minimal values of the bioeffects were observed at certain (identical for the different test-systems) values of the amplitude/frequency - ratio of the AMF; the values of the bioeffects did not change with a simultaneous proportional change of the amplitude and the frequency of AMF.

The theoretical analysis of the obtained experimental data has shown, that in the range of frequencies and amplitudes used in our experiments, the value of bioeffects of EW AMF strongly depends on the parameter $\gamma B_{AC}/f$, where γ - gyromagnetic ratio for the particular type of magnetic moment, and B_{AC} - and f_{AC} - correspond to magnetic induction and frequency of the alternating magnetic component [19]. We have shown, that experimental dependence of the value of bioeffects on the frequency of alternating component (in a range from 10 to 320 Hz) at constant amplitude ($B_{AC}=1.6 \mu\text{T}$) may be approximated by a theoretical curve with $\gamma = 42.578 \text{ Hz}/\mu\text{T}$, corresponding to the gyromagnetic ratio of the nuclear spins of hydrogen atoms. The dependence of bioeffect's value on $\gamma B_{AC}/f$ - parameter is polyextremal: well expressed maxima are observed at $\gamma B_{AC}/f = 0.9; 2.75$ and minor maxima - at $\gamma B_{AC}/f = 4.5; 6.1$. The bioeffects are absent at $\gamma B_{AC}/f = 1.8; 3.8; 5.3; 6.7$ [19].

In order to estimate the biotropic action of the particular extremely weak power-frequency magnetic field (on the background of the geomagnetic field), it is necessary to obtain the dependence of the bioeffect's value on the amplitude of the field at fixed frequency. Here we present the corresponding experimental data, indicating that at rather small amplitudes ($0 < B_{AC} < 10 \mu\text{T}$) of 60 Hz magnetic field the maxima and minima of the corresponding bioeffects are observed at exactly the same values of the $\gamma B_{AC}/f$ - parameter, which were found earlier [19] in the frequency- dependence studies (as it was expected).

2. Experimental section.

2.1. Magnetic fields.

The exposure of the test-systems to the power - frequency magnetic field (60 Hz) with the value of magnetic induction, B_{AC} , was carried out on a background of an ambient static magnetic field, $B_{DC} \cong 42.0 \mu\text{T}$. The alternating (sinusoidal) magnetic field, generated with the use of Helmholtz coils (39 cm in diameter) was oriented co-linear with a vector of the Earth's magnetic field. The Helmholtz coils have been fed by standard signal generators G4-153 or G6-28. The control test-systems were exposed to the static Earth's magnetic field. The necessary values of alternating magnetic field were established taking into account the transmission coefficient for a Helmholtz coil, equal to $10 \mu\text{T}/1\text{V}$.

The experiments were performed using EW AMF with the following parameters:

$$f_{AC} = 60 \text{ Hz}; 0.1 \mu\text{T} < B_{AC} < 140 \mu\text{T}; B_{DC} = 42.0 \mu\text{T}.$$

The value of magnetic induction of the background alternating (50 Hz) magnetic field at the position of experimental test-systems inside of the Helmholtz coils was 15 nT . Experiments were conducted at room temperatures of about $20\text{-}22^\circ\text{C}$.

2.2. Test-systems.

2.2.1. Regenerating planarians. Preparation, computer morphometry, data analysis.

The flat worms (planarians *Girardia tigrina*), asexual laboratory race were reared in pond water at room temperature and were fed once a week with the Diptera larvae. For the experiments the animals of about 7-8 mm in length were selected. The feeding of the selected planarians was stopped one week prior to the start of the experiment. The head portions of planarians were amputated with an eye scalpel under a binocular microscope: approximately 1/5 part of a body containing head ganglion was dessected. Then regenerants were placed in two glass vessels filled with 50 ml of pond water (30 regenerating planarians per vessel).

The rate of regeneration in experimental and control animals was estimated with the use of computer morphometry method, based on of photocontrast between old (pigmented) and new (transparent) parts of a planarian's body. Each planarian has been photographed with the use of binocular microscope and videocamera in 3 days after amputation. It takes about 30 minutes to get photo pictures of a group of 30 animals. The video images of regenerating planarian were introduced into computer. Using the special program for image analysis, we determined the area, S , of whole planarian and the area, s , of the newly formed (transparent) blastema (Fig.1). The results of these measurements were used in calculations of the regeneration index, $R = s / S$, averaged over 30 planarians in control and experimental animals. The values of the EW AMF bioeffect was determined according to the expression:

$$\Delta R (\%) = \frac{(R_{\text{exp}} - R_{\text{con}}) \pm (\delta_{\text{exp}} + \delta_{\text{con}})}{R_{\text{con}}} \times 100\%, \text{ where } \delta_{\text{exp}} \text{ and } \delta_{\text{con}} - \text{standard errors of the average values,}$$

obtained for the experimental and control animals.

2.2.2. Segments of flax stems. Preparation, stimulation of gravitropic bending, data analysis.

Seedlings of flax (*Linum bienne*) were grown from the seeds at thermostat at 26°C in complete darkness during 4 days. In 4 days the stems seedlings were about 3-4 cm long. The apical parts (2.5 cm in length of stems) were excised and the leaves were removed from the obtained segments. The segments were placed horizontally in the Petri dishes (90mm in diameter) on the filter paper moistened with 2 ml of distilled water. The basal ends of the segments were fixed by the rings cut off from the silicon tube. Two dishes (with 20 segments per dish) were exposed to magnetic field and two dishes were used as a control. The gravitropic upward bending in segments begins in about 30 min after placing them in horizontal position and in about 3 hours the apical ends of segments attain the vertical positions with the tips directed against the gravity force vector. The value of the gravitropic bending in segments was defined as an averaged (over the number of 40 segments) angle formed between the apical end of a segment and the horizontal plane, $\alpha \pm \delta$, where δ - standard deviation of the mean (Fig. 2).

The measurements were performed with a protractor in 2 hours after beginning of the experiment. The collection of data on bending angles for 20 segments in one dish takes 3-4 minutes. All experiments were performed at $25 \pm 0.5^{\circ}\text{C}$.

The value of the bioeffect induced by 60 Hz magnetic field was expressed as the relative difference between the average angle of bending in the experiment, α_{exp} , and in the control, α_{con} , according to the equation: $\frac{(\alpha_{\text{exp}} - \alpha_{\text{con}}) \pm (\delta_{\text{exp}} + \delta_{\text{con}})}{\alpha_{\text{con}}} 100\%$, where δ_{exp} and δ_{con} - standard errors of the means.

Figure 2. The scheme of measurements of the gravitropic bending angle in a segment of flax stem.

3. Results and discussion.

Earlier we have shown, that the value of bioeffects, I , induced by EW AMF can be described by the expression:

$$I = kJ_1(\gamma B_{AC}/f) \times [J_2(\gamma B_{AC}/f) - J_0(\gamma B_{AC}/f)] \quad (1),$$

where k - constant, $\gamma B_{AC}/f$ - argument of Bessel's functions, $\gamma = 42.578 \text{ Hz}/\mu\text{T}$ - gyromagnetic ratio of the nuclear spin of hydrogen atom, B_{AC} and f_{AC} - magnetic induction and a frequency of an alternating component of the EW AMF [19]. As it may be seen (Fig. 3 and Fig. 4), the expression (1) reasonably well approximates the experimentally observed dependence of bioeffects on the amplitude of the 60 Hz magnetic field: the maximal values of bioeffects (i.e. activation of the rate of regeneration in planarians and activation of the gravitropic bending in the stem segments of flax) appear at the values of $\gamma B_{AC}/f$ equal to 0.9 and 2.75, while at $\gamma B_{AC}/f$ equal to 1.8 and 3.8 the effect of the field is absent. These results confirm our earlier conclusion, according to which the nuclear spins of hydrogen atoms are the primary targets in the the interaction of EW AMF with biosystems [19]. It should be noticed, that according to expression (1) at standart experimental conditions the value of bioeffects of EW AMF for the particular type of magnetic moment is completely defined by the amplitude/frequency - ratio of the alternating component and practically does not depend on the exact value of a static magnetic field.

An increase of the amplitude of the 60 Hz magnetic field up to 8-10 μT is accompanied by a change in a sign of the bioeffect - activation of planarian's regeneration is replaced by its inhibition. In Fig. 3 we have given only one experimental point. In fact, the inhibition of regeneration, characterized by a decrease in the regeneration index, s/S, by 20-30 % was observed with an increase of the amplitude in the range from 10 μT to at least 140 μT . Apparently a change of a sign of effect is caused by the induction of eddy currents in the vessels with planarians at relatively high amplitudes of the 60 Hz magnetic field.

It seems quite instructive to compare the results and conclusions represented in this paper with those of another study devoted to the influence of sinusoidal 60 Hz magnetic fields with amplitude ranging from 1 μT to 20 μT on the enzymatic activity of ornithine decarboxylase (ODC) in cultured fibroblast cells, exposed to the field during 4 hours [20]. The authors came to the following conclusions: 1) the enchancement of ODC activity induced by exposure of culture cells to a 60 Hz magnetic field suggested a sigmoidal relationship to magnetic field amplitude; an approximate doubling of the ODC activity was observed at field amplitude of 7 μT or higher; 2) the observed bioeffects are caused by the induced electric fields in a test-system, which is a function of the orientation of the magnetic field relative to the exposed sample, and the geometry and electrical properties of the sample; therefore, the threshold amplitude - value of the 60 Hz magnetic field may substantially differ for the different test-systems.

Figure 3. The dependence of the rate of planarian regeneration on value of $\gamma B_{AC}/f$ - parameter. The solid curve represents theoretically expected dependence. The parameters of combined magnetic field: $B_{DC} = 42 \mu\text{T}$, $f_{AC} = 60 \text{ Hz}$ $B_{AC} = 0.7; 1.3; 2.1; 2.5; 3.9; 5.4; 6.3; 7.4; 8.6; 9.8 \mu\text{T}$ corresponding to $\gamma B_{AC}/f = 0.5; 0.9; 1.5; 1.8; 2.75; 3.8; 4.5; 5.3; 6.1; 7.0$.

Figure 4. The dependence of the value of gravitropic bending in the segments of flax stem on value $\gamma B_{AC}/f$ - parameter. The solid curve represents theoretically expected dependence. The parameters of the combined magnetic field: $B_{DC} = 42 \mu\text{T}$, $f_{AC} = 60 \text{ Hz}$ $B_{AC} = 1.3; 2.5; 3.9; 5.4 \mu\text{T}$ corresponding to the values $\gamma B_{AC}/f = 0.9; 1.8; 2.75; 3.8$.

As it can be seen, the experimental results and conclusions presented by Mullins et al. [20] seem to be drastically different from those obtained in this paper. However, it is necessary to point out that the experimental results published by Mullins et al. [20] and by some other groups [6, 7, 14, 15] were obtained with the use of μ -metal shielded Helmholtz coil pairs, so that the amplitude of a residual static Earth's magnetic field at the location of the test-systems was not exceeding 0.1-0.2 μ T. It means that in these studies the test-systems were exposed to very weak sinusoidal 60 Hz magnetic field in the practical absence of a static magnetic field. It is known, the effects of AMF in the presence and in the absence of a static magnetic component may be essentially different [21, 22]. Obviously, in the real environment and work places both EW AMF and geomagnetic static field are present. Therefore, the experimental data obtained with a shielded Earth's magnetic field do not seem to be directly related to the effects of power – frequency magnetic fields, which may occur at real environmental conditions.

4. Conclusions.

The experimental results presented in this paper and earlier [18, 19] show, that the combined magnetic fields with the extremely weak amplitudes of the alternating component are capable to influence substantially the properties of biological test-systems derived from the animal's and plant's sources (regenerating planarians and gravitropically responding stems of flax). Our data clearly show that the dependence of biological effects on the amplitude of the 60 Hz magnetic field ranging from 0.5 to 8 μ T is polyextremal. In particular, the maxima of effects is observed at $B_{AC} = 1.3$ and 3.9 μ T, while at $B_{AC} = 2.5$ and 5.4 μ T the value of bioeffects are close to zero. The experimental points can be reasonably well approximated by the theoretical expression, which we obtained earlier [19]. These results confirm our earlier conclusion, according to which the nuclear spins of hydrogen atoms are the primary targets in the interaction of some types of EW AMF with biosystems. At the values of $B_{AC} > 8$ -10 μ T the bioeffect changes its sign – in particular an activation of planarian's regeneration starts to be replaced by its inhibition. The inhibition takes place for the range of the amplitudes from 10 to 140 μ T. The change in the sign of the effect may appear due to the prevalence of the effect caused by the induction of the alternating currents in the test-system at relatively high B_{AC} – amplitudes. These results allow to clarify the interaction mechanism of the weak power-frequency magnetic fields with biosystems and provide the basis for planning of the epidemiological studies and interpretation of the corresponding results.

This study was supported by the Russian Foundation for Basic Research (grant № 04-04-97324) and by the Programm " Fundamental sciences in medicine".

MAGNETIC FIELD ZONING IN THE FRAMEWORK OF THE DUTCH POWER LINE POLICY

GERT KELFKENS, MATHIEU PRUPPERS

RIVM, NATIONAL INSTITUTE FOR PUBLIC HEALTH AND THE ENVIRONMENT, P.O. BOX 1, 3720 BA BILTHOVEN, THE NETHERLANDS, E-MAIL: GERT.KELFKENS@RIVM.NL

Abstract

The possibility of a greater risk of childhood leukaemia due to magnetic fields caused by overhead power lines is currently a matter of scientific and public debate. However, a causal relationship has not been proven and it is not obvious whether the magnetic fields are the cause. In October 2005 the Dutch government issued a power-line policy based on the precautionary principle aimed at avoiding new situations in which children undergo prolonged exposure to magnetic fields exceeding 0.4 microtesla. For this purpose, a 0.4 microtesla magnetic field zone in the vicinity of overhead power lines would have to be established. However, defining such a zone is complicated, firstly, because the width of the zone varies continuously with the actual line load and, secondly, because the width of the magnetic field zone should account for future growth in the use of electricity.

The Ministry of Housing, Spatial Planning and the Environment has succeeded, nevertheless, in developing magnetic field zoning in consultation with the grid companies. This paper describes the choices made in establishing the 0.4 microtesla zone. The approach used has led to a guideline for calculating the width of the 0.4 microtesla zone. The calculations are based on a line load equivalent to a fixed fraction of the maximum allowable line load, where the fixed fraction is deduced from an analysis of the line loads during 2003.

Introduction

Modern society benefits greatly from electricity, but generation, transport and use of electricity create electric and magnetic fields with extremely low frequencies (ELF-fields). In 1979 Wertheimer and Leeper [1] demonstrated an increased cancer risk for children living near electric wiring configurations. Since then the adverse health effects possibly induced by ELF-fields have been a matter of scientific and social debate. The scientific investigations focused on the possibility of an increased risk for childhood leukaemia associated with transport and distribution of electricity. Initially, not all studies met solid scientific standards and the scientific evidence was inconclusive and contradictory, but over the years the number and quality of the investigations improved. From the aggregate of the epidemiological evidence in the year 2000, the Health Council of the Netherlands – an advisory council to the Dutch government - inferred a consistent statistical association between the occurrence of childhood leukaemia and living near overhead power lines, although a causal relationship between childhood leukaemia and ELF-fields could not be proven [2]. Two pooled analyses published in 2000 (Ahlbom *et al.* [3] and Greenland *et al.* [4]) support the statistical association between childhood leukaemia and exposure to ELF magnetic fields. From these pooled analyses the Netherlands National Institute for Public Health and the Environment (RIVM) concluded that there is a possibly elevated risk of childhood leukaemia at magnetic field strengths above a value somewhere between 0.2 and 0.5 microtesla [5]. On the assumption of a causal relationship between exposure to magnetic fields and development of childhood leukaemia, which is not proven, and the relative risks observed by both Ahlbom and Greenland, RIVM calculated the number of additional cases of childhood leukaemia due to overhead power lines [6]. In the Netherlands, with a childhood leukaemia incidence of 110 new cases every year, approximately 0.5 cases may be attributable to the magnetic fields due to overhead

power lines. In 2002 the International Agency on the Research of Cancer (IARC), which is related to the World Health Organisation, also concluded a consistent statistical association between ELF magnetic fields and childhood leukaemia, and designated the ELF magnetic fields as ‘possibly carcinogenic to humans’ [7]. A recent investigation yielded a statistical association between childhood leukaemia and living in the vicinity of overhead power lines in Great Britain [8].

Because of the public concern and the inconclusive scientific evidence the Dutch government indicated, in the Fourth National Environmental Policy Plan (NMP4), that the present evidence formed sufficient reason for further research and for taking appropriate precautionary measures in relation to social costs and benefits [9]. Studies were started into the actual number of dwellings in the vicinity of the overhead power lines [10], into the expected rise in the number of ‘exposed’ dwellings during the next 25 years due to realisation of plans for new dwellings [11, 12] and into the costs of the reduction of magnetic field strengths [13].

Finally, in 2004 the State Secretary of Housing, Spatial Planning and the Environment, P.L.B.A. van Geel, stated his policy aim with respect to overhead power lines in the policy document ‘Nuchter omgaan met risico’s’¹ [14]. The objective of this policy is to prevent the development of new situations in which children are exposed to magnetic fields near overhead power lines whenever possible. The policy to achieve this goal was designed in consultation with stakeholders (municipalities, provinces, grid companies). On October 3, 2005 this policy was issued in a policy letter [15]. The policy letter is addressed to stakeholders with ‘recommendations with regard to overhead high-voltage power lines’.

Overhead power lines

In the Netherlands overhead high-voltage power lines have five voltage levels: 380, 220, 150, 110 and 50 kilovolts (kV). Occasionally circuits of different voltages are attached to the same pylon, the so-called combi-lines (380 and 220 kV circuits, 380 and 110 kV circuits, 220 and 110 kV circuits). In the framework of a previous study [10] the Dutch network of overhead power lines was digitised from topographic maps (1:25,000) by KEMA (a technical consultancy with expertise in the energy sector). The map of the high-voltage power grid in the Netherlands is depicted in Figure 1.

The total length of overhead high-voltage power lines amounts to nearly 4000 km (Table 1). The regional grid of 150 kV has the highest share in this total, approximately 45%.

Table 1 Summary of the overhead power lines in the Netherlands

voltage level (kV)	total line length (km)
50	164
110	778
150	1781
220	249
380	840
combi	159
total	3971

¹ English translation: Coping Rationally with Risks

Figure 1 Overhead power lines in the Netherlands (2002)

Children living near overhead power lines

As a first step to calculating the number of children living in the vicinity of overhead power lines RIVM analysed the number of dwellings close to overhead power lines [11, 12]. A total number of 45,000 dwellings are located within 100 m (on both sides) of the overhead power lines. About 23,000 dwellings are situated within the 0.4 microtesla zone.

The average Dutch dwelling is inhabited by 2.6 persons, including 0.49 children aged 0-15 years [6]. As a result the number of children living within the 0.4 microtesla zone is estimated at 11,000.

For the next 25 years 800,000 new dwellings have been planned for the Netherlands. In a 'business-as-usual' scenario 10,000 of these dwellings will be built within the 0.4 microtesla zone. Consequently the number of children living within this zone may increase by 5,000 over the next 25 years.

Outline of the Dutch power line policy

Legal status

The Dutch power line policy was sent on October 3, 2005 as a policy letter by the State Secretary. The policy letter is addressed to stakeholders (municipalities, provinces, grid companies) with 'recommendations with regard to overhead high-voltage power lines'. Stakeholders are advised to act in accordance with this advice whenever this is reasonably possible, but the recommendations have no force of law. As a consequence stakeholders have no obligation to act according to the proposed policy.

New situations versus old situations

The Dutch power line policy is based on the observed statistical association between ELF magnetic fields and childhood leukaemia and the social concern on possible health effects, and follows the precautionary principle. The State Secretary has limited his policy to new situations, because the effects on health are unclear and because measures in existing situations often have substantial social consequences, and are expensive. In new situations prevention is possible at lower costs. With regard to the power line policy there are two types of 'new situations':

- new spatial plans (or changes in existing ones) in the vicinity of an existing overhead power line
- new overhead power lines (or changes in existing ones) in the vicinity of existing buildings

Sensitive designated uses

The statistical association between ELF magnetic fields and childhood leukaemia is observed in children living near overhead power lines. As a precaution the Dutch power line policy is not restricted to dwellings only. Some other places where children may undergo long-term exposure to the ELF magnetic field are indicated as 'sensitive uses'. The Dutch policy defines dwellings, schools, crèches and day-care centres as sensitive uses. The restrictions formulated in the Dutch overhead power line policy only apply to these sensitive uses. Other locations where children spend shorter periods in comparison to how long they spend at home, like sports centres, playgrounds, swimming pools etc. are not indicated as sensitive use. The Dutch policy does not apply to these locations. The purpose of the policy is to prevent the realisation of new sensitive uses within the magnetic field zone.

Magnetic field zones

Specific zone

In an Annex to the recommendations by the State Secretary the magnetic field zone is characterised as being:

... the area which extends along both sides of the overhead high-voltage power line and within which the magnetic field is, on average over a year, higher than 0.4 microtesla or can become so in the future.

This magnetic field zone is referred to as 'specific zone'. The value of 0.4 microtesla is a somewhat arbitrary choice in the range of 0.2 – 0.5 microtesla, the range where the childhood leukaemia risk possibly begins to be elevated [5]. The value of 0.4 was firstly mentioned with respect to overhead power lines in a letter from the former Minister of Housing, Spatial Planning and the Environment, J.P. Pronk, in 2001 [16]. The value of 0.4 microtesla was advocated by the Ministry and acceptable to the grid companies. The specific zone is calculated at a given location with the actual parameters (representative line load, pylon type, number of circuits, phase conductor geometry and earthing) for the specific section of the power line. RIVM has developed 'Guidelines for the calculation of the specific 0.4 microtesla zone in the vicinity of overhead high-voltage power lines'.

At the launching of the Dutch power line policy in 2005 no specific zones were known. To facilitate municipalities in the implementation of the policy the indicative zone was introduced in addition to the specific zone.

Indicative zone

Prior to the launching of the power line policy the indicative zone was established for all overhead power lines in the Netherlands [17]. The indicative zone is meant as an indication of the width of the specific 0.4 microtesla zone. In establishing the indicative zone, typical parameters for power lines at a given high-voltage level were used. Based on these typical parameters, zone widths were calculated for all power lines with the same voltage level. The 90th percentile of these zone widths was chosen as the indicative zone for that voltage level. Table 2 gives the values calculated for the indicative zone widths. The width of the indicative zone is not location-specific. Because the choice for the 90th percentile and due to the fact that for some of the parameters the 'worst-case' value was chosen, the specific zone is expected to be smaller than the indicative zone in most cases.

Table 2 *Indicative 0.4 microtesla zone widths used in the Dutch power line policy: zone widths are rounded off to the nearest multiple of five*

voltage level (kV)	zone width (m)
50	2 x 40
110	2 x 50
150	2 x 80
220	2 x 150
380	2 x 125
combi	2 x 200

TenneT, the operator of the national grid of 220 kV and 380 kV lines, was not satisfied with the established indicative zone in [17], because it gave only a rough indication of the specific zone. Consequently, TenneT recalculated the magnetic field zones for all 220 kV and 380 kV power lines. For line load, number of circuits, phase conductor geometry and earthing, TenneT used power line specific values in the calculation. One type of pylon was chosen for the entire power line. The zone from this recalculation is referred to as the ‘improved indicative zone’.

The indicative (or the improved indicative) zone is used as a first check for a new spatial plan. If the plan does not overlap the indicative zone, the power line policy has no further consequences for the planning procedure. If the new spatial plan and the indicative zone overlap, it is advised to calculate the specific zone.

As a service to municipalities and provinces the indicative zone for every power line is given on a clickable Gridmap. This Gridmap is part of an internet site [18], developed by RIVM, to support implementation of the power line policy.

Establishing the specific zone

The definition of the specific zone is the result of a series of discussions between the Ministry and the grid companies. The discussions focused on two aspects of the calculation of the specific zone. The first problem to tackle was establishing which load of the power line best accounted for the actual line loads and for the expected future growth in electricity use. The second topic was how to average the magnetic field over time.

Estimating power line load

Power line loads during 2003

As a first step to estimating the line loads RIVM analysed the load of the power lines during the year 2003. Because not enough detailed information is available for the regional grid (150 kV, 110 kV, 50 kV) analyses had to be restricted to the 220 kV and 380 kV lines. The grid operator (TenneT) kindly provided RIVM with measurements of the 5-minute averaged current flowing through the circuits during 2003. Line loads vary over the day, over the days of the week and during the seasons. Figure 2 shows the variation of the line load over the day and Figure 3 over the year for a typical 380 kV power line. As the current through the power line changes the width of the actual 0.4 microtesla zone will change too. Figure 4 shows the variations of the distance of the 0.4 microtesla contour to the heart of this typical power line.

MAGNETIC FIELD ZONING IN THE NETHERLANDS

Figure 2 Line load (two-hourly averaged current) of a typical 380 kV circuit on a typical day (July 7, 2003)

Figure 3 Line load (daily averaged current) of a typical 380 kV circuit during 2003

Figure 4 Variation of the zone width for a typical 380 kV power line over the year 2003; the distance of the 0.4 microtesla contour to the heart of the power line was calculated based on the daily averaged current

Estimating the representative current

A last, but crucial step, is to estimate the current used for the calculations of the magnetic field zone. In principle the actual yearly averaged current over the year 2003 could be used in this calculation for every power line. However, this approach does not account for the growing use of electricity, and the heavier line loads for the power lines expected in the coming decades. Calculating the width of the 0.4 microtesla zone on basis of the 2003 line load data would underestimate the width of the zone in the near future. Accounting for this growing use of electricity is one of the explicit requirements, as can be judged from the wording ‘can become so in the future’ added to the definition of the specific zone. In fact most power lines in the Netherlands are designed for heavier line loads than observed in 2003, and are likely to get loaded more heavily in the near future. All power lines have been designed for a maximum allowable line load, the so-called ‘maximum design load’. This maximum design load is mainly determined by the cross-section of the conductors, the material (aluminium, copper) of the conductors, the surface treatment of the conductors, the ambient temperature and the wind speed. The maximum design load for a power line sets an absolute maximum to the width of the 0.4 microtesla zone. However, deriving the 0.4 microtesla zone directly from this maximum design load places a strain on the available land. Moreover, from the viewpoint of operational safety the maximum allowable yearly averaged load must be below the maximum design load.

To get an insight into the relationship between the yearly averaged load and the maximum design load the ‘load fraction’, defined as the yearly averaged line load divided by the maximum design load, was calculated for the year 2003. Load fractions for the 220 kV and 380 kV lines are plotted in Figure 5.

Figure 5 Relative load of all 380 kV and 220 kV power lines: the load fraction is defined as the yearly averaged load (over 2003) divided by the maximum design load

From Figure 5 it is evident that in 2003 these power lines were not heavily loaded. Averaged over all the 220 kV and 380 kV circuits the relative load is 0.17, and 90% of the circuits have a load fraction below 0.3. Based on this analysis the grid companies and the Ministry agreed to use a fraction of 30% of the maximum design load for the 220 kV and 380 kV power lines as yearly averaged load for the calculation of the specific 0.4 microtesla zone. For most power lines a load fraction of 30% will not be reached in the near future, and the calculated specific zone will maintain its validity during the next decades.

For the regional power lines (150 kV, 110 kV, 50 kV) a similar analysis could not be done because of the lack of sufficient data. For these lines a load fraction of 50% of the maximum design load was chosen as a ‘worst case’ estimate.

Time averaging the magnetic field

The epidemiological studies showing an association between the magnetic field and an increased risk for childhood leukaemia relate the leukaemia risk to magnetic field strength averaged over relatively long periods of time [3, 4]. Most studies measure the magnetic field in the dwelling, typically over a period of 24 hours. Other studies calculate the magnetic field in the dwelling, based on the yearly averaged current. From Figure 4, it can be concluded that averaging over a relatively short period may

lead to erroneous and divergent values for the magnetic field zone. For instance, averaging over a twenty-four-hour period in the beginning of January would result in a full zone width of 2 x 50 metres, whereas averaging over the same period in the beginning of November would yield a full zone width of 2 x 160 metres. In view of the epidemiological studies and the strong variation of the line load and zone width over the year the Ministry decided to base the power line policy on the yearly averaged magnetic field.

For practical purposes in calculating the width of the 0.4 microtesla zone, the yearly averaged current through the power line is estimated and with this current the width of the specific zone is calculated with one of the available software packages. For this calculation commercially-available software packages may be used. Although no comparative research into these software packages has been carried out yet, the packages used in the Netherlands² are regarded to yield equivalent results.

Comparison with the Swiss situation

In Switzerland precautionary emission limitations, so-called installation-limit values must be respected at places of sensitive use. For high-voltage power lines the installation limit value is 1 microtesla at the maximum rated current for the power line. In practical terms the 0.4 microtesla zone calculated at 30% of the maximum load (380 kV, 220 kV) or at 50% of the maximum load (150 kV, 110 kV, 50 kV) according to the Dutch guidelines leads to widths for the magnetic field zone that are nearly the same. For a typical 380 kV power line the 'Swiss' 1 microtesla zone is 2 x 77 metres, whereas the 'Dutch' 0.4 microtesla is 2 x 70 metres. For a typical 150 kV the 'Swiss' 1 microtesla zone is 2 x 57 metres and the 'Dutch' 0.4 microtesla zone 2 x 65 metres. Starting from quite different viewpoints the Dutch and the Swiss policies lead to comparable magnetic-field zoning. Apart from this similarity there are a number of differences between the Swiss and the Dutch policies. The most striking are:

- the Swiss installation limit values have power of law and must be respected³, whereas the Dutch policy only advises stakeholders to abandon certain activities in the 0.4 microtesla zone;
- the Dutch policy only applies to overhead power lines as sources of magnetic fields; in Switzerland the installation limit value of 1 microtesla also applies to magnetic fields generated by transformer stations, substations and switchyards; and
- the Swiss policy applies to a larger number of sensitive uses; in the Netherlands only dwellings, schools, crèches and day-care centres are designated as sensitive uses. The Swiss list of 'places of sensitive use' encompasses dwellings, schools, hospitals, playgrounds and permanent workplaces.

Discussion

Several European countries are considering a precautionary policy for overhead power lines. The basis for such a policy is the observed statistical association between childhood leukaemia and living near overhead power lines. The epidemiological studies suggest that the association holds for childhood leukaemia and long-term exposure to magnetic fields, although a causal relationship between leukaemia and magnetic fields has not been proven. According to the epidemiological data, a possibly elevated risk is observed at magnetic field strengths above a value somewhere between 0.2 and 0.5 microtesla. The Ministry of developed a precautionary power line policy. This policy is founded on a 0.4 microtesla zone, the value of 0.4 microtesla being a somewhat arbitrary choice within this 0.2 - 0.5 range. This value of 0.4 microtesla is often compared to the exposure limit of 100 microtesla for 50 Hz recommended by the European Union [19]. But in fact these two magnetic-field strengths are incommensurable. The recommendations of the European Union are derived from the International Commission on Non-Ionizing Radiation Protection and based on well-established short-term effects.

² In the Netherlands magnetic field calculations are based on EFC-400 (Program package developed by Forschungsgesellschaft für Energie und Umwelttechnologie: FGEU, GmbH, Berlin, Germany), CDEGS (Current Distribution, Electromagnetic Fields, Grounding and Soil Structure Analysis Program package developed by Safe Engineering Services & technologies Ltd., Quebec, Canada) and ATP (Alternative Transient Program European EMTP-ATP Users Group (EEUG), Osnabrück, Germany). These software packages cannot directly calculate the width of the 0.4 microtesla zone, but calculate profiles for the magnetic field as a function of distance to the heart of the power line. To calculate the actual zone width these profiles need to be exported for further processing.

³ Exemptions are granted if the line operator shows that all measures to limit radiation that are technically and operationally possible and economically acceptable have been taken.

The 0.4 microtesla, on the other hand comes from epidemiological evidence for a possible long-term effect.

Summary

In the Netherlands, a policy has been implemented to prevent new situations where children are exposed to magnetic fields due to overhead power lines. To achieve this goal municipalities and provinces are advised to avoid realisation of new sensitive uses (dwellings, schools, crèches and day-care centres) within the specific 0.4 microtesla zone. RIVM developed guidelines for the calculation of the 0.4 microtesla zone. This paper describes the choices that have been made in dialogue between the Ministry of Housing, Spatial Planning and the Environment, and the grid companies for the calculations of this specific 0.4 microtesla zone.

In accordance with the epidemiological studies, the specific 0.4 microtesla zone is based on a yearly averaged magnetic field. To calculate this yearly averaged magnetic field a 'representative' yearly averaged current through the power line has to be estimated. This representative current should reflect the present load of the power lines as well as the growth of the load expected during the coming decades. The growth potential for the load of a power line is set by the maximum design load and operational safety criteria. Analysis of the line loads during 2003 led, after careful consideration between the Ministry and the grid companies, to a choice for the representative load. For 380 kV and 220 kV the yearly averaged load is estimated as 30% of the maximum design load. For lack of data on the 150 kV, 110 kV and 50 kV overhead power lines, a 'worst case' estimate of the yearly averaged load is used: 50% of the maximum design load. Based on this representative load and location specific data on the power line section (type of pylons, number of circuits, phase conductor geometry and earthing) the specific 0.4 microtesla zone at a specific location can be calculated with commercially-available software.

ABSTRACT

The Council of the European Union has made recommendations to its member states regarding specific actions on magnetic field exposure of the general public [1]. These recommendations are based on the reference values by ICNIRP, published in 1998 [2].

In the year 2000 two pooled analyses were published, both dedicated to epidemiological studies on the incidence of leukaemia among children living in the vicinity of overhead power lines. Especially the paper by Ahlbom c.s. [3] was and still is giving rise to a lot of concern for governments, as well as for many people living close to overhead power lines.

In the past few years, the Dutch government has initiated additional research, based on the assumption (consistent with the conclusion of Ahlbom c.s. [3]) that the leukaemia risk indeed increases twofold for children with a long-term mean exposure to magnetic field strengths higher than 0,4 μT , originating from overhead high-voltage power lines [4]. This research contained investigations of e.g.:

- the number of “extra” children that may develop leukaemia due to the presence of overhead high-voltage power lines each year in The Netherlands (i.e. 0.5 per year)
- the number of Dutch dwellings situated within the zones around high-voltage power lines with long-term magnetic field strengths $> 0,4 \mu\text{T}$, at present (i.e. 23.000 in 2003) and in the future (i.e. 33.000 in 2028)
- implementation costs of field reducing measures, on a national scale.

Consequently, the Dutch government has published new recommendations for municipal executives, other local authorities and grid operators in October 2005 [5]. This advice is based on the recommendations of the European Council as mentioned above, but with the addition of some important precautionary measures: for new situations in the vicinity of overhead high-voltage power lines the government recommends to prevent that children experience long-term exposure to magnetic fields, with annually averaged field strengths higher than 0,4 μT .

As an aid to local authorities and grid operators, magnetic field zoning around high-voltage power lines has been introduced. Two types of zones have been defined:

- an indicative magnetic field zone: a rough estimate of the zone, based on known indicators for Dutch high-voltage power lines in general
- a specific zone: a more accurate calculated estimate of the zone, based on actual phase configurations and electrical current of the high-voltage power line.

The recommendations are accompanied by a set of guidelines to calculate the specific magnetic field zone, as a surrogate for the “long-term mean magnetic field” of a Dutch high-voltage power line [6].

During the past few months, municipal executives, local authorities and grid operators have been managing this new Dutch policy on power lines. They have initiated or already performed several practical solutions to meet the recommendations. These solutions can be based mainly on two principles:

- reduction of the magnetic field by technical measures
- reduction of the exposure by revision of new housing development plans.

During the presentation, several implications and consequences of the Dutch recommendations for local authorities, grid operators, as well as for the general public will be discussed. This will be illustrated by presenting some examples of practical solutions.

Abstract

The purpose of this paper is to introduce the current state of the German Mobile Telecommunication Research Programme (DMF). The Programme was initiated by the German Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (BMU) and is performed by the Federal Office for Radiation Protection (BfS). In the period from 2002 to 2007 a total of 51 research projects in mobile telecommunications are proceeded in four fields: biology, dosimetry, epidemiology and risk communication. The total financial volume of the program is 17 million €. Final results of the programme are expected at the end of 2007.

Keywords: high frequency electromagnetic fields; mobile communication, health impact, research programme, Germany

1 Introduction

High frequency electromagnetic fields such as those found, for example, near transmitters (e.g. radio frequency towers and mobile telephone base stations) or when using mobile end devices (cell phones) are often suspected by the public of having adverse health effects on human. There is some indication that such electromagnetic fields can cause biological or physiological effects at levels below international limit values. In which extent they pose a health risk to the general public can't be completely determined at this time.

The German Mobile Telecommunication Research Programme (DMF) was initiated by the German Federal Ministry for the Environment, Nature Conservation and Nuclear Safety (BMU) and the Federal Office for Radiation Protection (BfS) to take part in the international efforts clarifying the above question. The total financial volume of the program is 17 million € appropriated half by half by the BMU and the network providers. Coordination and implementation is carried out by the BfS. The research projects chosen for the program are based on the findings of two expert workshops in 2001 and 2003 in Berlin and additional comments expressed by the general public. The first preliminary results were presented in April 2005 at a public expert workshop.

Detailed information on the single projects can be found on the DMF website <http://www.emf-forschungsprogramm.de/>. Project descriptions, current results and workshop results are presented. Regular reports on the state of the research projects can be found on this web-site. The researcher's Final Report together with an evaluative statement by the BfS will be made available to the public at the conclusion of every project. Further general information on electromagnetic fields and cellular telecommunication can be found on the BfS websites under <http://www.bfs.de/>.

2 Research Projects

In the period from 2002 to 2007 51 research projects in mobile telecommunications are realized in four scientific fields: biology, dosimetry, epidemiology and risk communication. With state of Oktober 2006 23 of them are already finished, the remaining will be completed within 2006 and 2007. The topics cover a broad spectrum, reaching beyond current GSM and UMTS standards. One objective, among others, is to clarify fundamental effects and mechanisms. Another will be to delve into the possible causes of electromagnetic sensitivity. The programme will seek results pertinent not only to existing mobile telecommunications but in order to make statements on future developments as well.

2.1 Biology

The 23 projects investigating possible biological and effect and health consequences of high frequency electromagnetic fields cover about 56 % of the financial volume of the DMF. Four projects are already completed. It could be shown, that a life-long exposure with GSM and UMTS signals does not influence the survival and the incidence of lymphoma in a genetically modified mice stock especially susceptible to lymphoma (AKR-mice). Though, the hypothesis, that chronic exposure to high frequency electromagnetic fields promote neoplastic development in the hematopoietic system in genetically predisposed mice was not supported. The "melatonin hypothesis", claiming that ELF as well as HF electromagnetic fields result in decreased melatonin levels, could not be confirmed during investigations on explanted pineal organs of hamster. A feasibility studies was successfully finished and made it possible to start investigations on the age dependence of the action of HF EMF. A study on the sleep quality of population living close to mobile phone base stations started as well.

2.2 Dosimetry

13 projects, covering about 14 % of the total financial volume of the DMF, are concerned with dosimetry and exposure assessment, eleven of them are already finished. The topics cover on the one hand the field distribution around transmitters and far-field exposure of the population by mobile phone base stations, WLAN transmitters, transmitters of the digital TV, etc. On the other hand, near-field scenarios are investigated predominantly by modelling the indoor field distribution in homes, offices, shielded rooms, etc. SAR and temperature variations in the heads and trunks of persons using mobile communication devices are determined. The SAR distribution in experimental animals was investigated as well. Investigations of the real exposure due to daily use of mobile phones have shown, that GSM-mobile phones regulate quite often to the maximum transmission power, predominantly as a result of frequent handovers and poor signal quality, and cause therefore correspondingly high SAR-values in the heads of the user. The different regulatory mode of UMTS-mobiles results in drastically reduced exposure of the user by a factor of about 1000. Determination of human exposure caused by indoor wireless communication technologies applied in homes and offices showed that in general the exposure values lay far below the prescriptive limits. Another study analysed the exposure from transmitters worn near the trunk of the body. In generic and anatomical models was revealed that under far-field-like conditions standing waves can develop, and a rise of the SAR value specifically in the skin was determined. The limit values were not exceeded. In near-field-like conditions standing waves do not arise. Although the temperature rise due to HF exposure was calculated. With free convection a maximum of 0.8 °C was determined. Using anatomical models the values determined are up to 0.31 °C at the body surface. The temperature rise determined under these conditions for the internal organs is negligible as long as the SAR limit values are kept. A project concerning the exposure of the head has shown that the temperature increase in the skin. This is caused more by the heat accumulation under the phone than by the radiation. The temperature increase within the skull (brain, pineal, inner ear) was up to 0.01 °C. One project concerned determination of exposure to the population living near digital radio and television transmitters. The measurements in Bavaria before and after introduction of the digital transmitters showed an increasing of mean exposure in the areas with "portable indoor" coverage around the transmitter sites caused by the introduction of DVB-T.

2.3 Epidemiology

Eight epidemiological projects are performed covering about 19 % of the financial volume of the DMF. Four projects are already finished. A feasibility study has shown, that an occupational cohort study on persons highly exposed to HF EMFs cannot be performed due to a lack of a highly exposed cohort of an acceptable size and without conflicting confounders. Furthermore, the feasibility of a prospective cohort study on handy users failed because of a response rate of only 5 %. The effort necessary to recruit a sufficient number of participants would be enormous and is not practicable within the DMF. The German part of INTERPHONE study is finished, the results of the evaluation of the internationally pooled data are expected in 2006. According to preliminary national results, there seems to be no increased risk for brain cancer due to a regular handy usage for up to 10 years. Two epidemiological studies on children are just starting – one investigating childhood leukemia around powerful radio and TV transmitters, another concentrating on health effects in the vicinity of mobile phone base stations. In the later one, personal dosimeters will be used to assess the exposure.

2.4 Risk Communication

Seven projects are concerned with risk perception and some other social aspects of mobile communications, covering about 9 % of the financial volume of the DMF. Yet, four projects are already finished. The analysis of target groups for differentiated information showed, that different population groups are differentially worried about possible health effects of electromagnetic fields. The results of the project "Examination of the knowledge and effects of information activities in the field of mobile telecommunications and determination of further approaches to improve information of different population groups" gained from the focus groups and the mobile phone survey in 2005 illustrate the importance of differentiating between target groups. The essential differences but also potential similarities between the views of the different citizens' groups and the experts have become apparent. The quantitative and qualitative survey performed in the framework of the project "Supplementary information about electromagnetic hypersensitive persons" provide more detailed findings of persons who see the origin of certain physical disorders in the existence of electric, magnetic or electromagnetic fields (EMF). According to the working definition, this group is considered as electrosensitive persons. The study also reveals, however, that only a small part of this group declares themselves to be "electrosensitive". The important factor is rather their handling and/or the significance of "radiation" in the context of their everyday lives, irrespective of terms and definitions. The findings obtained are an important basis for improving the communication with people who feel impaired. They also help to adapt the way information is offered to the particular needs of this group of people.

3 Summery

A large portion of the projects will be finished in 2006 and 2007. To provide a scientific evaluation of all results of the German Mobile Telecommunication Research Programme (DMF) in the international context, single thematic topics will be presented internationally in scientific workshops and discussed with national and international experts. First, the workshop with the topic "dosimetry" was proceeded in July 2006. The next workshop with the topic "risk communication" will take place at October 2006. The biological and epidemiological projects are combined in three workshops with the topics "Acute health effects" (December 2006) as well as "Action mechanism" and "Long-time health effects" in 2007.

A final evaluation of the combined national and international research on the health effects of high frequency electromagnetic fields within and outside of DMF is planned in the form of an international scientific conference, together with international experts and the WHO. The results will be presented in a final national expert workshop at the end of 2007 and will be the base for a re-evaluation of the limits.

4 Appendix: Projects of the DMF

4.1 Biology

Completed

- Feasibility study on age dependent effects of RF electromagnetic fields on the basis of relevant biophysical and biological parameters
- Investigation of mechanisms of action in cells exposed to the high frequency electromagnetic fields of mobile telephone technology. B. Pineal gland
- Influence of low and high frequency electromagnetic fields on spontaneous leukaemia in AKR/J mice
- *in vivo* experiments on exposure to the high frequency electromagnetic fields of mobile telecommunication. B. carcinogenesis

Assigned – results in 2006 and 2007

- Investigation of mechanisms of action in cells exposed to the high frequency electromagnetic fields of mobile telephone technology. A. Demodulation / communication
- Investigation of mechanisms of action in cells exposed to the high frequency electromagnetic fields of mobile telephone technology. C. Functions
- *in vivo* experiments on exposure to the high frequency fields of mobile telecommunication. A. Long-term study
- *in vitro* experiments on exposure to the high frequency fields of mobile telecommunications. C. Blood-brain barrier
- Influence of mobile telecommunication fields on the permeability of the blood-brain barrier in laboratory rodents (*in vivo*)
- Influence of high frequency electromagnetic fields of mobile telecommunications on sensory organs. A. The auditory system
- Possible influence of high frequency electromagnetic fields of mobile communication systems on the induction and course of phantom auditory experience (tinnitus)
- Influence of high frequency electromagnetic fields of mobile telecommunications on sensory organs. B. The visual system
- Possible genotoxic effects of GSM signals on isolated human blood
- Influence of GSM signals on isolated human blood. B. differential gene expression
- Long-term study on the effects of UMTS signals on laboratory rodents
- Influence of high frequency electromagnetic fields of mobile telecommunications on the metabolic rate in laboratory rodents
- Investigation of age-dependent effects of high frequency electromagnetic fields based on relevant biophysical and biological parameters
- Investigation of sleep quality in persons living near a mobile base station - Experimental study on the evaluation of possible psychological and physiological effects under residential conditions
- Investigation of sleep quality of electrohypersensitive persons living near base stations under residential conditions
- Studies of the effects of exposure to electromagnetic fields emitted from mobile phones on volunteers
- Investigation of the phenomenon of 'electromagnetic hypersensitivity' using an epidemiological study on 'electrosensitive' patients including the determination of clinical parameters
- Investigation of electrosensitive persons with regard to accompanying factors or diseases, such as allergies and increased exposure or sensitivity to heavy metals and chemicals
- Influence of HF-EMF of mobile communications on the metabolic rate in an animal model (laboratory rodents)

4.2 Dosimetry

Completed

- Investigation of SAR distribution in laboratory animals exposed to electromagnetic fields
- Development of measurement and calculation methods for the determination of the public exposure due to electromagnetic fields in the vicinity of mobile phone base stations
- Determination of the exposure of groups of people that will be investigated within the scope of the project 'Cross-sectional study for ascertainment and assessment of possible adverse effects by the fields of mobile phone base stations'
- Determination of human exposure caused by indoor wireless communication technologies applied in homes and offices
- Determination of the specific absorption rate (SAR values) occurring during day-to-day mobile phone use
- Exposure from transmitters worn near the trunk of the body
- Determination of exposure distribution from high frequency fields in the human body with regard to small structures and relevant thermo-physiological parameters
- Determination of the real field distribution of high frequency electromagnetic fields near wireless LAN installations (WLAN) in inner cities
- Determination of the real field distribution from high frequency electromagnetic fields near UMTS transmitters
- Determination of the real exposure from using mobile phones in partially shielded rooms as compared to exposure under optimal conditions outdoors
- Determination of exposure to the population living near digital radio and television transmitters

Assigned – results in 2006

- Investigation of the validity of macroscopic dielectric tissue properties at cellular and subcellular level
- Determination of exposure by ultra-wideband-technologies

4.3 Epidemiology

Completed

- Feasibility study for a cohort study: the cohort study should investigate highly exposed (occupational) groups to estimate the risk associated with high frequency electromagnetic fields.
- Feasibility study for a prospective cohort study on mobile phone users
- Extension of an international epidemiological study on the association between high-frequency electromagnetic fields and the risk of brain cancer (INTERPHONE)
- Addendum to a case control study on uveal melanoma and radio frequency radiation (RIFA Study)

Assigned – results in 2006 and 2007

- Cross-sectional study to record and evaluate possible adverse health effects due to electromagnetic fields from cell-phone base stations
- Addendum to the cross-sectional study on acute health effects caused by fields of mobile phone base stations
- Epidemiological study on childhood cancer and proximity to radio and television transmitters
- Acute health effects by mobile telecommunication among children

4.4 Risk Communication

Completed

- Knowledge-based database of literature describing the effects of electromagnetic fields on the organism and implants
- Analysis of target groups for differentiated information
- Supplementary information about electromagnetic hypersensitive persons
- Examination of the knowledge and effects of information activities in the field of mobile telecommunications and determination of further approaches to improve information of different population groups

Assigned – results in 2006

- Identifying the general public's fears and anxieties with regard to the possible risks of high frequency electromagnetic fields of mobile telecommunications (annual survey)
- Innovative methods of conflict mediation when determining the location for mobile phone base stations
- Support of the cooperation of the mobile telecommunication players by the local agenda 21

Abstract

A traffic accident by a car becomes a social problem all over the world. Therefore, the requirement for safety system of a car is increasing. In Japan, there are many car accidents with pedestrian, a performance enhancement of the pedestrian detection with an in-vehicle sensor such as millimeter wave radars is demanded. In this report, we were aimed for construction of a human body electromagnetic phantom for millimeter wave, we derived a reflection and an absorption characteristic in the human body by an experiment. As a result, the reflection coefficient (S11) when we irradiated a millimeter wave on the human body surface was about -5dB. In addition, we measured a transmission coefficient (S21) of meat for the purpose of evaluating an absorption characteristic in the human body of millimeter wave. As a result, we understood that most of electricity was absorbed within around 2mm by the surface. Based on these results, we developed a human body phantom for automotive radar designs.

1. Introduction

A traffic accident by a car becomes a social problem all over the world. Therefore, the requirement for safety system, such as the Forward Collision Avoidance Assistance System (FCAAS), has been increasing. The radar sensor of such a safety system has to be capable of detecting not only other vehicles but also pedestrians, bicycles, and roadside objects [1]. Furthermore, such a safety system should be able to make a decision without any mistake as to whether a collision occurs. Therefore, the radar sensor must be capable of detecting objects immediately before a collision would otherwise occur. The development of a radar sensor for safety system requires that we know the radio wave reflection characteristics, such as the average value of the radio wave reflection intensity, of an object relatively close to the sensor, as well as the range of fluctuation. That is, if the radio wave reflection characteristics of objects are known, the performance of a safety system using a radar sensor can be refined.

In this paper, we evaluated a reflection and an absorption characteristic when a millimeter wave was irradiated by the human body by an experiment. In addition, we evaluated a reflection and an absorption characteristic for the wearing cloths quantitatively.

2. Measurement method

2.1 Reflection characteristic

We measured a millimeter wave reflection characteristic in the human body surface by free space method (figure 1). In this method, we set a calibration plane in the back side of the acrylic board which is fixed at a position of 0.27m by a lens antenna. Then, a reflection characteristic of a forearm part is measured by a network

analyzer accurately. When it measures a millimeter wave reflection from the human body, it is a problem to suppress a fluctuation of the reflection depended on movement of a body. However, the high precision measurement is possible by pushing an arm to an acrylic board. This measurement frequency range is 75GHz - 110GHz.

2.2 Absorption characteristic

It is difficult to measure a millimeter wave absorption characteristic in a body tissue directly, so we measured it by the following method. At first, we measure a complex permittivity of the human body surface by a coaxial probe method. Then, we measure the complex permittivity of meat (chicken, a chicken cuticle, pork, etc.) of some thickness. We measure a transmission characteristic of meat by free space method. So, the absorption characteristic of millimeter wave in the human body is derived equivalently.

3. Measurement result

3.1 Reflection characteristic

Figure 2 shows a millimeter wave reflection characteristic of a forearm part of four persons (30-40 generations). Although there was some difference in a value by frequency, the reflection characteristic was almost -5dB to -4dB. The difference by a person was small with less than 1dB. From this result, It understand that 30% of millimeter wave incidence energy reflect in an incidence direction in the human body surface

3.2 Absorption characteristic

Figure 3 shows the complex permittivity of the human body surface by a coaxial probe method. In this coaxial probe method, only a characteristic up to 50GHz is provided precisely, so the complex permittivity more than 50GHz estimated by extrapolation. As a result, the complex permittivity (real part) of the human body surface at 70GHz was 3 to 4. Figure 4 shows the complex permittivity of the meat (pork) by a coaxial probe method. The complex permittivity of a fat and a muscle at 70GHz was 4 and 7 respectively. In addition, compare with the complex permittivity of the human body surface, fat characteristic was near to the human body surface one. Transmission characteristics of several kinds of meat are shown in figure 5. The transmission characteristic was about -10dB at thickness 0.3mm, and it was about -60dB more than thickness 3mm. When a millimeter wave was irradiated by the human body, about 30% of electric power was reflected and other electric power was absorbed at less than 2mm by the surface of human body. From these results, it is thought that a millimeter wave reflection in the human body has little influence of inside composition. In addition, this experiment result accords with an analysis result by FD-TD method very well.

4. Reflection and transmission characteristic of clothes

It is thought that a millimeter wave reflection and absorption characteristic of the person who wore clothes is different from the state that does not wear clothes. In this chapter, we evaluated a millimeter wave reflection and transmission characteristic of clothes by an experiment. Same as the measurement of a reflection and transmission characteristic of the human body and meat, we applied free space method. Table 1 shows measurement results. Average values of reflection and transmission characteristics from 75GHz to 110GHz are shown in this table. From these results, the reflection characteristics were -13dB to -30dB, and the transmission characteristics were -0.1dB to -0.8dB. The transmission losses in one piece of cloth were less than 1dB. There were less transmission losses of chemical fiber materials such as polyester than a loss of cotton materials.

Furthermore, we performed the measurement that assumed wearing clothes one over another. As a result of three pieces of cloth (No.2, No.3 and No.4), the reflection and transmission characteristics were -13.2dB, -1.51dB respectively. A reflection characteristic depends on cloth of large reflectance, and a transmission characteristic is almost a total of each transmission characteristic. When we examine a millimeter wave reflection and absorption characteristic of pedestrian of a wearing clothes, we have to consider these influence.

5. Conclusion

We evaluated a reflection and absorption characteristic experimentally when a millimeter wave was irradiated by the human body. In addition, we evaluated a reflection and transmission characteristic of cloth used for

wearing clothes in the same way.

When a millimeter wave was irradiated by the human body, about 30% of electric power was reflected and other electric power was absorbed at less than 2mm by the surface of human body. Furthermore, the reflection characteristics of clothes were -13dB to -30dB, and the transmission characteristics were -0.1dB to -0.8dB. Based on these results, we developed a human body phantom for automotive radar designs and development of millimeter wave radar for pedestrian detection.

ELECTROMAGNETIC INDUCTION THROUGH THE BIOLOGICAL TISSUE

N. M. SALEM

*DEPT. OF ENGINEERING PHYSICS, FACULTY OF ENGINEERING,
CAIRO UNIVERSITY, EGYPT*

Abstract

The study of the BIA has firstly been introduced as an effective tool to assess many of the biological and biochemical activities of the body. Due to the ubiquitous exposure to electromagnetic waves in our environment and the recent extensive use of mobile handsets, another trend appeared to exploit the BIA, namely its relation to electromagnetic absorption of the body especially in terms of its frequency dependence and the possible ability of power attenuation. In the present study we concentrate on the biological impedance of the body when subjected to high frequency and low energy microwaves. Full mathematical analysis is introduced to examine the fraction of power transmitted via the body impedance and the possible wave shape delay or distortion of the incident wave.

Introduction

Perhaps the term bioelectrical impedance analysis (BIA) was first introduced in 1940's [1], to assess the induced changes in hydration status as it is related to the total body changes in resistance and capacitive reactance. BIA was also associated with the dynamic changes in pulsatile blood flow to organs, arterial pulse waveforms and respiration [2]. The applications of impedance plethysmography, to detect dynamic blood volume changes, have been widely confirmed by numerous research workers [3-6].

The significant correlation between total body water (TBW) and the BIA has been reported by hundreds of peer reviewed papers [4,7,8].

Measurement of the electrical impedance of biological tissue in vitro and in vivo has entered into several prominent classes of biological research and biomedical applications. More than half a century ago, Fricke [9], then followed by Cole and Curtis [10], have measured the electrical self-impedance of a variety of cell and tissue systems; these measurements were made across a large spectrum of frequencies ranging from the audio to the high radio frequencies. Their results were studied in the usual impedance domain of resistance and reactance rather than in the electrically equivalent admittance domain of conductance and susceptance, thus a series of organized circuit models were obtained.

Most of the body tissue contains large amounts of water and conducting electrolytes, and represents a low resistance electrical pathway; hence the resistance is indirectly related to the extracellular mass. This equivalent electric resistance has conductivity σ . Also the body tissue has an equivalent electric capacitance which reflects the ability of the tissue to store electrical energy. This reactance originates from the cell membrane that consists of two conductive layers of protein molecules having a nonconductive lipid material of relative permittivity ϵ_r . The dielectric constant of the biological tissue is anisotropic and frequency dependent. The reactance is a measure of the volume of cell membrane capacitance and an indirect measure of the intracellular volume or body cell mass.

In the present work the emphasis is on the dependence of the BIA on the frequency particularly in the microwave region. Moreover, the power attenuation through a biological tissue is examined.

Models for the equivalent biological circuit

Different models have been put forward to describe the human body. As of yet, there is no consensus on the equivalent biological circuit that will serve all purposes.

The basic concept of the proposed models depends on the assumption that human tissues can be treated as a set of resistors and capacitors connected together in series or in parallel. Two effective simple models of the skin barrier will be assumed. Firstly, Model A consists of a capacitor and resistor connected together in series, where the resistor represents the input ohmic impedance of the rest of the body. Secondly, Model B consists of a capacitor and a resistor connected in parallel, and all the rest of the human body may be represented by an ohmic resistor, R_2 , which represents the input impedance of the body. The electromagnetic wave enters as V_{in} and the induced wave is represented by V_{out} . The capacitor in Model A, and the parallel combination in Model B represent the skin barrier.

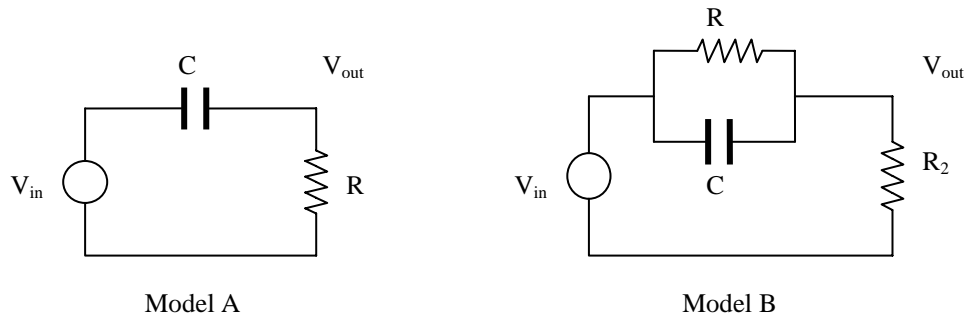

Fig. 1. Two bioelectric equivalent circuits, Models A and B, respectively.

We investigate two assumptions: firstly that the dielectric constant of either model is frequency independent and secondly, as it should, a function of the incident frequency. The particular treatment in the present work considers that the tissue is subjected to pulsating microwaves that are emitted from sources like mobile network antenna or mobile handsets.

Mathematical Analysis

Typically, for mobile communication, the incident wave comprises pulses of sinusoidal waves. The frequency of the pulses is around 100 KHz, while that of the sinusoidal waves is of the order of GHz. The pulses may be considered as square waves of periodic time T . For the first period the square wave is nonzero in the region $-T_1 \leq t \leq T_1$ where its value is unity. The sinusoidal wave may be simply represented by $V_o \cos(m\omega_0 t)$, where $\omega_0 = \frac{2\pi}{T}$ is the angular frequency of the square wave, while $m\omega_0$ is the angular frequency of the sinusoidal wave; V_o is the amplitude of the incident signal. Therefore the input signal may be considered as the direct multiplication of the square and sinusoidal functions and is given by

$$V_{in}(t) = \begin{cases} V_o \cos(m\omega_0 t) & -T_1 \leq t \leq T_1 \\ 0 & T_1 \leq t \leq T - T_1 \end{cases}$$

The input signal is illustrated in Fig. 2. $V_{in}(t)$ is then represented as a Fourier series [11] such that

$$V_{in}(t) = \sum_{k=-\infty}^{\infty} c_k e^{jk\omega_0 t}$$

The Fourier coefficients c_k are evaluated; to elaborate

$$c_k = \frac{1}{T} \int_{-T_1}^{T_1} V_{in}(t) e^{-jk\omega_0 t} dt = \frac{V_o}{T\omega_0} \left\{ \frac{\sin(k+m)\omega_0 T_1}{(k+m)} + \frac{\sin(k-m)\omega_0 T_1}{(k-m)} \right\}$$

Fig. 2. The input signal.

As soon as the signal is converted into its Fourier series and the coefficients are obtained for each harmonic component, each frequency may be treated separately such that $V_{in}(k\omega_0) = c_k$. The output signal, V_{out} , is calculated by standard circuit analysis; namely

$$V_{out}(\omega) = \frac{R}{Z(\omega)} V_{in}(\omega); \quad Z(\omega) = R + \frac{1}{j\omega C} \quad (\text{Model A})$$

$$V_{out}(\omega) = \frac{R_2}{Z(\omega)} V_{in}(\omega); \quad Z(\omega) = \frac{R}{1 + j\omega CR} + R_2 \quad (\text{Model B})$$

where $\omega = k\omega_0$. The total output signal as a function of time is given by

$$V_{out}(t) = \sum_{k=-\infty}^{\infty} V_{out}(k\omega_0) e^{jk\omega_0 t} = \sum_{k=-\infty}^{\infty} d_k e^{jk\omega_0 t}$$

The average power of a signal that is dissipated in a resistor is given by Parseval's relation and is proportional to

$$V_{rms}^2 = \frac{1}{T} \int_T |V(t)|^2 dt = \sum_{k=-\infty}^{\infty} |a_k|^2$$

where a_k are the Fourier series coefficients of $V(t)$.

Results

The dielectric characteristics, permittivity and conductivity, of the human tissues have been subject to a great research [12,13]. As of yet there is no agreement among research workers regarding their values. In this work the values used for the specific absorption rate (SAR) calculations according to the IEEE 1528-200x [14] are used as a guideline. A summary of these values is given in Table 1. The extrapolated values [13] from Hartsgrrove's *et al.* [15] formula for simulating body tissues at higher frequencies are supplied as well

Table 1. The permittivity and conductivity as a function of frequency.

Frequency MHz	ϵ_r	σ S/m	Reference
900	41.5	0.97	IEEE 1528-200x [14]
1800	40	1.4	
2100	39.8	1.49	
2450	39.2	1.8	
3000	38.5	2.4	
8000	26	9	Hartsgrrove <i>et al.</i> [15]
10000	23	11	

Two calculations for each of Models A and B were conducted. The first one explicitly considers the frequency dependence of the permittivity and conductivity and, by curve fitting, relations are obtained that satisfy the above data. The fitted relation for the permittivity as a function of frequency is:

$$\varepsilon_r(f) = 10^4 \times (0.8871f^{-8} - 4.5381f^{-6} + 6.544f^{-5} - 3.9988f^{-4} + 1.2852f^{-3} - 0.2507f^{-2} + 0.0376f^{-1} + 0.0001)$$

Whereas the fitted relation for the conductivity as a function of frequency is:

$$\sigma(f) = (0.0002f^8 - 0.01f^7 + 0.163f^6 - 1.2121f^5 + 4.2548f^4 - 6.1646f^3 + 8.1443f^2 - 4.0236)$$

For the sake of simplicity and the lack of experimental data, it is assumed that the above equations hold for the other frequency values that are not included in the table. In the second approach constant average values were taken, namely $\varepsilon_r = 40$ and $\sigma = 2$ S/m. As usual, $C = \frac{\varepsilon_0 \varepsilon_r A}{d}$ and $R = \frac{d}{\sigma A}$. The length d and area A are taken to be unity in SI units, thus our results are for unit length and unit area. The obtained results are summarized in Tables 2 and 3.

Conclusion

The main objective of the present work is to demonstrate the behaviour of the BIA as a power attenuator at different values of modulated high frequency. Comparison was set out between two simplified models of the skin barrier of a body. This is considered under the two assumptions that firstly the dielectric constant is sensitively dependent on the frequency or, secondly, its variation with the frequency is insignificantly small within the given frequency range.

Regarding the frequency dependent assumption, the results show that for both models the input induced voltage is slowly attenuated at frequencies below 10^7 Hz, but over this frequency Model B shows no attenuation while Model A indicates that as the frequency increases a considerable amount of energy is absorbed within the skin.

On the other hand when the dielectric constant is insensitive to frequency variation, Model A shows large attenuation at low frequencies which decreases gradually as the frequency increases, whereas Model B displays an opposite behaviour such that the attenuation is very poor almost at all frequencies in the range from 10^7 to 10^{10} Hz. This seems reasonable since according to the first model the skin behaves as a high pass filter, while the second model shows insensitivity to the variation of frequency.

We believe that the problem is more sophisticated than the proposed two models, which can only be considered as a first order approximation of the problem. There are other important factors that should be considered such as the multilayered structure of biological tissues, the effect of blood circulation, as well as the active elements incorporated in living tissues.

ABSTRACT

We proved that the centrioles were the device used for the detection of an artificial infrared source external to 3T3 fibroblast and epithelial CV1 cells. The fundamental contribution of the cytoskeleton explains the cell motility. In effect the strain due to the physical pressure on the plasma cell membrane is a sufficient stress to activate Hsp 27 which results in actin polymerization and motility of the cell. We calculate the diffracted field inside the cell due to the current induced along the centriole equivalent to a cylindrical dipole. We deduced the centriole bistatic area function of the directions of the incident and diffracted fields. Some idea of the theoretical pressure equal to several $\text{nN}/\mu\text{m}^2$ is in good agreement with recent experiments. About the two centrioles in orthogonal positions 100 % of the space is covered, while during the experiments 88 % of 3T3 and 50 % of CV1 cells were put in motion in presence of a near infrared source. So we must consider than the strain due to the pressure on the membrane can be transmitted to the side facing the light source throughout the actin cytoskeleton. The stress fibers serve as force transmitters in fast mechanotransduction and act as mechano-sensors with direction sensitivity on slow mechanotransduction. We determine the spectral emission power of a single cell from the black-body one. Finally a cell scatters a weak ambient black-body theoretical power radiation. The cellular aggregate radiation is able to be detected by one cell located at a certain distance following recent measurements.

INTRODUCTION

Albrecht-Buehler showed that 3T3 mouse fibroblast cells and epithelial CV1 cells could react to a near-infrared light by moving either towards or away from the light source. The type of response depended on the cell type and on the temporal pattern of the emission of the light. He also proved that the centrioles were the detection device for the direction of the infrared source [1] - [4].

CONTRIBUTION OF THE CYTOSKELETON CONCERNING THE CELL MOTILITY (fig. 1)

Fig. 1 : Schematic diagram of a focal adhesion.

(From INGBER : Journal of Cell Science 2003, 116 : 1397-1408)

A, B : forces from the extracellular matrix (EM) or applied to the cell surface

Alpha, beta : integrin receptors.

Focal adhesion proteins : vinculin (Vin), paxillin (Pax), talin (Tal).

The plasma membrane is an assembling of various proteins inserted in the fluid matrix of a lipid bilayer. In non muscle cells integrins receptors are membrane spanning proteins that ligate extracellular matrix proteins and link to actin skeleton on the inside of the cells [5] providing a great degree of mechanical coupling across the cell surface. The cytoskeleton is composed of microtubules, actin microfilaments and intermediate filaments. Application of forces to integrins receptors and associated focal adhesion proteins results in physical distortion of the membrane surface and repositionning of the cytoskeletal filaments along applied field lines within the cytoplasm [6]. Among the three filament systems that form the cytoskeleton, the actin network plays the principal role in determining the cell dynamic response [7]. The cell motility is driven by the sum of asymmetric traction forces exerted on the substrate through adhesion foci that interface with the actin skeleton [8] stimulating polymerization of monomeric globular actin to filamentous actin [9]. Polymerization of actin filaments is necessary for the extension of membrane structures, creating a propulsive force that pushes forward the lamellipodia at the front of migrating cell [10], [11]. Stress proteins, called heat shock proteins (Hsps), are synthesized by cells in case of stress. In the small heat shock protein family, Hsp27 participated in regulating the organization of the actin cytoskeleton in both control and stress conditions. When Hsp27 is phosphorylated, it stimulates actin polymerization and modulates the rate of polymerization, therefore determining the motility of the cell [10], [12], [13], [14], [15]. So we could assume that the strain due to the pressure on the plasma

membrane, resulting from the near infrared radiation, constituted a sufficient stress to activate Hsp27 which resulted in actin polymerization and motility of the cell.

INFLUENCE OF A FLUCTUATING NEAR-INFRARED EXTERNAL SOURCE ABOUT THE CENTRIOLE DIFFRACTION INSIDE THE CELL

Albrecht-Buehler G. showed [1], [4], that a pair of centrioles is able to detect the direction of a near-infrared pulsed source of a $0.8 \mu\text{m}$ wavelength. Recently [16] we introduced the theoretical selective transparence of the cell membrane deduced from experimental results in the range stretched from 0.2 to $1 \mu\text{m}$. It was called the transmission coefficient T_{13} . Then from an isotropic radiated power of $4 \mu\text{W}$ of the light source located at $60 \mu\text{m}$, we calculated, inside the cell, an electric field E_i equal to 40 V/m . The wave attenuation along the path and the transmission through the membrane (T_{13}) were taken into account. Inside the cell the mean incident power per unit of area is equal to :

$$p_i = \frac{1}{2} \sqrt{\frac{\epsilon_0}{\mu_0}} |\vec{E}_i|^2 \quad (1)$$

We compare each protofilament of the centriole to a cylindrical dipole of length $2h$ and diameter $2a$, which is equivalent to an opened transmission line of characteristic impedance Z_c and linear propagation constant : $\gamma = \alpha + jk$ [17].

We use the following parameters without dimension :

$$\left. \begin{aligned} K = kh = 2\pi h / \lambda, \quad \Omega = 2 \log_e (2h/a), \\ A = \alpha h = (kh)^2 / 2(\Omega - 3.4) \end{aligned} \right\} \quad (2)$$

Fig. 2. Cell bistatic area $\sigma(\theta, \theta_0)$

The figure 2 shows the centriole lighted by a plane-wave from the θ_o direction with an electric field $\vec{E}_i(\theta_o)$. The diffracted field at point M : $\vec{E}_d(\theta, \phi, \theta_o, R)$ ($0 \leq \phi \leq 2\pi$), inside the cell is due to the current $I(z, \theta_o)$ induced along the centriole. The distance between the center of the centriole and M is R. The bistatic area of the centriole related to the two directions θ_o and θ is given by the following expression :

$$\sigma(\theta, \theta_o) = \frac{\lambda^2}{\pi} |S(\theta, \theta_o)|^2 \quad (3)$$

$$\text{with : } \left| \frac{\vec{E}_d(\theta, \theta_o, R)}{\vec{E}_i(\theta_o)} \right|^2 = \frac{|S(\theta, \theta_o)|^2}{(kR)^2} = \frac{\sigma(\theta, \theta_o)}{4\pi R^2} \quad (4)$$

The expressions (3) and (4) are valid when $R \geq 8h^2/\lambda$ (5), that is when the diffracted field is associated with an electromagnetic plane-wave.

$I(z, \theta_o)$ and $S(\theta, \theta_o)$, which depend on A, K and Ω parameters are given in the annex of calculation.

The whole power P_d diffracted inside the cell by the centriole is :

$$P_d(\theta_o) = \frac{1}{2} \sqrt{\frac{\epsilon_o}{\mu_o}} \int |\vec{E}_d|^2 ds = \frac{1}{2} \sqrt{\frac{\epsilon_o}{\mu_o}} |\vec{E}_i|^2 \int \frac{\sigma(\theta, \theta_o) ds}{4\pi R^2} = \frac{P_i}{2} \int_0^\pi \sigma(\theta, \theta_o) \sin \theta d\theta \quad (6)$$

with $ds = R^2 \sin \theta d\theta d\phi$.

For the pulse light emission the form factor is the product of the length of time τ by the frequency f_r . In a corresponding stochastic way the energy is stored inside the cell of radius ρ , where it is trapped because its transmission through the membrane is lower than 10 percent [16].

The stored energy during a length of time Δt will be equal to :

$$W_S = P_d(\theta_o) \Delta t \tau f_r \quad (7)$$

The density of energy u_S and the mean pressure P applied on the membrane are then :

$$u_S = \frac{W_S}{(4/3)\pi\rho^3} \quad (8) \quad P = \frac{u_S}{3} \quad (9)$$

In the fig. 2 we present the bistatic area (3) in terms of θ for several θ_o values with the following parameters given in (2) :

$$2h = \lambda = 0.8\mu\text{m}, \quad 2a = 40\text{ nm}, \quad \Omega = 7.38, \quad K = \pi, \quad A = 1.24$$

The validity condition (5) is fulfilled when : $R \geq 1.6\mu\text{m}$. Whatever, the chosen incident angle θ_o , the max of σ and P_d occur for $\theta \geq 90^\circ$. The active diffracted beam draws an asymmetrical cone-shaped zone around the centriole axis so that the diffracted light propagation goes away from the light source.

The Table I shows P_d , W_S , u_S and P with $p_i = 2W/\text{m}^2$ (1), $\tau f_r = 1/2$,

$\rho = 11\mu\text{m}$ and $\Delta t = 600\text{s}$.

θ_o (degrees)	90	75	60	45	30
P_d (watts) (6)	3.10^{-13}	3.10^{-13}	$2.6 \cdot 10^{-13}$	$1.4 \cdot 10^{-13}$	$7 \cdot 10^{-14}$
W_S (Joules) (7)	9.10^{-11}	9.10^{-11}	8.10^{-11}	4.10^{-11}	2.10^{-11}
u_S (Joules/ m^3) (8)	$1.6 \cdot 10^4$	$1.6 \cdot 10^4$	$1.4 \cdot 10^4$	$7.4 \cdot 10^3$	$4 \cdot 10^3$
P (nN/ μm^2)	5.0	5.0	4.6	2.3	1.2

**Table I : Power and energy diffracted by a 3T3 cell.
Pressure applied on the membrane**

Some idea of the size of the pressure P has been obtained in recent experiments [18]. In the abstract we can read: “we measure dynamic traction forces applied by epithelial cells (monolayer) on a substrate. The force sensor is a high-density array of elastomeric microfabricated pillars that supports the cells. Traction forces induced by cell migration are deduced from the measurements of the bending of these pillars and are correlated with actin localization by fluorescence microscopy”. Each post or pillar is a cylinder of radius r and length L . The deflection Δx of the free end of the post is due to a force F exerted by the cell on its underlying substrate given by :

$$F = \left(\frac{3}{4} \pi E \frac{r^4}{L^3} \right) \Delta x \quad (10)$$

E is the Young’s modulus of the pillar.

With $\Delta x = 0.1 \mu m$, $r = 1.5 \mu m$, $L = 5 \mu m$, $E = 2 \cdot 10^6 P_a$, we find : $F = 19 \text{ nN}$.

This force applied to the area of the pillar $\pi r^2 = 7.07 \mu m^2$ corresponds to a pressure of $2.7 \text{ nN}/\mu m^2$.

This pressure is in good agreement with our theoretical results shown in Table I.

Previous analysis (2001, 1999), related in [18], have indicated a $5.5 \text{ nN}/\mu m^2$ value relating force and contact area.

Note : Albrecht-Buehler said (April 23, 2003) : “*The cells used were always moving. The first sign of changing direction, i.e the extension of a new lamellipodium in the direction of the light source, was usually visible after 5-10 min (factor 2) since the beginning of the lighting*”. This explains the choice of $\Delta t = 600 \text{ s}$ in W_S (7).

Then the radiation by one centriole is the most efficient when $45^\circ \leq \theta_o \leq 135^\circ$ which correspond to a diffraction zone : $60^\circ \leq \theta \leq 120^\circ$ (fig 2) for a variation of σ and P_d by a same factor 2. If the two centrioles are in orthogonal positions 100 % of the space is covered. According to Albrecht-Buehler about 88 % of 3T3 cells and 50 % of CV1 cells were put in motion in presence of near-infrared source. This information is related in [19].

CELL SCATTERING OF A NEAR-INFRARED FRACTION OF THE BLACK-BODY RADIATION

Recently Albrecht-Buehler G. explains that a cell can scatter the near-infrared portion of the ambient black-body radiation to become a light source, as a result of the experiments [20]. The present purpose is to justify a

such hypothesis giving some theoretical development. We are sure that the scattered light of the black-body radiation for one cell in the near-infrared range is very small and cannot be detected, but may be by a group of aggregated cells.

Fig. 3. Spectral emission powers E_λ and e_λ (for $T=310^\circ\text{K}$).

The spectral-emission power E_λ is given by :

$$E_\lambda = \frac{2hc^2}{\lambda^5} \cdot \frac{1}{\exp\left(\frac{hv}{kT}\right) - 1} \quad (11)$$

In international units it is expressed in W/m^3 :

$$E_\lambda = \frac{1.19 \cdot 10^{-16}}{\lambda^5} \cdot \frac{1}{\exp\left(\frac{14.4 \cdot 10^{-3}}{\lambda T}\right) - 1} \quad (12)$$

The whole specific intensity E_T of the black-body expressed in W/m^2 is :

$$E_T(\lambda, T) = \int_0^\infty E_\lambda d\lambda \quad (13)$$

The spectral-emission power of one cell is equal to :

$$e_\lambda = \alpha_\lambda E_\lambda = |T_{13}|^2 \cdot E_\lambda \quad (14)$$

$\alpha_\lambda < 1$ is the absorption coefficient, and T_{13} the transmission coefficient through the cell membrane given in [16] by :

$$|T_{13}|^2 = 1 / \left[ch^2(\Gamma_2 d) + k_2^2 sh^2(\Gamma_2 d) / 4n_1^2 \right] \quad (15)$$

d is the membrane thickness and $\Gamma_2 d = 2\pi k_2 d / \lambda$. k_2 is the index of absorption of the membrane and n_1 is the index of refraction of the interstitial medium. We present in fig. 3 the spectral-emission powers E_λ and e_λ in terms of λ for $T = 310^\circ \text{K}$. The parameter λ_1 is the maximal wavelength which limits the near-infrared absorption range. The max of E_λ is equal to 10^7W/m^3 for $\lambda = 9.3 \mu\text{m}$.

The whole specific intensity e_T of the cell is then given by :

$$e_T = \int_0^{\lambda_1} e_\lambda d\lambda \quad (16)$$

It appears in the table II :

$\lambda_1 (\mu\text{m})$	1	1.5	1.75	2
$e_T (\mu\text{W/cm}^2) \quad (16)$	10^{-16}	10^{-9}	2.10^{-7}	8.10^{-6}

Table II (valid for $T = 310^\circ \text{K}$)

According to the second principle of thermodynamics, at $T = 310^\circ \text{K}$, the power radiated by a cell of radius ρ is : $P_d = 4\pi\rho^2 e_T \quad (17)$

For a 3T3 cell with : $\rho = 11 \mu\text{m}$, P_d is shown in Table III.

$\lambda_1 (\mu\text{m})$	1	1.5	1.75	2
$P_d (\text{watts}) \quad (17)$	$1.5 \cdot 10^{-27}$	$1.5 \cdot 10^{-20}$	3.10^{-18}	$1.2 \cdot 10^{-16}$

Table III – Power radiation by a 3T3 cell

We note the great importance of the limit of the membrane cell transparency upon its natural radiation power. So a cell scatters a weak ambient black-body radiation. Only aggregate cells is able to be detected by one cell located at a certain distance as recently measured [20].

BIOLOGICAL HYPOTHESE

Could the pressure P calculated in (9) be the cause of the displacement of the cell to protect the overall integrity of the membrane ?

The strain (fig. 1, A) due to the pressure P , is received in focal adhesion proteins and integrins activate the signaling pathway leading to actin polymerization and motility of the cell towards the light source. However Albrecht-Buehler observed more cells were going forward than backward. So we must consider that the strain on the membrane can be transmitted to the side facing the light source. Externally applied forces (fig. 1, A) are transmitted throughout the actin cytoskeleton and result in immediate repositioning of cytoskeletal filaments along applied tension field lines within the cytoplasm [6], [21]. Stress fibers, composed of actin filaments, myosin and α -actinin, are anchored at focal adhesions at one side of the cell, and at focal adhesions on the other side of the cell. They serve as force transmitters in fast mechanotransduction and act as mechanosensors with direction sensitivity on slow mechanotransduction [22]. So the strain due to the pressure could be transmitted to the opposite side of the cell where it would determine the moving of the cell away the light source. This can be akin to the transmission of tension due to fluid shear stress from the apical surface of endothelial cells through the cytoskeleton to the integrins which then change in tension (23). Moreover, in the Albrecht-Buehler's experiments, the percentages of cells that were either attracted or pushed away from the light source depended on the pulsing frequencies of the light source. Were the threshold between a fast and a slow mechanotransduction linked to the difference in frequency ?

SUMMARY

The 3T3 fibroblast and epithelial CV1 cells motility has been explained :

- firstly by their centrioles diffraction under the influence of a fluctuating near-infrared artificial external pulsed source. The diffraction light propagation is such that, due to the physical pressure on the plasma cell membrane, the cell goes towards the light source.
- secondly when a sufficient strain, transmitted along the cytoskeleton, can move the cell away the light pulsed source.

On the other hand, we show that a cell scatters a weak part of the natural near infrared ambient black body radiation.

All these theoretical results are in good agreement with recent published measurements.

APPENDIX

Induced current along the centriole due to the incident electric field $\vec{E}_i(\theta_o)$ (figure 1)

It is given by the following equation [17] :

$$I(z, \theta_o) = C \left\{ -j \frac{\sin(K \cos \theta_o)}{\text{sh}(A + jK)} \text{sh} \left[\frac{z}{h} (A + jK) \right] - \frac{\cos(K \cos \theta_o)}{\text{ch}(A + jK)} \text{ch} \left[\frac{z}{h} (A + jK) \right] + \exp(jKz \cos \theta_o) \right\}$$

$$\text{with : } C = \frac{2hE_i}{Z_c} \frac{(A + jK) \sin \theta_o}{\left[(A + jK)^2 + K^2 \cos^2 \theta_o \right]}, \quad Z_c = \frac{Z_o}{2\pi} \left(1 - j 2 \frac{A}{K} \right)^{1/2} (\Omega - 3, 4)$$

With the previous parameters, $E_i = 40 \text{ V/m}$, and $Z_o = 377 \text{ ohms}$, the module of the current $\frac{2hE_i}{Z_c}$ is equal to $0.12 \mu\text{A}$.

Bistatic area of the centriole

The function $S(\theta, \theta_o)$ is extracted from [17] : $S(\theta, \theta_o) = j \frac{K Z_o}{2\pi Z_c} F(\theta, \theta_o)$

$$\text{with } F(\theta, \theta_o) = (p + q + r) \cdot \frac{s}{u}$$

$$\text{and } p = K \frac{\text{sh} x}{x} \left[\frac{-z}{\text{ch}(A + jK)} + j \frac{t}{\text{sh}(A + jK)} \right] \quad q = - \left(K \frac{\text{sh} y}{y} \right) \left[\frac{z}{\text{ch}(A + jK)} + j \frac{t}{\text{sh}(A + jK)} \right]$$

$$r = 2 \frac{\sin(Kv)}{v} \quad s = (A + jK) \sin \theta \sin \theta_o$$

$$u = (A + jK)^2 + K^2 \cos^2 \theta_o \quad x = A + jK(1 - \cos \theta)$$

$$y = A + jK(1 + \cos \theta), \quad z = \cos(K \cos \theta_o), \quad t = \sin(K \cos \theta_o), \quad v = \cos \theta + \cos \theta_o$$

Hypersensitivity to Electricity: The effect of the current waveform on the perception level.

Contact email : JL.Lilien@ulg.ac.be

Abstract - Hypersensitivity to electricity has been reported many times in the literature. From another point of view, numerous measurements have been performed on perception level. Even if it appears that part of the population has a lower perception level of current, there is no clear link with the so called “hypersensitivity to electricity” which is more related to declared physiological disorders in part of the population (sleeping problem, headache ...). Such declared hypersensitivity is currently not yet related to any biological parameter.

Our research team is currently trying to determine a relationship between hypersensitive declared people and the perception level when injecting current in the low frequency range 50-1000 Hz.

We have performed current perception tests with individuals under different conditions (different wave shapes, frequencies, influence of external electric field, male and female...) using a particular protocol and our own designed system for current injection.

This paper will present our test system design (current injector, wave shape converter, safety aspects) and our first results based on both sine wave (different frequencies) and wideband signal.

I. Introduction

Hypersensitivity to electricity, i.e. non-specific health symptoms such as headache, sleep disturbance, nervousness, concentration disturbances or skin arousal, attributed by the patient to the “electromagnetic pollution”, has been frequently reported in the literature (Hilert et al, 2002, Leitgeb, 1998) but until now, no clear link has been shown between the electromagnetic field and the symptoms of these persons.

In (Leitgeb and Schrötner, 2003), a subgroup of people with significantly increased electrosensitivity was detected. Herein, the electromagnetic sensibility is described as the ability to perceive electric and electromagnetic exposure, and electromagnetic hypersensitivity, developing health symptoms due to exposure to environmental field. The measurements showed a clear difference between men and women. A log-normal law was proved to fit fairly well to their results (see fig 1).

Fig1: Distribution of the cumulative probability perception Threshold current I_w (following Leitgeb-2003)

The existence of the very “electrosensible” subgroup can be seen as the second log-normal distribution on the fig 2.

Fig 2: Best least square fit of two ideal log-normal distributions with the frequency distribution of measured electric current perception thresholds of men (following Leitgeb-2003).

Similarly to the work in (Leitgeb and Schröter, 2003), but in a wide band of frequency, and signal shape, we try to determine a link between the “hypersensitivity to electromagnetism” and the sensibility to electricity. Our aim is to measure the smallest current intensity that a given person can feel when electrical current is flowing between two electrodes placed on the forearm of this person.

A home-made device, that allows injecting any waveform current within the frequency range 50Hz-1kHz, has been designed. This injector will be described in detail hereafter.

This paper will be focused on the sensitivity to electricity of a person according to the frequency. The first results of measurements will be shown for two different frequencies (50Hz and 1 kHz).

II. Measurements method

The developed experimental system is composed of a computer, a current injector and an external supply (see fig 3).

Fig3: Experimental System

A home-made program creates an audio signal (wave file) which is transmitted via the sound card to the current injector. The latter converts the voltage in a stable current flowing between the two electrodes through the body of the volunteer. For safety reasons and to prevent any electric current pathways across the heart, the investigations were done on the forearms on the volunteers. The complete description of the current injector can be found on the Section 3.

The sinusoidal current is applied by trains of constant rms (root mean square) value with dead time of 5 ms between each of them. Between two sequences, the rms current level is increased following a given law, which has been chosen in these experiments as exponential. Our system can easily handle any dead time or increasing law at a given frequency. Currents were increased by step until the program was interrupted by the volunteer's push of the computer's space bar (or any other computer's button) when perceiving the current flow. To minimize random influences, measurements were performed six times with 5 seconds break between each. The mean value of this first test was considered as the first evaluation of the perception level. After 30 sec, the measurements were performed six more times, but with a more precise range of current, according to the first evaluation. The tests evaluated the sensitivity to a 50 Hz sinusoidal wave and 1 kHz sinusoidal wave. The value of 1 kHz was arbitrary chosen to compare the sensibility at two different frequencies. Recruitment method of volunteer was done essentially on the student of the University of Liège; they were informed about the procedure and explicitly expressed their consent to the measurements.

III. Technical specification and safety aspect

The electronic scheme of the current injector is shown on the Fig.4. It is composed of seven "blocks".

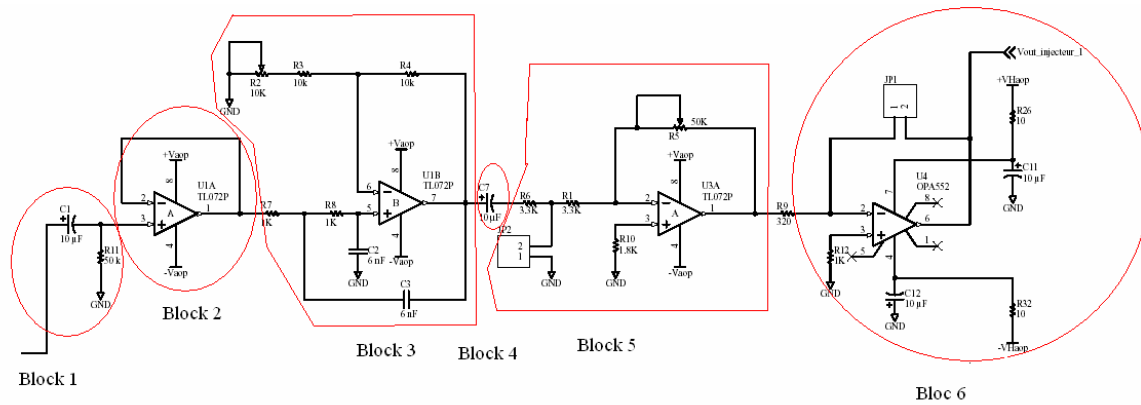

Fig4: Scheme of the current injector

- **Block 1: RC high pass filter:**

Its role is to eliminate the DC component of the signal. The value of the cut down frequency is 0.3 Hz. The DC part has to be eliminated because it could damage the tissues of the volunteer.

- **Block 2: Follower circuit**

It makes sure that there is no interference between the part one and the part three of the circuit.

- **Block 3: Butterworth low pass filter,**

This block eliminates the high frequency parasites. Its cut down frequency is 25 kHz

- **Block 4: RC high pass filter:**

It serves to eliminate the DC component of the signal. Indeed, the signal can have been perturbed by the precedent part of the circuit and have again a DC component. Its cut down frequency is the same than the block 1's : 0.3 Hz.

- **Block 5: Amplifier with variable gain:**

This part of the circuit is used to adjust the output (calibration) of the device.

- **Block 6: Current injector circuit :**

This part of the circuit is the current injector itself; it uses the human body resistance as feedback resistance.

We have characterized the bandwidth of the device in order to be sure that our signals are not altered (attenuated). The results are shown on the following figure (voltage peak to peak taken on the output of the device in function of frequency). The results measurements showed that in the range of our experiment, i.e. 50 Hz to 1 kHz, the signals are not altered.

Fig 5: Frequency response of the current injector

On such a kind of device, the safety aspect is crucial. In order to be sure that any perturbation of the electric network is rejected, a system of low pass filter, in the external supply, has been designed to eliminate the high frequency component, as the perturbation can be seen as a high frequency signal, it is thus eliminated. The device is also limited with a maximum output current of 5mA.

As already mentioned, we have ensured, by a system of high pass filter, that the signal injected in the body does not have a continuous (DC) component, as a DC component would be dangerous for the tissues.

The last feature that guarantees the security of the person tested is a stop button that disconnects immediately the person from the current injector. When the user pushes the button, the entry of the amplifier (Block 5) is forced to the mass, so the entry of the amplifier is zero.

IV Results and discussion

It was possible to perform measurement on 150 persons. These persons were aged between 17 and 60 years, in order to avoid bias by including possibly more sensitive children or less sensitive elderly. As the persons were generally students of the university, almost all of them were under 25 years old.

Our first data clearly show a difference to the perception level at 50 Hz and 1 kHz. It has already been shown that the sensitivity to electricity varies according with the frequency (Dalziel & Manfield, 1950) of the signal; but our study is focused on the low frequency range.

Fig 6: distribution of the cumulative frequency

We have compared our data concerning the 50Hz sinusoidal current to Leitgeb's results (Leitgeb and Schrötner, 2003). Our results superpose to their results are shown on the Fig 7. The mean value of the perception threshold in our study (760.23 μA) is higher than the mean value they found (for men, near 300 μA). Nevertheless the mean value we found is still lower than the related mean value (Reilly, 1998). It seems also that the mathematical law is different; the kind of frequency distribution of perception level was analyzed by Kolmogorov-Smirnov testing. The null hypothesis of log-normal distribution data was rejected by a significance $P < 0.01$. Until now, we hadn't found a proper law to fit our results. The histogram of the frequency distribution of measured electric current perception threshold is shown on the Fig 7

Fig 7: histogram of the frequency distribution of measured electric current perception threshold

It is possible that the observed differences are due to the differences in the measurements protocol, Leitgeb (Leitgeb and Schrötner, 2003) increased their current linearly, but we increased it exponentially, they also took six measurements, but did not proceed to a refining like us and take a break of 3min after each measurement whereas we took only 5sec. Two other differences are the facts that our volunteers were almost all under 25 years old. The results are not separated between male and female because we had only 19 percent of female volunteers. It has to be said that the two “weak perception volunteers” were male.

Fig 8: Our results superposed to Leitgeb's data

The current injector and its program can be used to generate a more complex waveform than a sinus. The Fig 8 and 9 show a typical waveform used during the last year in our study. Even if our device is now able to generate any wished waveform, the problem is to have a comparison point between two waveforms. Up to now, we have chosen to compare the RMS (Root Mean Square) value, but we have doubts about the validity of this approach. A value linked to a biological characteristic such as the Action Potential of the nervous cells would certainly be more suitable.

Fig 9: Wideband signal

Fig10. Frequential analysis by the wavelet method of the wideband signal.

V. Conclusion

We have designed a device that has shown to be a useful tool to study the human sensibility to electricity. One of our priorities was to ensure the security of the volunteers.

The measurements obtained with our device were quite different from those published in a similar work. We concluded that the protocol chosen influences considerably the results.

A study on the effects of the frequency and the waveform on the perception level has begun. The first results, even if few measurements have been done, clearly show that the human sensibility decreases with the frequency. This effect is maybe due to a “relaxation effect” of the neurons. Our device is able to generate any waveform, but the problem is to have or select a comparison magnitude between two waveforms. This magnitude could maybe be linked to a biological characteristic like the Action Potential of the nervous cell.

Acknowledgments

This research has been supported by Elia, the Belgium's transmission system operator. We would like to thanks Pascal Harmeling for the realisation of the electronic part of this work and David Lilien for the implementation of the wave-generating software.

MOBILE TELECOMMUNICATIONS RISK PERCEPTION AND COMMUNICATION IN EGYPT

HAMDY ELLAITHY, EBI ELOMBI

VODAFONE EGYPT

Abstract

Health concern of mobile telecommunications is widespread and found in all countries with the technology. The level of perceived risk varies among countries depending on a number of factors. In developing countries such as Egypt, the level of concern and perceived risk is heightened mainly due to the overall average lower level of education, lack of understanding of the technology as well as the natural fears of an invading and extensively used technology.

This paper discusses the current level of concern and risk perception in Egypt and how various factors have contributed to their changes over the past three years. Various risk communication strategies are discussed; in particular a project to address the public's concerns regarding emissions from mobile telecommunications base stations.

This project, called HORUS, continuously measures the electric field levels from GSM base stations across Egypt with the use of solar-powered GSM EMF monitoring stations. The 24-hour a day measured field readings are compared with national and international limits and published on a dedicated website.

Introduction

In 2003, an EMF perception survey, commissioned by Vodafone, was carried out in several countries including Egypt by an independent marketing research company - MORI. The main aim of the survey was to assess the level of concern among the public and to assess how this could be addressed. This survey provided Vodafone with an objective view of how the mobile telecommunications industry and technology is perceived in terms of health concerns and how this public concern differs from that in other countries [1, 2]. The results of this survey guided communication strategies to address the public's concern and attempt to reduce the level of concern.

Another survey carried out by the same company in 2005 in Egypt, showed the current level of public concern and highlighted areas where there have been significant changes. It is clear that several factors including communications programs put in place after the 2003 EMF perception survey may have had an impact in the way the public perceives the technology.

I. The Ipsos-MORI EMF Perception survey

A total of 1,000 interviews were conducted in Egypt, among the general public, using CATI (Computer Assisted Telephone Interviewing). This was in contrast to the 2003 survey when the interviews were conducted face-to-face [2]. Respondents were aged 18+ and were from across the whole of Egypt. Quotas were set on age, gender and region. The results are weighted to reflect the population of Egypt.

The main aim of the survey was to assess the nature and level of concern among the Egyptian public and to determine what impact this concern may have for the telecommunications business.

II. Key Findings of the 2005 EMF survey in Egypt

The results of the 2005 survey summarised below is taken from the independent Ipsos-MORI report [3].

Mobile phones, masts and health were not a major top-of-mind concern; ranking 8th amongst the issues mentioned such as air pollution, smoking or cancer. On prompting, mobile phones and masts rose in importance to 4th place.

Concern appeared to be caused largely by the respondent having read or heard information on this issue, as opposed to direct personal experience. Only 10% of all respondents were concerned about mobile phones and masts with 79% of those concerned (8% of the population) because of information read or heard, see Figure 1.

Figure 1: Causes of Concern

Despite this initial low level of concern, 36% of the Egyptian population surveyed, thought that mobile phones were not safe to use, with about 50% believing that masts were worse for health than mobile phones. However, the majority (90%) agreed that they have more important things to worry about. This reiterates the observation obtained from the initial concern result, that is that mobile phones, masts and health are an issue for some, but when put in context other health problems are of a greater priority.

Many believed that mobile phones cause some kind of physical effect, whether that be headaches, a warming of the ear or, more seriously, cancer – Figure 2.

Figure 2: Claimed health problems

Knowledge of the role of masts in mobile operation was still an issue. 17% did not understand the necessity for masts in the operation of mobile phones, stating that they believed a mobile phone could work without being near to a mast.

49% of respondents were aware of a mast anywhere e.g. neighbourhood, work, other locality. However, the majority of mobile phone users were indifferent, with a small minority (6%) actively objecting.

62% of respondents believed that there was no conclusive information on mobile phones, masts and health, whilst 81% stated that they did not know whom to believe. Despite this reservation, 77% believed the benefits of using a mobile phone outweighed any potential risks involved.

13% stated on an unprompted basis that they required information on how mobile masts work. On prompting, the information sought ranged from information on how mobile phones work through to the relative safety of a mobile phone in comparison to other items.

The study revealed a lack of trust, with 72% of the public believing that the industry was withholding

information on this issue, whilst large numbers did not know whether the industry takes this issue seriously or not.

40% would speak more highly of an operator who supplied information on this issue. 3% would be less inclined to trust their operator should they do this.

III. Changes in attitude and concern between 2003 and 2005

The most significant changes in the attitude of the Egyptian public has been in the level of concern and the understanding of the role of masts or base stations in the operation of mobile phones. Some of the key changes are illustrated in Figure 3.

Issue	2003	2005
Prompted concern on Mobile Phones/Masts	43%	10%
Percentages who do not believe mobile phones are safe to use.	71%	36%
Percentages who believe benefits outweigh the risk	68%	77%
Percentages who do not understand the necessity of masts in the operation of mobile phones.	41%	17%

Figure 3: Comparison of attitudes between 2003 and 2005

The general level of concern dropped by more than 70% to 10% in 2005 while concern regarding the safety of mobile phones was halved to 36% in 2005. The level of knowledge and understanding of the technology has also increased with significantly more people understanding the relationship between masts and mobile phone operation.

These changes could be attributed to some communication initiatives implemented by Vodafone after the 2003 survey as well as to changes in the technological environment.

Over this period, Vodafone organised and sponsored several seminars on mobile phones, masts and health across Egypt, targeting various segments of the public. Providing material for and speaking to local councils, landlords and the press as well as leaflets made available to customers. One of Vodafone Egypt's key initiatives has been the implementation of a project called Project HORUS, which continuously monitors field levels from GSM base stations in selected locations across the country and makes the readings available to the public through a dedicated website.

Other influencing factors include the fact that the penetration level moved from 8% in 2003 to 18% in 2005; increased familiarity with the technology over time; government support for a third operator into the market as well as ongoing coverage campaigns by the existing operators.

IV. The project HORUS

This project was an initiative to inform the general public about Radio Frequency (RF) Radiation, through the continuous (24-hour) monitoring of RF field levels in selected locations. Through Project HORUS the public are able to monitor RF radiation levels in several locations across Egypt 24 hours a day.

Vodafone Egypt has deployed over 54 electro-magnetic radiation probes across Egypt. The probes measure radio frequency field levels emitted in the GSM frequency bands at 900 MHz and 1800 MHz, and are powered by solar cells Figure 4. This makes it easy to relocate the units to monitor new areas where there is public concern.

Figure 4: A PMM8055S EMF monitoring station deployed on a rooftop

The readings from each probe are downloaded daily to a web server, which then displays readings on a dedicated website. These readings are displayed on graphs, which can be viewed in comparison with the maximum allowable levels set by the Egyptian authorities and the ICNIRP (International Commission on Non-Ionizing Radiation Protection). Typical readings are hundreds of times below standards as illustrated in Figure 5. More details on the project can be found on the project's website www.projectthorus.com.

Figure 5: Readings from a monitoring station in the Alexandria governorate

The average reading during this period was 1.15V/m, which is less than 3% of national or international safety limits.

The project was a direct result of the 2003 survey which showed that a significant proportion of the public was concerned about emissions from base stations. Vodafone Egypt first launched Project HORUS in early 2005 across 13 governorates and has expanded the project to cover all 27 governorates. The project has been a useful tool in communication with the public as it demonstrates compliance with standards and an openness and transparency on Vodafone's part which seems to have a positive impact on the public's level of concern.

V. Conclusion

Mobile phones, masts and health is an important issue, but not a primary health concern. This low level of concern mirrors the findings of MORI's research for Vodafone in 2003. The majority of the population are more concerned about other health issues. However, the industry as a whole needs to respond to concerns that important information is being withheld.

The principal trigger leading to concern is information on health effects that people have heard or read, not their personal experience. Lack of understanding, especially on the need for masts, is also fuelling concern. Many people would like to receive more information, including explanations of how the technology works. Communication material will need to be tailored to specific requirements, as different people would like to receive information on a variety of topics.

Open and transparent communication on the issue seems to have an effect on reducing concern, with the continuous EMF monitoring project HORUS, serving to reduce both concern and build operator trust and confidence.

Abstract

A network for the monitoring of the non-ionizing electromagnetic radiation levels in several areas of Greece is presented in this paper. During its 4-year operation more than 4,000,000 measurements of the electric field strength have been performed and recorded. The results aided by useful scientific information are open to the public through a devoted web site. The network measurement results have shown that the field values are several times below the EC recommended and Greek law safety values.

I. Introduction

During the last decade, the installation and operation of several wireless networks, such as the GSM, UMTS and TETRA system has led to increasing public concerns about the exposure to electromagnetic radiation emitted from these sources. In conjunction with traditional broadcasting systems such as FM Radio and TV services, RADAR systems etc. these concerns call for the continuous information of the public regarding their exposure to EM radiation levels. The conduction of repetitive, on site, “ad-hoc” measurements is a first step for estimating the exposure levels. Nevertheless, ad-hoc measurements refer to a specific time period (usually 1-2 hours). On the other hand the notion of continuous measurement of EM radiation levels on a 24-hour basis is more appealing to the concerned public. This is due to the fact that the recorded values can be compared to the public exposure safety values, called reference levels, which are set by the relevant organisations, such as the EC [5] and government authorities [6].

Therefore, a network for the measurement and recording of non-ionizing Electromagnetic Radiation (EMR) emissions on several sites and on a 24-hour basis is one of the best solutions for keeping the public informed. Another important parameter of such a network is the possibility to present the results via a public accessible and user-friendly web site.

As described above, monitoring networks are a valuable tool in attempting to deal with public concerns about the

potential health effects of non-ionizing radiation of electromagnetic radiation. As a result, several monitoring networks are implemented all over Europe and Africa (Italy, Spain, Portugal, United Kingdom, Malta, Egypt etc.) [1]-[4]. Moreover network deployment entails a number of challenges, in terms of hardware certification, network control and daily maintenance. With all the above considerations in mind an Electromagnetic Radiation Monitoring System was developed in Greece. It is known as the “Hermes” project [7], and it is fully operational since November 2002 and currently expanding in several areas around the country.

The paper below is structured as follows: Section II gives a general technical description of a monitoring network, as well as a framework which may be applied in any similar system. Section III presents the system developed for the “Project Hermes” and the measurement results to date. Finally, Section IV presents the current project phase and future planning.

II. Design Aspects of the Monitoring Network

The system architecture is depicted in Figure 1.

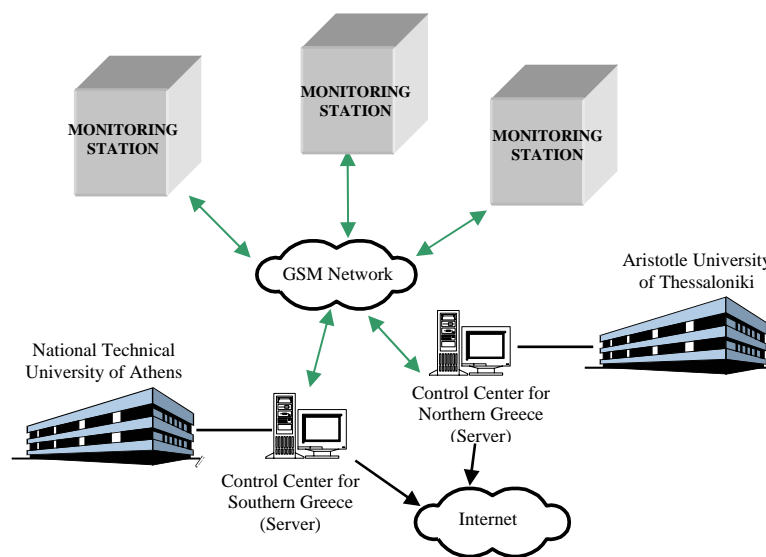

Figure 1: Block diagram of the monitoring network.

The system consists of:

- (a) The remote monitoring stations, which are located on the desired sites and perform continuous measurements of the Radio frequency (RF) radiation levels and,
- (b) The two central control stations (one for Southern and one for Northern Greece), which are located at the corresponding administrative authorities. The control units are responsible for the control of the monitoring stations and the publication of the measurement results on the web site.

a. The Measuring Equipment

The Measuring Equipment must be able to: (a) operate continuously (24 hours per day) (b) perform Electromagnetic Radiation measurements in the frequency range of interest covering the main sources that contribute to the total electromagnetic pollution, (c) store the measurements in its internal memory and transmit them to the Control Centre via a wireless interface for further elaborations, (d) supplied either by the main power supply or a solar panel (preferable), (e) be fully remotely controlled, which means that after their installation no human presence is needed on site and (f) detect abnormal operation of any kind (self diagnostics such as power loss and overheating problems) and inform the central control stations of the problem. To fulfil these requirements, the remote monitoring station consists of a broadband isotropic and triaxial electric field sensor, a module containing the necessary electronics, a GSM modem, as well as temperature and humidity sensors. A major problem encountered in this system is the periodic calibration of the monitoring stations. The calibration procedure requires the deinstallation of the stations, which means the interruption of the measurements, unless a spare station is available for the replacement.

Regarding the measurement quantities, either broadband or narrow-band measurements can be conducted. Broadband Measuring Stations record the Electric Field Strength for a given frequency range. A range of 100 KHz - 3 GHz is usually enough in order to take into account the multitude of the sources. Other possible ranges are for example 880 - 960 MHz (the GSM900 band), 1880 - 2100 MHz (GSM-1800 + UMTS bands), etc. In [8], [9] and [10] the interested reader could find a plethora of such monitoring units. Recently, selective (spectrum analysers) monitoring systems became commercially available. The referred stations are fully autonomous and can be remotely controlled via the GSM/GPRS protocol.

The main drawback of broadband stations is that they cannot estimate the radiation level from each source; rather they estimate the total exposure. Equipment such as a spectrum analyser is capable of measuring and quantifying the contribution of each electromagnetic radiation source to the total exposure level. Nevertheless, this equipment is not designed for continuous operation. If selective monitoring stations are not installed, the best solution is the use of a continuous broadband monitoring station for 24-hour recording and conducting “ad-hoc” narrow band measurements with a period of 3 - 6 months for every measurement site.

b. The Control Centre

The Control Centre is equipped with a Server Station, a wireless modem and the necessary software applications and it is responsible for: (a) controlling the remote monitoring stations and configuring the operational parameters, (b) downloading the measurement data via the wireless interface (e.g. GSM network), (c) storing the data in its hard disk and (d) processing the measurement results and publishing them to the corresponding web site.

The measurement data is stored in a Database (such as MS Access, SQL Server or MySQL) after their checking and processing. Therefore the full historical record for every measurement site is kept on the Server. In addition, a Web Server (such as MS IIS or Apache) hosts the web site.

c. The Web Site

The Web Site contains both static and dynamic pages and it aims at presenting the measurement results for every monitored site. It also provides thorough information concerning the electromagnetic radiation issue. Through the web site the user may view electric field strength graphs with custom time interval selection and statistical quantities about the measurements. Furthermore, a comparison of the measured quantity with the Greek legislation reference levels is presented. A feedback form can be also available to the public in order for them to express questions or comments to the administrators of the system.

III. The “Hermes” Monitoring Network

a. General Description

A monitoring network based on the principles described above has been developed and operating since November 2002. The system at its present state (April 2006) comprises 27 remote monitoring stations spread all over Greece (23 active and 4 inactive) and two control units located in two University laboratories (National Technical University of Athens – NTUA and Aristotle University of Thessaloniki – AUTH). The stations are located at schools, universities, public authorities’ buildings and private flats. The following figure depicts the spreading of the monitoring stations.

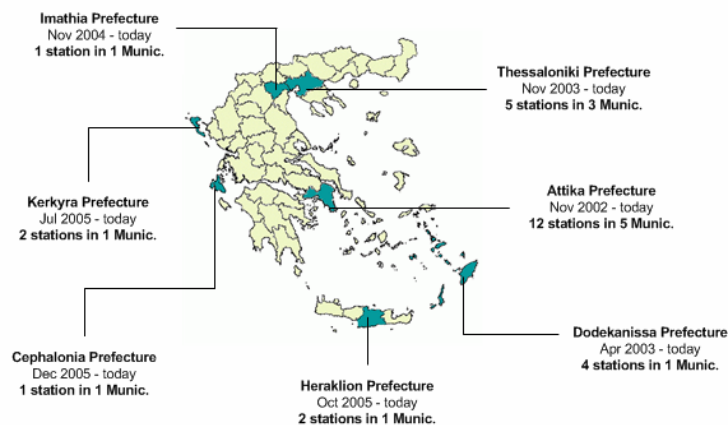

Figure 2 : “Hermes” Monitoring Network

AN EM RADIATION MONITORING NETWORK IN GREECE

The measuring devices record the broadband electric field strength quantity for the range 100 KHz - 3 GHz [10]. Three slightly different monitoring units' models are used.

- EE4070 - WB model which records the Electromagnetic Field Strength in the band 100 KHz - 3 GHz
- EE4070 - SL which records the field strength for three bands: 100 KHz - 3 GHz, GSM-900 Band and GSM1800 + UMTS band.
- MCE410 - SL, which records the field strength for two bands: 100 KHz - 3 GHz and 900 MHz - 3 GHz.

A detailed description of the specific units and the measurement procedure can be found in [11]. In the following figures several measurement sites are presented.

Figure 3: *EE4070-WB Station at Koskinou, Rhodes*

Figure 4: *EE4070-SL Station at Menemeni, Thessaloniki*

Figure 5: *MCE410-SL station at Heraklion, Crete*

Regarding the “ad-hoc” measurements, the guidelines proposed in the ECC recommendation [12] serve as the basis for our measurement procedure. A set of directional antennas covering the frequency range of 20 MHz – 3 GHz and a Spectrum Analyzer for measuring the received RF Power comprise the measurement apparatus (see Figure 6). Each frequency band is scanned and the power of each RF source, such as a FM or TV radio stations, a GSM channel etc is recorded. After the needed processing the total exposure levels and the contribution of each frequency band are estimated. A similar procedure is performed if we substitute the Spectrum Analyser with a Selective Radiation Meter such as the one presented in [13] and the directional antennas with broadband isotropic triaxial E-field probes (see Figure 7).

Figure 6: *“Ad-Hoc” Measurement Apparatus (Spectrum Analyser based)*

Figure 7: *“Ad-Hoc” Measurement Apparatus (SRM based)*

b. Measurement results

On the Web Site, both broadband and narrow-band measurement results are presented. The broadband measurements are updated on a daily base. Below, at first a table containing the most significant information about the monitoring stations is given. Afterwards in the following figures sample diagrams from the web site are drawn (Figure 8 - Figure 11). Finally, cumulative results regarding all the stations are presented (Figure 12 - Figure 13).

In Figure 8 the measured points correspond to 6-minute average electric field (E-field) values as is proposed in [5]. An immediate comparison with the reference levels can be done based on this diagram. Moreover the

variation of the field during one day or a longer period is distinguishable. The time span can vary from 1 hour to the whole measurement period (several years). In Figure 9(a) and 9(b), the mean and the maximum of the total set of 6-min average E-field values are presented and compared with the corresponding reference levels, for both EE4070 – SL and MCE410 – SL models.

Sample measurement results from two “ad-hoc” measurements are depicted in Figure 10. Specifically, one can see how many times below the safety values were the measured field values, in terms of the Power Flux Density (Watt/m^2) (Figure 10(a)) and in terms of the Electric Field Strength (V/m) (Figure 10(b)), for each frequency band such as FM, TV, GSM900, UMTS etc. The total exposure level is also evaluated and presented. The comparison between the results of Figures 9(b) and 10(b) (which correspond to the same measurement site) shows that the values of the monitoring station measurements are close to the “ad-hoc” measurement values. In addition, Figure 11 illustrates the percentage contribution of each frequency band to the total EMR exposure level.

Finally, the last two diagrams (Figure 12 and Figure 13) present cumulative results regarding the mean 6-min average E-field strength (continuous measurements) and the exposure level in terms of the Power Flux Density extracted by “ad-hoc” measurements.

Figure 12 : Percentages of electric field strength compared to reference value (overall)

Figure 13: Comparison of monitored power densities to reference value (overall)

c. Comments on the Measurement results

Based on the above diagrams and the cumulative results from our measurement database, several general conclusions could be drawn:

- The electric field strength / power flux density values are several times lower than the safety reference levels, even on sites close to antennas (see Figure 4). As far as the mean E-field, the higher values have been recorded at the National Technical University of Athens (Table 1– Station ID 9) and at Aristotle University of Thessaloniki (Table 1– Station ID 21). The first is located near the Imittos Mountain hosting the Antenna Park of Attica (FM and TV broadcasting stations, Radars, etc.). The second measurement site is on the roof of the 9-floor Rectorate building, almost at the maximum of the main lobes of the antennas located at the Antenna Park of Hortiatis Mountain. Still, the mean values are respectively 2.9 V/m and 3.7 V/m, that is, 13% and 16.5% of the adopted reference level (22.4 V/m).
- The variation of the E-field on each site is negligible except for the two stations located in Heraklion, Crete. The standard deviation computed over the whole measurement period varies between 0.1 – 0.3 V/m for the majority of the sites.
- The measured E-field depends on the relative position between the site and the antennas, that is, the distance between them and the radiation pattern of the transmitting antenna(s).
- The recorded values to date indicate that in general higher E-fields are present on urban and dense urban sites in comparison with rural areas. Nevertheless, the contribution of mobile telephony cellular emissions to the total exposure is higher in rural areas.

IV. Summary - Future work

An automated nationwide monitoring network of the electric field strength in the RF spectrum was presented. The system uses reliable hardware based on electric field strength probes and the measured data is presented openly to the public using the Web. More than 4,000,000 E-field strength values have been recorded in our database and 63 “ad-hoc” measurements have been conducted in the context of “Hermes” Project. Since the commencement of operation the measured EM Radiation levels are significantly below the safety reference levels.

We are currently planning the installation of more remote stations in dense urban and rural environments. Our

intention is to extend the network of the monitoring stations. In the long-run and in conjunction with repetitive “ad-hoc” measurements using a Spectrum Analyser or a Selective Radiation Meter, a more detailed statistical analysis of the RF radiation levels in urban and rural areas is going to be performed. Our interest will be focused mainly in the proximity of cellular base stations.

THE NEW EMF PROTECTION FRAMEWORK REGARDING ANTENNA STATIONS IN GREECE

E. KARABETSOS G. FILIPPOPOULOS

***NON IONIZING RADIATION OFFICE
GREEK ATOMIC ENERGY COMMISSION
P. O. BOX 60092, 15310 AGIA PARASKEVI, GREECE***

Abstract

In February 2006, the Greek Parliament passed a Law setting new standards for siting antenna stations. According to this Law, the permissible general public exposure levels for EMF in the vicinity of all kinds of antenna stations are set in general to 70% of the EU Recommendation and ICNIRP's limits, and to 60% of them for stations located closer than 300 meters from the perimeter of schools, kindergartens, hospitals or eldercare facilities. Installation of mobile phone base stations at the premises of these facilities is now prohibited. Furthermore, it is not allowed to build a new antenna station before the approval by the Greek Atomic Energy Commission of a technical study showing that the EMF levels in the vicinity of the station will be lower than the aforementioned limits. The Greek Atomic Energy Commission will be monitoring EMF exposure levels by performing in situ measurements, ex officio or within 20 working days after request of any interested party. These measurements should, on an annual basis, concern at least 20% of all the antenna stations installed in urban areas and their results will be announced on the web site of the Greek Atomic Energy Commission. The provisions and ramifications of this new Law are presented in this paper.

Introduction

In 2000 Greece implemented legally binding measures for the protection of the public from exposure to electromagnetic fields by putting into force a national legislative act concerning all kinds of land-based antenna stations, [1]. In this legislative act, the basic restrictions and the reference levels set in the Council Recommendation, [2], and ICNIRP's guidelines, [3], for general public protection have been implemented. However, the Greek legislation applied additional safety parameters to the allowed EMF exposure levels. Hence, the safety limits for the exposure of the general public to all land based antenna installations were set to 80% of the EU values. Also, with this legislation the Greek Atomic Energy Commission is set as the national authority, responsible for the protection of the environment and the general public against man-made electromagnetic radiation.

In February 2006, the Greek Parliament passed a Law, [4], setting new standards for siting antenna stations. According to this Law, the permissible general public exposure levels for EMF in the vicinity of all kinds of antenna stations are now set, in general, to 70% of the EU Recommendation and ICNIRP's limits, and to 60% of them for stations located closer than 300 meters from the perimeter of schools, kindergartens, hospitals or eldercare facilities. It must also be noted that installation of mobile phone base stations at the premises of these facilities is now strictly prohibited. The Greek Atomic Energy Commission will be monitoring EMF exposure levels by performing in situ measurements, ex officio or within 20 working days after request of any interested party. These measurements should, on an annual basis, concern at least 20% of all the antenna stations installed in urban areas and their results will be announced on the web site of the Greek Atomic Energy Commission.

In the next paragraphs the EMF protection in Greece, after the introduction of the new Law is analysed.

Competent Authorities in Greece

The competent national authority for the protection of the general public and the environment against artificially produced non-ionising radiation is the Greek Atomic Energy Commission (EEAE, www.eeae.gr), which lies under the Ministry of Development. Specifically the EEAE:

- Publishes prototype technical studies-notes for all kinds of antennas (such technical notes have been

published for mobile phone base stations, earth satellite stations and microwave antennas, <http://www.eeae.gr/el/services/templates/>)

- Defines the measurements protocol based on international standards
- Organises educational programs for the personnel of all public sector and all interested groups concerning the protection of the general public to electromagnetic fields, informs and replies to requests from the public authorities and citizens about the possible health hazards induced by non-ionising radiation.
- Provides all details concerning the authorisation of teams that perform measurements in all non-ionising radiation installations and controls the measurements procedure.

Measurements in antenna stations according to the legislation, may also be performed by the Ministry for the Environment, Physical Planning and Public Works, the Ministry of Health and Welfare and the Ministry of Transport and Communications or other, authorised by the EEAE, laboratories (e.g. University laboratories).

Public Information

The EEAE is responsible for providing information to all interested public groups for matters concerning the health effects of electromagnetic fields. To this end, the EEAE published in 2001 a 16-page informative brochure entitled: “Non-ionising radiations: Mobile phones and base stations” (also available at www.eeae.gr), distributed freely to all interested parties. Recently (after the new Law) EEAE has published a new updated 36-page brochure entitled “Mobile telephony and health” that is also freely distributed (also available at www.eeae.gr).

The EEAE also organises or participates in lectures; courses and workshops open to the local authorities, the public and the media. Some major risk communication events have been the organisation of 5 one-day workshops, in the years 2001-2003, entitled: “Exposure of the general public from mobile phones base stations” open to the local authorities, the public and the media, organised by the Ministry of Transport and Communications, the National Committee of Post and Telecommunications, the EEAE and/or the municipal authorities (proceedings from some of these workshops have been published as booklets and are freely distributed from the National Telecommunications and Post Commission, EETT).

It must be also stated that the EEAE was recently financed by the General Secretariat of Research and Technology of the Ministry of Development in order to produce informative material in electronic and paper format (cd-roms and brochures) and to organise workshops for specially selected target groups (representatives of the ministries, the local authorities and the media) for matters concerning EMFs and Health. The scope of organising such workshops is to inform and train persons able to form a “critical mass” necessary for further dissemination of this information to the general public.

Exposure Limits

In 2000 legislative act [1], the basic restrictions and the reference levels set in the Council Recommendation, [2], and ICNIRP’s guidelines for general public protection, [3], have been implemented. However, this legislation applied additional safety parameters to the allowed EMF-exposure levels. Hence, the safety limits for the exposure of the general public to all land based antenna installations were set to 80% of the EU values.

In accordance with the new Greek Law, the limits for general public exposure to electromagnetic fields are set to 70% of EU Recommendation Values. In case that an antenna is sited at a distance lower than 300m from the perimeter of the premises of kindergartens, schools, hospitals or eldercare facilities the Greek limits are set to 60% of EU Values. Furthermore, it is not allowed to install mobile phone antenna stations at these premises. All existing installations at the above mentioned premises must be removed in 6 months from the publication of the new Law.

Technical Studies

According to the Greek Legislation, [1], before the construction and the operation of an antenna station a special license must be issued by the National Telecommunications and Post Commission, (EETT). The EEAE is involved in the license issuing process since a technical study of electromagnetic emissions is mandatory to be submitted to EEAE before the antenna station owner submits the application to the competent authority for issuing a license for an antenna station in a particular location. These studies include architectural blueprints and

topographical charts of the station as well as technical information about the operation of station's antenna system. The intensity of the incident electromagnetic radiation is calculated in places accessible to general public. The existence of any other antenna station at a distance lower than 50 meters from the examined antenna station is also taken into account.

Through these calculations it must be proven that the intensity of the electromagnetic radiation is lower than the established limits in the Greek Legislation at any place that is freely accessible to the public in the vicinity of the station. Of course, very close to the antenna systems (for example for mobile phones base stations usually till 4 to 8 meters), at the directions of maximum emission and at the height where the antennas are located it is possible that the radiation exceeds the established limits. If there is public access to these places the study foresees that it will be forbidden. The EEAE after the examination of the study sends its expert opinion (given that the study is not deficient or inadequate or mistaken) to the competent authority in order to issue license for installing the antenna.

It is noteworthy that these studies are composed on the basis of the very strict technical prototype studies that have been issued by the non ionizing radiation office of EEAE. These prototype studies adopt worst case considerations and assumptions, due to which the intensity of the electromagnetic radiation is overestimated in relation to the actual intensity in the vicinity of the station. This has been confirmed through the comparison of the calculated values in the studies with the results of measurements at areas close to antenna stations.

In accordance with the existing legislation [1], if the process of checking the technical study by EEAE took over 1 month the license by EETT for this installation could be issued without EEAE's positive expert opinion. However, with the new legislation [4], it is no longer allowed to build a new antenna station before the approval by the Greek Atomic Energy Commission of a technical study showing that the EMF levels in the vicinity of the station will be lower than the aforementioned limits. Also, due to the change of exposure limits the owners of all the installed antenna stations are obliged to submit new technical studies to EEAE showing that their stations adhere to the new limits.

Audits

In accordance with the existing legislation, the levels of the emitted electromagnetic fields from all kind of antenna stations are regularly monitored, in order to ensure compliance with the safety limits for the public or, if this is not the case, to ensure that all necessary protection measures around an antenna base station, are being taken in every case. To that end, the EEAE also carries out measurements in all kinds of antenna stations in order to monitor whether the general public exposure limits are being adhered to. It must be stated here that from the year 2000 until today, the non - ionising radiation office of the EEAE has performed over 1700 inspections and measurements at various sites in Greece, where all kinds of antenna stations are installed. Concerning cellular phone base stations, the EEAE has conducted measurements in the vicinity of 1200 such stations. The major part of this information is in the form of written measurement reports that have already been delivered to the authorities or persons who asked for these measurements, but are also available to everyone interested.

The non ionising radiation office of GAEC has expert personnel and suitable measuring equipment and is accredited in accordance with the requirements of the EN ISO/IEC 17025 standard by the Hellenic Accreditation Council (ESYD - the Greek National Accreditation Body) for performing measurements of low and high frequency fields, as it is determined in the accreditation certificate No. 117 (22-01-2003) for tests.

With the new legislation, [4], the audits of the electromagnetic fields in the vicinity of antenna stations are drastically intensified. To this end, the EEAE or other laboratories authorized by it, performs inspections and measurements in the vicinity of antenna stations either:

- a) ex officio, through a sampling process and annually in the vicinity of 20% of all antennas installed in urban areas, or,
- b) after the request of any interested party, in 20 working days

The results of these inspections are immediately published at EEAE's web site and collectively per year. Soon all this information about the already measured sites as long as the results for every new measured antenna station will be posted to the web page of EEAE

Penalties

In case EEAE finds through measurements an excess of the limits, it informs the competent license-issuing authority, which then notifies the antenna owner in order to do the following:

- immediately cease the operation of the responsible equipment and then inform about this the competent license-issuing authority;
- clear the causes of malfunction before resuming operation
- inform the competent license-issuing authority about the operation resumption, providing explanations about the causes of the malfunction.

If, at any time after the initial notification, an irregular operation of the same equipment is found again, then the license is permanently recalled for this location.

Environmental aspects

According with the new Law, [4], the approval concerning all environmental aspects related to each antenna installation foreruns the license for the construction of this installation issued by EETT. Hence, a technical study examining the environmental impact of a new antenna station should be submitted to the General Secretariat of each District, which in 10 days sends it to EEAE asking its expert opinion. The General Secretariat of each District has to answer for each technical study, after a positive opinion by EEAE. However, the content and the process of these environmental studies are to be defined in a new decision by the Minister of Environment and Public Works. All the existing antenna stations that have not an environmental permission have to acquire one in 12 months from the publication of this ministerial decision.

Funding

According with the new Law, [4], the owners of all antenna stations are billed annually by EETT the sum of 200€ for each station and the total amount is transferred to EEAE. In this way, EEAE will have the necessary funds to achieve its duties.

Conclusions

The existing legislation in Greece imposed a strict framework for the protection of the general public from the electromagnetic fields emitted by antenna stations. It sets exposure limits based on the well-established limits of the EU recommendation and ICNIRP Guidelines. Furthermore, it established a mechanism for checking compliance with these limits before and after the installation of antenna stations. The new legislation reduced the exposure limits (towards the safe side) and made the control mechanisms stricter and intense.

NON-IONISING ELECTROMAGNETIC FIELD EXPOSURE MONITORING AND MEASUREMENT CAMPAIGNS IN MALTA

CHARLES V SAMMUT

DEPARTMENT OF PHYSICS, UNIVERSITY OF MALTA, MSIDA, MSD 06, MALTA

charles.v.sammuto@um.edu.mt

ABSTRACT

This paper reports first on a completed three-year campaign to assess exposure of the public to electromagnetic fields from mobile phone base station antennas. The project was commissioned by the Malta Communications Authority (MCA) and consisted of information gathering and construction of a comprehensive database, field simulation at all sites in operation and detailed measurements at over half the base station sites installed on Malta.

The measurement results were analysed to supply useful information of a statistical nature. Measurement techniques are also described in the light of a recent preliminary standard (prEN 50413). Correlation exists between measured and calculated field intensities, although absolute values are not in good agreement. This occurs mainly on account of fluctuating power output from base stations, multiple reflections and diffraction effects due to surrounding structures. Field calculation is, however, useful for worst-case site assessment.

The paper proceeds by outlining the present non-ionising radiation monitoring and measurement campaign, which now includes all broadcast frequencies, and gives a brief account of a recent extensive survey conducted around the leading telecommunications tower situated in a village. Recent measurements show that, notwithstanding the proximity of some residences, radiation levels in publicly accessible areas rarely exceed much above 5% of ICNIRP reference levels for public exposure.

1. INTRODUCTION

The advent of mobile telephony and liberalisation of the telecommunications market in Malta brought about a proliferation of radio antenna sites. There are currently two companies operating mobile telephone networks in Malta, Vodafone-Malta (GSM900) and Mobisile Communications (GSM1800). Together they have about 300 base stations in operation and are developing UMTS networks, due to start operating later this year.

The country's high population density and restricted land area necessitate location of base station antennas predominantly within a densely built environment. An initial lack of public information and rapidity of base station deployment in response to increasing consumer demands have contributed to public concern that the perceived increase in exposure to radio frequency electromagnetic fields could be harmful to health. This concern was also fuelled by reports from various sources of possible exposure-related health effects. In this respect, the Stewart Report [1] has unwittingly contributed to this concern, as some of the recommendations made therein were based on the precautionary principle, which has often been misunderstood and misinterpreted by the media and the general public.

Public concern has led to some court cases instituted locally against the operators in order to prevent them from setting up new antenna sites. Some individuals living close to base station sites claimed they were suffering from adverse health effects and radio interference linked to radiation from these antennas. In some instances, adverse effects were reported soon after the installation of the base station hardware and even before its coming into operation.

In order to allay such fears and to ensure that the local mobile phone companies operate within the national guidelines [2], the MCA, which is the regulatory agency for electronic communications, post and e-Commerce, commissioned the Malta National Laboratory (MNL), as an independent provider of testing services, to conduct an extensive survey. Some preliminary results appeared in [3] and [4].

This project constituted the first phase and is followed by an ongoing programme of monitoring and measurement of emissions from all radiofrequency sources in use for telecommunications. This paper proceeds by outlining the elements of the first phase project and discussing the subsequent results. An outline of the present monitoring and field measurement activities then follows.

2. PHASE I: SURVEY OF MOBILE PHONE BASE STATION SITES

This project was spread over three years and consisted of three distinct tasks:

1. compilation of a detailed database of all base stations;
2. calculation/simulation of electromagnetic field exposure based on the transmission specifications contained in the database for each base station site;
3. measurement of electromagnetic fields at a sample of 150 of the transmission sites.

To the author's knowledge, the survey element of this project is relatively one of the most extensive yet reported in Europe, in that the measurement campaign involved over half of the licensed sites. This section describes each task, discusses calculations/simulations of electromagnetic field power density and the survey methodology, as well as analysing the measurement results.

2.1 Mobile phone base station database

The database was designed so as to enable easy record maintenance and update, as well as providing for easy access to site details, including antenna types, physical layout and transmission characteristics, as required for field calculations. The records are searchable through a number of fields and the user can retrieve associated information, such as polar plots of the antenna gain profiles in the vertical and horizontal planes and copies of field survey reports in the case of audited sites.

2.2 Field calculations and simulations

Field calculations are useful in cases where certification of site compliance is required as a precondition to granting of permits for transmission. Given maximum output power, field calculation and simulation results could generate worst case exposure scenarios. This is also useful in the case of operational transmitting stations, especially those, such as GSM, which are characterised by a fluctuating power output depending on network use. Field measurements will only reveal the prevailing emissions at the time of measurement and rarely result in registering maximum possible values.

Field simulation was an integral part of the project. Two-dimensional field intensity plots were generated for all the base station sites on the Maltese islands over planes containing publicly accessible areas. Both commercially available and in-house field calculation and simulation software were used. In both cases, far field strengths were calculated using manufacturer-supplied antenna gain profiles in the vertical and horizontal planes, and utilising height, vertical tilt, azimuth and power input information provided by the operators [3].

Figure 1: A typical two-dimensional field plot generated by MBSFIPTM. A three-sector antenna is situated at the centre.

The commercial software used was Telstra's Mobile Base Station Field Intensity Plotter (MBSFIPTM). This enabled two-dimensional colour mapping of field intensity which could be overlaid on the site plan (Figure 1). MBSFIP allows the user to select either a direct or a two-ray path model for the RF propagation loss calculations and if the two-ray model is selected, then calculations assume flat ground with ground constants (relative permittivity and conductivity) that have to be specified by the user. The program calculates reflection for vertical, horizontal or slant polarization. Information about the transmit antenna polarisation is obtained from an antenna pattern library. Thus, in the two-ray path model, the program combines the field intensity calculated along the direct path and combines this with the two ray path calculation.

Comparison between measured and calculated fields at some locations showed moderate agreement in absolute terms but high correlation [3, 10], suggesting

NON-IONISING ELECTROMAGNETIC FIELD EXPOSURE MONITORING AND MEASUREMENT CAMPAIGNS IN MALTA

a systematic error, thought to be mostly due to fluctuating output power determined by network use. However, there are other factors, such as multiple reflections and diffraction effects due to surrounding structures.

2.2 Field measurement

The central and most publicly visible element of the project was the field measurement campaign which aimed to carry out audit measurements of electromagnetic field emissions at half the base station sites in operation. In fact, 151 base station sites were surveyed out of a total of 271. The sites can be classified as single operator GSM900 or GSM1800, shared (by the two GSM operators) and shared multiple technologies (GSM and other RF transmission technologies).

The aims of the base station emissions audit were to:

1. ascertain compliance of base station emissions with the ICNIRP guideline reference levels for exposure of the general public;
2. establish a baseline for typical emission scenarios which would help in deciding if and where to grant permission to operate base stations;
3. address public concerns in respect of perceived hazards of radiofrequency emissions from base stations;
4. inform and educate the public in matters concerning radiofrequency emissions.

At the beginning of the project, public concern about the possible hazard from mobile phone base station antennas was high. Selection of sites for audit was therefore a delicate task as we had to balance technical considerations with the need to allay public concerns. A broad representation of audit sites based on type and geographical location was sought. Sites were therefore selected roughly on the basis of the number of base stations installed per locality, which is indicative of population density and frequency of use. Within each locality, base station sites close to schools were audited and in all such cases the adjacent school premises were also surveyed carefully. The bulk of the base stations selected for the audit survey were sited over commercial buildings and private homes within or in the vicinity of densely built residential areas. In general, and wherever possible, measurements were taken over properties neighbouring the selected base station sites. Surveyed areas included accessible recreational open spaces situated in the vicinity of base station sites selected for audit. Table 1 lists the base station sites by type. Commercial buildings included hotels, shopping outlets of varying sizes, showrooms, stores and industrial units.

Owing to expected higher power density levels and for reasons of greater public concern, 80% of shared sites were audited, compared to 62% and 45% respectively of single operator GSM900 and GSM1800 base stations. Broad representation on the basis of geographical location and population density was also achieved.

Table 1: Base station sites classified by type

SITE TYPE	Number of base stations	Number surveyed
Commercial buildings	105	61
Private residences	94	41
Social clubs	15	10
Churches	11	9
Public buildings	9	4
Transmission stations	6	1
Old people's homes	5	5
Hospitals	2	2
Schools	2	2
Other	22	16
TOTAL	271	151

2.3 Field survey methodology

The project started when European measurement standards for non-ionising radiation safety assessment were still in a state of flux. The methods adopted were inspired by Canadian [5] and US [6] recommendations and developed by the author in the light of his own research and local experience. However, the methods subsequently described in the CENELEC preliminary standard prEN 50413 [7] and the ECC Recommendation [8] are similar and additional techniques were shown to generate useful data for assessing exposure realistically at most transmission sites [3, 4, 9, 10].

Measurement procedures and subsequent analysis were geared principally toward assessment of the extent of human exposure arising from operation of the sources present at the investigated sites. Each survey started with a visual inspection of the antenna site and all transmitting antennas were photographed for the records. The antenna locations were marked on the site plan and notes were taken describing the site, access restrictions and antenna configurations.

The field survey equipment used consisted of the Narda 8718B survey meter in conjunction with the models 8760D and the D8722D broadband, isotropic electric field probes. Summary specifications of these isotropic probes are listed in Table 2. The field survey started with a preliminary scan of the site conducted by meandering within areas where exposure was expected to be relatively higher, i.e. along the transmission directions facing the antenna panels. This procedure allowed the surveyor to establish a set of measurement points that included regions of maximum exposure. However, measurement points were also chosen on grounds of site use by the public or authorised personnel, in cases where the site was not accessible to the public.

Table 2: Broadband isotropic field probes used during the phase field surveys

Model No.	Frequency Range	Nominal Measurement Range		Frequency Response	Sensor Type
		Power Density	E [Vm^{-1}]		
8760D	300kHz – 3.0GHz	5.0×10^{-2} – 1.0 Wm^{-2}	0.5 – 19.4	Flat	Compensated Diode
D8722D	300kHz – 50GHz	0.3 – 300% of Standard*	–	Weighted	Compensated Diode and Thermocouple

* Referenced to ICNIRP guideline levels for occupational exposure

Three main measurement modes were used, depending on site-specific suitability:

Time averaging (TAV) – measurement of field intensity at a given point over a pre-defined time interval, the survey meter storing average and maximum field strengths during the process. About 1,500 such measurements were made during the course of the survey. The intervals varied between 10 and 120 seconds, depending on signal variability. At none of the sites investigated was it found necessary to take six-minute time averages because the power density levels recorded were below the ICNIRP reference levels for exposure of the public, as recommended in [7] and [8].

Spatial averaging over the human body area (BAV) – vertical scan with the probe moved at a slow, steady speed between points distant 10 and 200cm above ground level [3] while the survey meter stores the average and maximum field strengths. Over 1,500 such measurements were made during the course of the project. This allowed a more extensive exposure assessment than would have been possible with the more laborious procedures described in [5], [7] and [8].

Extended spatial averaging (ESA) over a defined three-dimensional region – a scan of a defined region with the probe raised and lowered at a steady speed while zigzagging systematically through the designated area, the survey meter storing average and maximum field strengths during the process. This technique was reported in [3] and further validated in [4]. In all, 277 ESA measurements were conducted at various sites throughout the project.

2.4 Field survey results

A total of about 3,300 field strength measurements were made during the course of the project at 151 sites. Summary values are represented in Figure 2. These values represent site average and maximum recorded field strengths. More than half the surveyed sites were found to have average exposure levels between 0.08 and 0.47% of the ICNIRP public exposure level (PEL),

Figure 2: Normalised frequency distribution of measured site average and maximum field strengths.

while the maximum exposure level at over half the sites ranged between 0.27 and 2.14%.

At two sites the 25% ICNIRP PEL mark was exceeded but at locations that were not easily accessible to the general public. At one particular shared site, GSM900 and 1800 base stations were collocated on the roof of a hotel only accessible to authorised personnel for maintenance purposes. Broadcast radio and TV antennas were also in operation at that site. The maximum measured field strength recorded from the GSM base stations was 29.3%. A BAV of 61% and a maximum of 382% of ICNIRP PEL were also recorded at the same site with all sources operating together. It was possible to identify the GSM component by collaboration with the operators, who kindly switched off the relevant transmitting antennas during part of the

NON-IONISING ELECTROMAGNETIC FIELD EXPOSURE MONITORING AND MEASUREMENT CAMPAIGNS IN MALTA

survey to allow measurement of the non-GSM component.

Figure 3 shows the normalised frequency distribution of time average field strengths (TAV), along with the maxima recorded during these measurements. The data included all measurements recorded during the project at all the sites investigated, except for the extreme values mentioned in the preceding paragraph. The distribution indicates predominantly low field strengths. Half the time average field strengths measured were between 0.04 and 0.42% of ICNIRP PEL (Table 3), while half the maxima were between 0.05 and 0.51%.

Table 3: Statistical summary of measured field intensity in % of ICNIRP PEL

	TAV-AV	TAV-MAX	BAV-AV	BAV-MAX	ESA-AV	ESA-MAX
Lower quartile	0.04	0.05	0.03	0.06	0.04	0.16
Median	0.14	0.17	0.08	0.19	0.09	0.34
Upper quartile	0.42	0.51	0.28	0.55	0.30	1.05

The measured BAV field strengths show similar overall characteristics, in that they are predominantly low, as can be seen from Figure 4, which shows the frequency distribution, along with maxima recorded during the averaging process. This analysis also included all the BAV measurements made throughout the course of the project at all the sites investigated, except for the mentioned extreme values. As indicated in Table 3, half the values obtained were between 0.03 and 0.28% of ICNIRP PEL, while half the recorded maxima were between 0.06 and 0.55%.

Figure 3: Normalised frequency distribution of measured time average (TAV-AV) and maximum (TAV-MAX) field strengths.

The ESA field strength values obtained are represented in Figure 5, which shows the frequency distribution of measured extended spatial average field strengths and maxima obtained during the averaging process. Some of these measurements were made in areas not accessible to the public and in close proximity to radiating antennas and this explains the relatively higher ESA-MAX median and quartiles given in Table 2. The TAV-MAX and BAV-MAX statistics are close. This is explained when considering that, during the BAV scans, the maximum field strength was recorded predominantly at about 2m above ground level, where most TAV measurements were made close to the same spot. Measurements at this level tend to be higher in the vicinity of a transmitting antenna, which would typically have its main beam directed well above accessible heights.

The BAV measurement records (about 1500) were analysed for possible variation with weekday and time of day. From Figures 6 and 7, it is not possible to draw suitable conclusions, when one considers the large standard deviation in the data, ranging from 0.4 to 1.3 %

Figure 4: Normalised frequency distribution of measured body average (BAV-AV) and maximum (BAV-MAX) field strengths.

Figure 5: Normalised frequency distribution of measured extended spatial average (ESA-AV) and maximum (ESA-MAX) field strengths.

ICNIRP over the week days Monday to Friday (Table 3). Such variation arises as a consequence of the fact that field measurements were conducted at many different locations and heights with respect to the transmitting antennas and were not intended to monitor diurnal fluctuations at specific locations.

Figure 6: Variation of BAV-MAX by weekday.

Figure 7: Diurnal variation of BAV-MAX (all weekdays).

3. PHASE II: ONGOING PROGRAMME OF AUDIT SURVEYS

At some shared radio sites, non GSM sources were present that had been set up before the present guidelines [2] came into force. It had been clear from the outset that at such transmission sites, field intensity apportionment and careful assessment of the antenna layout and transmission equipment were required. Having completed the first phase, the scope of the audit surveys was therefore widened in 2004 to include all telecommunications sources within the remit of the MCA. Monitoring compliance is now the major objective, since increased awareness of the general public, partly resulting from the phase I project, has somewhat succeeded in allaying public apprehension toward mobile phone base station emissions.

MCA now has an ongoing programme to verify compliance of radio transmission sites with ICNIRP reference levels for exposure of the general public. MCA technicians were trained by the author to conduct RF emissions using frequency selective and broadband techniques based on those outlined in [7] and [8]. Most transmission sites have by now been audited at least once.

The main instrument being used for the frequency selective measurements is the Narda SRM 3000 in conjunction with an isotropic electric field probe, covering the range 75MHz to 3GHz. Conventional spectrum analysers in conjunction with single axis antennas are also used for more accurate measurements when required.

One of the most sensitive sites investigated extensively during the second phase was the area surrounding the island's main telecommunications tower installed at the village of Gharghur. The tower, which for some years

Figure 8: The Gharghur telecoms tower.

has been a source of concern to the residents, is situated about 400m from a primary school and close to private residences. It is host to the main broadcast TV and radio station repeaters, GSM and other communications antennas, as well as microwave links (Figure 8). Six-minute frequency selective time average field strength measurements were made at 15 carefully chosen locations in this village, including two inside the neighbouring school and several within private residences. Figure 9 represents the summary results including all emissions within the frequency range 75 MHz to 3 GHz. Again, the measured field intensities were relatively low, even within the tower precincts. The highest level recorded was 10% of ICNIRP PEL on a first floor terrace at a nearby residence.

Measurements conducted so far have rarely resulted in field strengths higher than about 5% of ICNIRP PEL. More accurate measurement techniques than those afforded by isotropic probes place an additional burden not required for the purpose of site compliance certification.

Field calculations will soon form part of the ongoing programme of radiation hazard assessment. The database will incorporate all licensed transmission sources and shall include technical details sufficient to permit field calculations. These will be used to generate worst-case

NON-IONISING ELECTROMAGNETIC FIELD EXPOSURE MONITORING AND MEASUREMENT CAMPAIGNS IN MALTA

exposure scenarios in support of the measurement campaigns and should serve as an important tool in educating the general public, apart from helping to dispel misconceptions concerning emission levels.

Figure 9: Summary of Gharghur survey results, indicating total field intensity from all sources obtained by taking six-minute time averages at 15 different locations in the village.

3. SUMMARY

A three-year national survey of emissions from GSM base stations in Malta started during 2002. This project was concluded and showed that the emissions in all areas accessible to the general public were well below the ICNIRP reference levels for exposure of the general population.

As part of this project, a detailed database containing relevant information on each operational base station was constructed and field simulations made on the basis of the data supplied by the operators. Although specific values of calculated and measured fields only concur moderately because of the variability of network use and clutter occurring within built environments, field calculation is a valuable tool that can be used to establish worst-case exposure to electromagnetic fields and is useful in cases where certification of site compliance is required as a precondition to granting of transmission permits.

Recently, MCA has updated measurement and survey techniques in line with the preliminary CENELEC standard prEN 50413 [7] and a Recommendation of the ECC [8]. All telecommunications sources are now being targeted in this second phase, which aims to survey fixed transmission sites periodically.

Finally, it is observed that broadband field measurement techniques used during the first phase resulted in many more measurements than were feasible with narrowband techniques, especially when conducting six-minute averaging. The case for narrowband measurements when conducting compliance-oriented field surveys can only really be justified at sites found close to the prevalent limit level as this would allow apportionment by source. Furthermore, although taking a six-minute time average is better than averaging over shorter time intervals, in the latter case more such measurements may be made with minimal additional effort. This could give a better picture of the prevailing exposure scenario at the site under investigation since, in the case of cellular networks, the power output fluctuates significantly over short time spans. Supporting such field surveys with reliable worst-case field calculations provides an economical and reliable means of examining site compliance.

ACKNOWLEDGMENTS

The author wishes to acknowledge the support of MNL, for providing the test equipment and logistics during phase I of the project and MCA for financing this phase and assisting in the often complicated logistical arrangements required during the measurement campaigns.

The author is indebted to John Bugeja (MNL) for assisting in the audit surveys conducted during phase I and acknowledges the support of Joanna Formosa Borg, Brian Sghendo and Kevin Aquilina from MCA, who have conducted most of the work during phase II.

THE ETIOLOGY OF MELANOMA

ÖRJAN HALLBERG

HALLBERG INDEPENDENT RESEARCH
POLKAVÄGEN 14B, 142 65 TRÅNGSUND, SWEDEN
<http://hir.nu>

Abstract

The main purpose of this project was to find a possible explanation for the steadily increasing incidence of melanoma in Western countries since the mid-20th century. A secondary purpose was to develop models with predictive value in order to estimate future melanoma trends. Results indicate that the immune defense system for cell repair and apoptosis was disrupted by body-resonant broadcasting radiation from FM towers, and that this disturbance can fully explain both local and temporal variations in melanoma incidence and mortality.

Introduction

In May 1998 the author became aware that at the end of the 1950's, there was a sudden increase in melanoma incidence in Sweden; this coincided with a time when the country was in the midst of the process of gradually becoming covered with FM and TV broadcasting towers. This realization led to a study comparing Nordic countries with the USA to see if there was any association between melanoma incidence and the appearance of large numbers of FM broadcasting towers. A second, later study investigated the geographical variation of melanoma incidence in Sweden and its possible correlation with the geographical variation of other cancers. In a third study, melanoma incidence over time was compared with the advent of FM broadcasting in Swedish counties and with increasing habits of taking charter travels to sunnier resorts. A fourth study investigated if melanoma incidence could successfully be modeled as a response to sudden changes in environmental stress. A theory and model to explain the increased incidence of melanoma were then developed, and the model was then refined to take into account the observation that UV radiation-induced cell damage is cumulative but normally compensated for by a cell repair process that was assumed to have become less efficient from a specific point in time.

Summary

An initial study showed that Nordic countries and the USA both appeared to have the same exposure-time-specific incidence of melanoma, despite the fact that the advent and subsequent spread of FM transmitter appearance differed among the different countries [1]. A second study showed that the incidence of some cancers correlated with variations in melanoma incidence across the Swedish counties, while others (e.g. leukemia) did not [2]. Melanoma also appeared to persist at a low and stable incidence in the counties as long as FM transmitters had not yet been substantially introduced. Mortality from existing cases of melanoma showed an immediate increase that correlated with the introduction of FM broadcasting towers, and the incidence of new cases started to increase a few years after the spread of FM towers [3]. Melanoma incidence appeared to be significantly correlated with the number of main FM towers simultaneously covering an area [4]. A model for melanoma incidence was developed based on a statistical distribution of the time from the introduction of FM broadcasting until the onset of melanoma [4, 5]. Finally, it was also shown that a model based on a precipitous decrease in the efficiency of the immune defense system (presumably caused by FM broadcasting towers) was able to accurately predict the reported age-standardized incidence and age-specific incidence of melanoma for all birth cohorts during the 20th century [6].

The project concluded that body-resonant radiation from FM broadcasting towers may disturb cell repair and apoptosis processes and that this may be one of the most important factors behind the observed increase in melanoma rates in the Nordic countries. Normal broadcasting radiation is not likely to be able to cause cellular damage *de novo*, but may be able to weaken defenses against cellular damage that may be caused by pervasive "natural" sources such as UV exposure etc. It would seem logical to extend this study to similarly review lung cancer and breast cancer to examine the possibility of a correlation between these cancers and FM broadcasting radiation.

Abstract

A calibration method for optical tweezers, based on equilibration with a dielectrophoretic force, is presented. The analytical method for the computation of the dielectrophoretic force is based on a mathematical model using Green's theorem. The dependence of the optical force profile on the particle position between the electrodes and on the vertical axis is rigorously analysed and the best operating conditions are determined.

In order to have an experimental validation of the model, we used a dielectrophoretic chamber with planar electrodes and a laser diode optical tweezers (800 nm). A suspension of red blood cells was placed between the electrodes of the dielectrophoretic chamber and the optical trapping force was measured under different conditions.

We show that by applying simultaneously dielectrophoretic and optical forces on a cell, the evaluation of intracellular dielectric parameters (i.e. cytoplasmic and membrane conductivity in normal and/or pathological states) at a single cell level is possible.

Introduction

Micromanipulation of cells has become in the last years an important tool for the fundamental research as well as for some clinical applications. There are different techniques to do this, including micropipettes, microelectrodes, optical and magnetic traps. When comparing these techniques, there are of course, for each of them, advantages and disadvantages, but, the most important and decisive advantage of optical and magnetic traps is the minimal mechanic contact with the cell, optical and magnetic trapping being nowadays considered to be the less invasive micromanipulation methods.

For research purposes, the method can be used to put cells into contact, to measure interaction forces between cells and / or molecules (e.g. ligand – receptor interaction forces). The main problem in pursuing such experiments is to calibrate the trapping force. In the following we will focus our attention only on optical trap force, but the rationale can be used as well for the magnetic trap.

We will show that one can use the dielectrophoretic force as a quite simple and reliable tool to calibrate the optical trap force, and, based on this, we'll show interesting possibilities to determine some physical properties of cells in relation with their physiological state.

Principles of the optical trap

Optical traps (or tweezers) were first described by Ashkin [1 – 3] and are based on the interaction of light with a particle. In this interaction different regimes of theoretical approach can be distinguished based on the ratio of the incident light wavelength λ to the diameter d of the irradiated particle: Rayleigh Regime ($\lambda/20 \gg d$), Lorenz-Mie Regime ($\lambda \approx d$) and Ray Optics Regime ($\lambda/20 \ll d$). The net force is the result of a combination of two different components: scattering force and gradient force. In the Rayleigh Regime the particle is acting like an induced dipole in the electric field of the laser beam. The expressions of the forces are:

$$\vec{F}_{scat}(\vec{r}) = \vec{z} n_m \frac{\sigma(S)_T}{c} \quad (1)$$

$$\vec{F}_{grad}(\vec{r}) = \frac{1}{2} \alpha \vec{\nabla} \bar{E}(\vec{r}, t)^2 \quad (2)$$

where $(S)_T$ is the temporal average of the Poynting vector, which defines the intensity of the laser beam, $\sigma = \frac{8}{3} \pi (ka)^4 a^2 \left(\frac{n^2 - 1}{n^2 + 2} \right)^2$ is the cross section of the particle, \vec{z} is the laser beam direction, n_m is the relative refractive index, a is the radius of the particle, $k = 2\pi/\lambda$ is the wave number, c represents the light speed in vacuum, \bar{E} is the electric field and n is the absolute refractive index of the particle.

For a spherical particle in Ray Optic Regime, Ashkin established formulae for these two forces as a function of the Fresnel coefficients [1]. The expressions can be deduced based on geometrical optics laws, their scalar form being:

$$F_{scat} = \frac{n_1 P}{c} \left\{ 1 + R \cos(2\theta) - \frac{T^2 [\cos(2\theta - 2r) + R \cos(2\theta)]}{1 + R^2 + 2R \cos(2R)} \right\} \quad (3)$$

$$F_{grad} = \frac{n_1 P}{c} \left\{ R \sin(2\theta) - \frac{T^2 [\sin(2\theta - 2r) + R \sin(2\theta)]}{1 + R^2 + 2R \cos(2R)} \right\} \quad (4)$$

where P is the power of the incident beam, n_1 is refractive index of the particle, R and T are the reflectance and transmittance coefficients, θ and r are the incident and refracted angles. The expressions (3) and (4) are true for a “normal” light ray. The laser beam, being a bundle of rays, has a specific profile which has a significant contribution to the gradient force.

Finally, the net force exerted on the particle is given by the expression

$$F_{optic} = Q \frac{n_{med} P}{c} \quad (5)$$

where Q is a scaling constant which depends on the size of the particle and the refractive index difference between the particle and the surrounding medium, P is the power of incident laser beam, n_{med} is the refractive index of the medium and c is the light speed in vacuum.

Summarizing, one can say that the optical force is proportional to the power of the laser beam, and depends on some physical properties of the particle. To calibrate the laser trap means to determine this scaling factor, Q .

Calibration methods

There are two main calibration methods which are presently used for optical traps:

- Brownian movement analysis: this method is based on the statistical analysis of the Brownian movement of a trapped particle, from which one can learn about the trapping force. The method implies an extremely rigorous temperature control of the microscope stage, which is not technically trivial considering that the laser beam itself provoke some local heating of the sample, and sophisticated mathematics for image analysis;
- Viscous drag of the trapped particle: the particle is placed in a capillary tube with a constant known diameter through which the suspension buffer flows with a constant speed. A particle is trapped, and the flowing speed is increased until the particle escapes. Assuming that the flow is Newtonian, one can calculate the viscous force, which, at that moment, equals the optical force. The major problem with this method is to ensure a real Newtonian flow through the capillary.

In this paper we describe a calibration method based on the dielectrophoretic force exerted on the trapped particle.

The dielectrophoretic force exerted on a particle depends on the induced dipole moment and is unaffected by the direction of the electric field, responding only to the field gradient. Accordint to Pohl [4], the dielectrophoretic force is given by the expression:

$$\vec{F}_{DEP} = \left(\vec{P}_{eff} \cdot \vec{\nabla} \right) \vec{E}_0 \quad (6)$$

For a spherical particle of radius r , the dielectrophoretic force is given by the expression:

$$\vec{F}(\omega) = 2\pi r^3 \varepsilon_m \operatorname{Re}[K(\omega)] \vec{\nabla} E^2 \quad (7)$$

with

$$K(\omega) = \frac{(\varepsilon_p^* - \varepsilon_m^*)}{(\varepsilon_p^* + 2\varepsilon_m^*)} \quad (8)$$

and

$$\varepsilon^* = \varepsilon - j \frac{\sigma}{\omega} \quad (9)$$

where ε_m^* , ε_p^* are the complex permittivities of the medium and the particle respectively and ω is the angular frequency of the applied field. For a particle with shell, the expression of the complex permittivity becomes:

$$\varepsilon_p^* = \frac{\left[\frac{r}{r-d} \right]^3 + 2 \left[\frac{\varepsilon_{\text{int}}^* - \varepsilon_{\text{mem}}^*}{\varepsilon_{\text{int}}^* + 2\varepsilon_{\text{mem}}^*} \right]}{\left[\frac{r}{r-d} \right]^3 - \left[\frac{\varepsilon_{\text{int}}^* - \varepsilon_{\text{mem}}^*}{\varepsilon_{\text{int}}^* + 2\varepsilon_{\text{mem}}^*} \right]} \quad (10)$$

The computation of the root mean square of the electric field at a specified point between and over the electrodes is made using the second Green's identity:

$$\int_V dV (\Phi \nabla^2 \Psi - \Psi \nabla^2 \Phi) = \oint_A dA \left(\Phi \frac{\partial \Psi}{\partial n} - \Psi \frac{\partial \Phi}{\partial n} \right) \quad (11)$$

One of the function (Φ) is chosen to be the potential between electrodes ($z=0$), $\nabla^2 \Phi = 0$ and the other (Ψ) is a Green function given by $\nabla^2 \Psi(\vec{r}, \vec{r}_0) = -4\pi\delta(\vec{r} - \vec{r}_0)$. Determination of the Green function is made using the mirror-image method.

$$\begin{aligned} \Psi &= \frac{1}{|\vec{r} - \vec{r}_0|} + \frac{-1}{|\vec{r} - \vec{r}_0'|} \\ &= \frac{1}{\sqrt{(x-x_0)^2 + (y-y_0)^2 + (z-z_0)^2}} \\ &\quad + \frac{-1}{\sqrt{(x-x_0)^2 + (y-y_0)^2 + (z-z_0)^2}} \end{aligned} \quad (12)$$

The first order approximation (assuming that the potential varies linearly between the two electrodes) is used, so that the boundary conditions are given by:

$$\Phi(x, y, z=0) = \begin{cases} \frac{V}{2} \cos(\omega t), & -l_x - \Delta \leq x \leq -\Delta \\ -\frac{V}{2} \cos(\omega t) \frac{x}{\Delta}, & -\Delta \leq x \leq +\Delta \\ 0, & -\infty \leq x \leq l_x - \Delta, l_x + \Delta \leq x \leq \infty \end{cases} \quad (13)$$

Where Δ is half distance between the electrodes.

The expression for the electrical field is then:

$$\Phi(x, y, z) = \frac{-V}{2\pi} \cos(\omega t) \left[\frac{z}{\Delta} \ln \sqrt{\frac{(x+\Delta)^2 + z^2}{(x-\Delta)^2 + z^2}} - \arctan\left(\frac{2xz}{z^2 + \Delta^2 - x^2}\right) + \frac{x}{\Delta} \arctan\left(\frac{2\Delta z}{z^2 - \Delta^2 + x^2}\right) \right] \quad (14)$$

After an algebric calculation, the root mean square of E^2 becomes, as it was shown by [5]:

$$E_{rms}^2 = \frac{V^2}{8\pi^2\Delta^2} \left[\frac{-8x^2z\Delta + [x^4 + 2x^2(z^2 - \Delta^2) + (z^2 + \Delta^2)^2] \arctan\left(\frac{2x\Delta}{x^2 + z^2 - \Delta^2}\right)}{[(x-\Delta)^2 + z^2][(x+\Delta)^2 + z^2]} \right]^2 + \frac{V^2}{8\pi^2\Delta^2} \left[\frac{4x\Delta(x^2 - z^2 - \Delta^2) + [x^4 + 2x^2(z^2 - \Delta^2) + (z^2 + \Delta^2)^2] \ln \sqrt{\frac{(x+\Delta)^2 + z^2}{(x-\Delta)^2 + z^2}}}{[(x-\Delta)^2 + z^2][(x+\Delta)^2 + z^2]} \right]^2 \quad (15)$$

For the particular case of our dielectrophoretic cell, the root mean square of E^2 has the profile shown in Fig. 1.

Figure 1: Distribution of root mean square of E^2 between the electrodes of the dielectrophoretic chamber. The x axis is along a direction within the plane of the cell and perpendicular to the electrodes, while the y axis is perpendicular to the plane of the cell and along the optical axis of the microscope.

The value of the dielectrophoretic force can thus be calculated by introducing this last equation in (7). As an example, we give the profile of the horizontal (x) component of the force in the case of our experimental setup, at two different constant heights (5 μm and 35 μm) above the plane of the cell, as a function of the position of the particle between the electrodes (Fig. 2). In this case the distance between electrodes is 100 μm ($\Delta = 50 \mu\text{m}$), and the voltage is $V = \pm 1.5 \text{ V}$

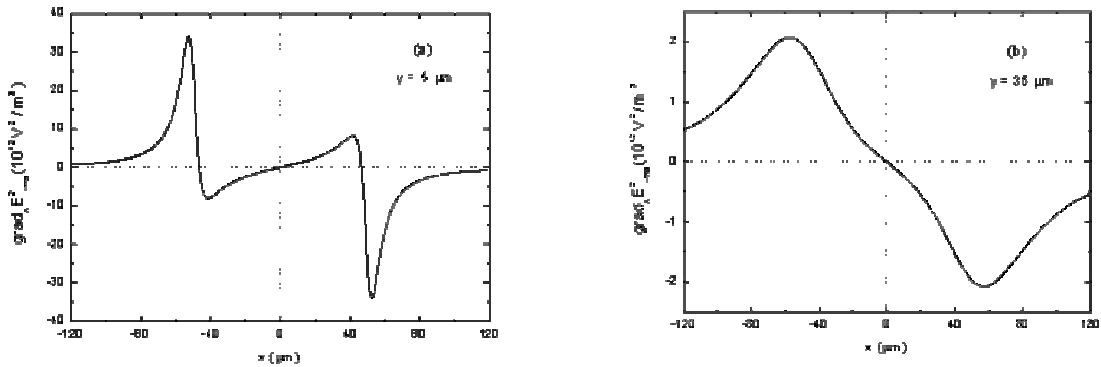

Figure 2: The x -component force profile computed as a gradient of E_{rms}^2 at two different heights above the plane of the dielectrophoretic cell : (a) $y = 5.5 \mu\text{m}$ and (b) $y = 35 \mu\text{m}$. The gap between the electrodes lays from

-50 μm to 50 μm along the x axis.

The vertical component of the force can be also computed, but it is less important for our purposes.

Experimental protocol and results

The optical tweezers we used was built on a normal optical microscope (IOR MC9) on which a laser diode of 830 nm wavelegth and 40 mW maximum power was mounted. Maximum 27 mW power was getting out of the lens in the focal plane, as measured by a power-meter. The diode was connected to a variable power supply which allows adjustment of the laser beam output power.

The dielectrophoretic chamber consisted of two thin planar electrodes deposited on a microscope slide at a distance of $2\Delta = 100\mu\text{m}$. The electric field was applied by a computer controlled function generator (PC Generator PCG10/K8016 Welleman Instruments). For calibration, red blood cells with dielectric parameters, $\epsilon_{\text{int}} = 50\epsilon_0$ and $\sigma_{\text{int}} = 0.5 \text{ S} \cdot \text{m}^{-1}$, $\epsilon_{\text{mem}} = 11.3\epsilon_0$ and $\sigma_{\text{int}} = 10^{-7} \text{ S} \cdot \text{m}^{-1}$ were used. The suspension buffer was a 0.3 M Mannitol solution at $pH = 7.4$ and dielectric parameters: $\epsilon_{\text{med}} = 80\epsilon_0$ and $\sigma_{\text{med}} = 235 \mu\text{S} \cdot \text{cm}^{-1}$.

All measurements were performed using a 100X microscope lens with 1.25 numerical aperture.

The first step is to determine the output force of hte laser beam at the focal point as a function of the applied voltage on the diode. This is done by using an appropriate power-meter and measuring the emitted power at different voltages. The results can be seen in Fig. 3.

Figure 3: Laser beam power calibration, as a function of the electric power applied to the laser diode.

After this first step, we used a standard procedure which consists in the following:

- a cellular suspension is placed on the dielectrophoretic chamber and mounted on the microscope;
- a cell which lays between the electrodes, but closer to one of them is trapped in the laser beam using the maximum laser power;
- then an AC field of 1 MHz frequency and very low voltage amplitude is applied on the electrodes. As a result, a dielectrophoretic force will act on the trapped cell, which depends on the cell diameter and its position between the electrodes (the x position) and along the vertical (y) axis;
- the voltage is then increased until the cell escapes the trap (at this moment the dielectrophoretic force equals the optical force); introducing this last value of the voltage in equations (15) and (7), one can compute the optical force exerted by the laser on the cell.

We measured these forces for red blood cells at different intervals after the blood collection and different times after withdrawal of the sample from the refrigerator.

Some representative results can be seen in Figs. 4 and 5.

Figure 4: Optical trap force as a function of the applied laser power, measured soon after the sample was taken out of the refrigerator (a) and 2 h later (b).

Inspecting Fig. 4 it can be seen that the dependence is linear. It can also be seen that in similar conditions, cells which were kept for longer periods at the room temperature (Fig. 4b) present a much higher dispersion than samples measured immediately after they were taken out of the refrigerator.

In Fig. 5 we present results obtained on cells with the same diameter ($2.6 \mu\text{m}$), at different storage times (1st day after blood collection (a) and 5th day after (b)).

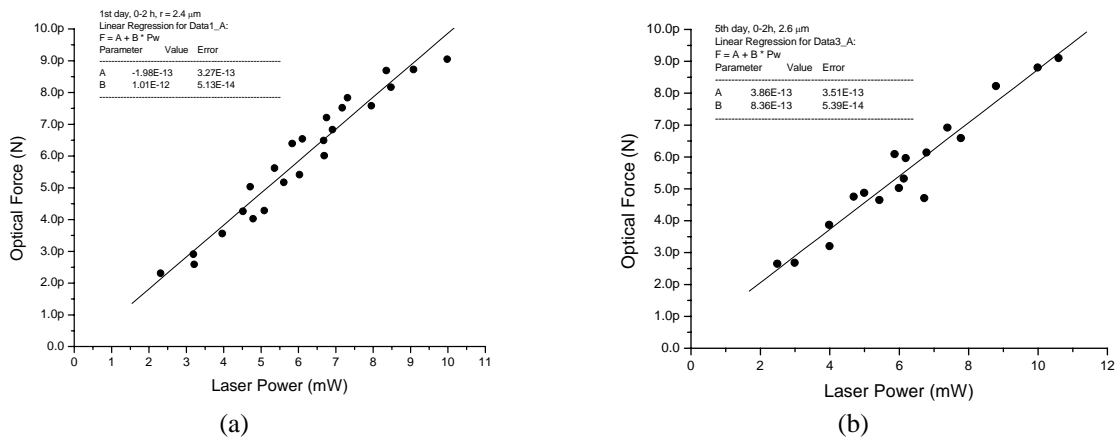

Figure 5: Optical trap force as a function of the applied laser power, measured at two different blood storage periods (a) – 1st day after blood collection and (b) – 5th day after blood collection.

It can be seen that at the same laser power, the resulting optical force is lower as the sample becomes older, although the dispersion of the data remains almost unchanged (e.g. for 6 mW laser power, the optical force is 5.5 pN in Fig. 5a, and 6.5 pN in Fig. 5b).

Discussions

We have shown that dielectrophoretic force can be used to calibrate an optical trap force using an adequate model. On the other hand, analysing the behaviour of the cells in an optical trap combined with dielectrophoresis, we were able to detect significant differences in the cell's response, depending on their metabolic state.

Considering that the optical trap force depends essentially on the cell surface and the cytoplasmic refractive index, it is obvious that biochemical modifications associated with different states of the cell will influence its

behaviour in the optical trap.

Abstract

Communication systems with several antennas at the transmitting and receiving end are called multiple input multiple output (MIMO) systems. In a first approach it is shown that demanding a certain capacity expressed as information per bandwidth and time (in bit/Hz/s) MIMO systems permit a significant reduction of transmit power. Therefore, also the specific absorption rate (SAR) in the human head decreases. In a second approach the total transmit power is held constant. In this case the increased capacity of a MIMO system leads to a performance increase by which the time of the data transmission can be reduced. There exist different MIMO schemes: systems without channel state information available at the transmitter or systems having full channel knowledge at the transmitter. Comparing these schemes we show that MIMO systems show a better performance in terms of exposure than classical single antenna systems. The exposure efficiency of a system as quotient of capacity and SAR is suggested as a measure of the exposure.

Introduction

There are limit values concerning the human exposure to electromagnetic fields (EMF). A lot of countries refer to the ICNIRP Guidelines [1]. For the far field exposure due to base stations the exposure can be conveniently described by the electric field strength (E) or the power density (S). For the human head held close to a mobile phone there is a strongly varying near field over different tissue types. Therefore, a determination of the specific absorption rate (SAR) is necessary. The exposures which encounter in real life due to base and mobile stations are very different compared to the limit values. Safety distances to base stations based on the ICNIRP Guidelines [1] are typically just a few meters [2]. Thus, the exposures due to base stations are usually well below the limits. However, concerning the exposure to mobile phones some phones are quite close to the SAR limit [3].

Classical systems consist of one antenna at the transmitter and one antenna at the receiver. These are named Single Input Single Output (SISO) systems. Recently, wireless communication systems with multiple transmit and multiple receive antennas are subject to many research activities. In these Multiple Input Multiple Output (MIMO) systems, smart antenna techniques are exploited on both sides of the link. Simple MIMO systems have got no information about the propagation channel at the transmitter. In systems with channel knowledge the antenna arrays are adapted to the spatial properties of the propagation channel. The increased performance of MIMO systems in terms of capacity can be used to lower the transmit power leading to a lower exposure. The first approach to examine the exposure of MIMO systems presented in this paper is based on the decrease of the transmit power to achieve the same capacity as in SISO systems. On the other hand in a second approach presented in this paper the transmit power is held constant for SISO and MIMO. The increase in capacity is set into a relation with the SAR. Therefore, this approach shows that MIMO systems will result in lower doses.

Since the propagation channel is non-static the capacity is a random variable. In the investigations done here the term capacity refers to an outage capacity of 10 %. I.e. the calculated capacities are not reached in 10 % and exceeded in 90 % of the realizations.

Handy Model

The simulation model of the handheld device consists of a metallic block, representing the battery and the display of the device, and a PVC housing (cf. Fig. 1). The size of the housing is $55 \times 115 \times 27 \text{ mm}^3$. The metallic block is $40 \times 80 \times 10 \text{ mm}^3$ in size. A standard type of miniaturized antennas (Inverted-F) is built in the mobile phone. One, three or four Inverted-F antennas are mounted onto the metallic block spatially separated and with different orientations to exploit different diversity techniques, such as spatial, pattern and polarization diversity. Usually Inverted-F antennas require an infinite ground plane, which is not available in the small hand-held device. Thus the metallic block, representing the ground plane, acts as a part of the antennas and influences the shape of the patterns and the mutual coupling impedances. Detailed results on design and performance of these MIMO hand-held models can be found in [4].

An operating frequency of 2 GHz and a bandwidth of 3.84 MHz are considered for all the simulations performed. The maximum value of the localized SAR is averaged over any 10 g tissue $\text{SAR}_{10\text{g}}$. The calculation is done numerically with FEKO [5].

Fig. 1: Model of a hand-held device equipped with four Inverted-F antennas.

The hand-held device is attached to a phantom head, which has the size and the shape of an adult human head (density 1000 kg/m^3) and adequate dielectric properties ($\epsilon_r = 40$, $\sigma = 1.4 \text{ S/m}$) (cf. Fig. 2).

Fig. 2: Model of the user's head where the mobile phone is attached.

Model for the Propagation Channel

The campus of the University of Karlsruhe was modeled. Therefore, an outdoor scenario is considered for the wave propagation channel. The base station is mounted 3 m above the roof top of one of the highest buildings of the campus. The mobile phone is located at about 1000 randomly chosen positions on street level. By a ray-tracing technique the waves between the mobile and the base station are calculated [6].

Base Station Antennas

The base station is equipped with one antenna for the SISO case and three antennas with spacings of 1 m for the MIMO cases. The commercially available base station antenna Kathrein type 735147 is used and modeled [2]. The radiation pattern illuminates a 120° sector in the azimuth plane. The elevation pattern is tilted down by 5° , see Fig. 3.

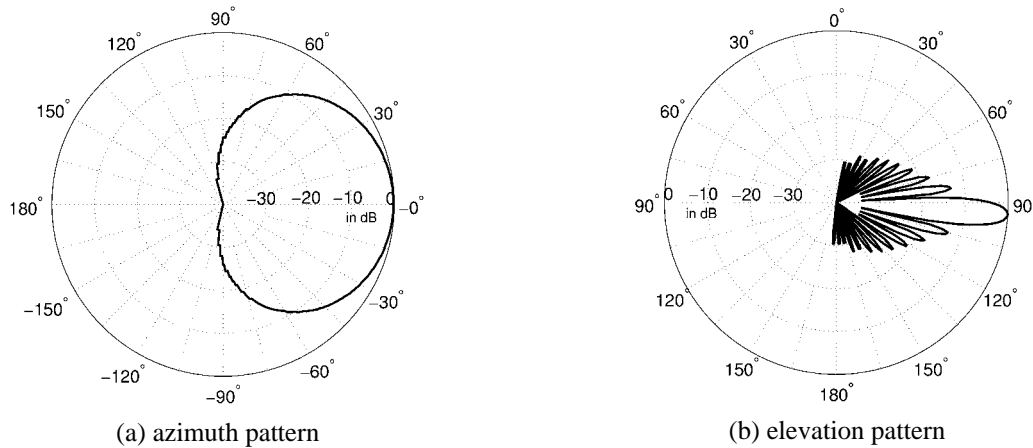

Fig. 3: Radiation pattern of a base station antenna in azimuth and elevation.

MIMO schemes

MIMO systems can be classified by the transmission scheme applied. It is important to distinguish between MIMO systems with and without channel state information (CSI) at the transmitter. In other words, it has to be distinguished between transmitters that do know or do not know the channel. The channel can only be estimated by the receiver. To supply the transmitter with the channel knowledge, it has to be transmitted back to the transmitter. (For time division duplex systems reciprocity may be applied). This back transmission of the channel state information is difficult to realize and reduces the data rate available for the user of the link. Therefore, MIMO systems which do not need to know the channel at the transmitter are very attractive. On the other hand, the optimal capacity of a MIMO system is only reached with perfect channel knowledge at the transmitter. Thus, to reach very high data rates, the transmitter must be informed about the channel. To reduce the complexity of MIMO systems, systems that do only beamforming on both sides of the link, are an attractive option. Those systems do not (except for a very small signal to noise ratio) reach the capacity of normal MIMO systems, because only one data stream is transmitted at one time – in contrast to the spatial multiplexing systems described before.

The following three MIMO schemes are considered:

- MIMO without CSI at the transmitter
- MIMO with CSI at the transmitter
- Beamforming-based MIMO

The capacity and the SAR are calculated and compared for several antenna configurations.

Excitation of the Antennas at the Transmitter

In general, an excitation voltage excites an antenna. Hence, the electric field strength and therewith the SAR in the human head depend also on the excitation voltages of each antenna element. In a SISO system, this voltage is directly related to the transmit power. In a MIMO system the transmit power is distributed over all antennas. Each antenna in the mobile phone can be excited by an individual excitation voltage. The distribution of the transmit power is dependent on the MIMO scheme applied. In the case of MIMO without CSI the transmit power is distributed uniformly. In the case of MIMO with CSI or MIMO-based beamforming the excitation voltages are adjusted to obtain a high capacity. Therefore, the propagation channel has to be taken into account. The model given in [7] is applied. It describes the propagation channel for a MIMO system including the transmit and the receive antennas. It is based on a scattering parameter description.

Investigated Antenna Systems

The following antenna configurations are considered:

- SISO: the handheld with one antenna next to a human head, transmitting to a base station with one antenna
- SIMO 1x3: the single antenna handheld next to a human head, transmitting to a base station with three antennas
- MISO 3x1: the three-antenna handheld next to a human head, transmitting to a base station with one antenna
- MISO 4x1: the four-antenna handheld next to a human head, transmitting to a base station with one antenna
- MIMO 3x3: the three-antenna handheld next to a human head, transmitting to a base station with three antennas
- MIMO 4x3: the four-antenna handheld next to a head, transmitting to a base station with three antennas

For the case of MIMO without CSI it is assumed that via each antenna an independent subchannel is transmitted. At the receiving end the transmitted signal has to be reconstructed. For a system without CSI only configurations are possible where the number of transmit antennas is smaller or equal to the number of receiving antennas.

Approach 1: Constant Capacity

To show the performance of MIMO systems a constant capacity $C = 0.25$ bit/s/Hz is considered. For simplicity a MIMO scheme without CSI at the mobile phone is regarded. I.e. only systems where the number of transmit antennas is smaller or equal to the number of receiving antennas are taken into account.

A classical SISO system will need a transmit power $P_T = 19.9$ dBm to reach the demanded capacity, resulting in a $SAR_{10g} = 0.46$ W/kg (cf. Fig. 4). Increasing the number of antennas at the receiving base station will lower the required transmit power to $P_T = 10.2$ dBm. Since the transmit power can be decreased by almost 10 dB by just adding more antennas at the base station, while using the same antenna at the mobile phone, there is a decrease in the SAR by the same amount to 0.049 W/kg. Further on, adding two antennas to the mobile phone will allow a further decrease of the transmit power ($P_T = 4.9$ dBm) yielding a $SAR_{10g} = 0.018$ W/kg.

Fig. 4: SAR_{10g} for systems without CSI. Constant capacity $C = 0.25$ bit/s/Hz.

Approach 2: Constant Transmit Power

Since there is an increasing demand for higher capacities the transmit power of the mobile phone was fixed to $P_T = 20$ dBm, which is 1 dB below the maximum transmit power of a UMTS class 4 mobile phone [8]. As a rule of thumb: The more antennas there are the higher will be the achievable capacity. This capacity increase can be used to transmit the same information in a shorter time interval. The product of the SAR multiplied by the time of the exposure duration will give a dose.

Therefore, for different antenna configurations and the three mentioned MIMO schemes the SAR_{10g} (exposure) and capacities C are evaluated.

Systems without CSI

The cumulative distribution function (cdf) of the MIMO capacity is given in Fig. 5 for the case of MIMO without CSI at the transmitter. Shown is the probability P that the capacity is smaller than the value on the x-axis. The run of the curves demonstrates that adding further antennas tremendously increases the achievable capacity while keeping the total transmit power constant.

Fig. 5: Capacity for SISO and MIMO systems without CSI at the transmitter. Constant transmit power $P_T = 20$ dBm.

The calculation of the SAR is independent of the channel matrix in this case, because the excitation voltages are kept constant due to the lack of the channel knowledge at the transmitter. There is only one SAR_{10g} value for all channel realizations. This SAR_{10g} value is shown in Fig. 6 for different antenna configurations. SISO A1 and SISO A4 correspond to SISO systems where different transmit antennas are excited. Since they show very similar capacities there is just one line in Fig. 5.

The antenna configurations with only one antenna at the mobile station lead to the largest SAR_{10g} . Especially if the antenna is close to the head as in the case of SISO A4 the SAR_{10g} is close to 1.4 W/kg. The SAR_{10g} can be decreased by using an antenna position which is more optimized in terms of exposure. The configuration SISO A1 and SIMO 1x3 use the same transmit antenna at the mobile phone. For the MIMO case the SAR_{10g} is reduced to a value of 0.36 W/kg, although the transmit power is the same as in the single antenna cases and the capacity is remarkably higher.

Fig. 6: SAR_{10g} for SISO and MIMO systems without CSI at the transmitter. Constant transmit power $P_T = 20$ dBm.

Systems with CSI

Figure 7 shows the cdf of the capacity for the optimum MIMO scheme with channel state information (CSI) at the transmitter. These MIMO systems by far exceed the other MIMO schemes in terms of capacity – keeping in mind that the total transmit power is kept constant for all systems.

Fig. 7: Capacity for SISO and MIMO systems with CSI at the transmitter. Constant transmit power $P_T = 20$ dBm.

The localized SAR_{10g} are shown in Fig. 8. Since the channel changes with time the mean value of 100 SAR values is considered. For the MIMO cases, the scheme with CSI at the transmitter leads to larger SAR values than the scheme without CSI at the transmitter. For the SISO systems, the SAR values do not depend on the scheme applied, because the amplitude of the excitation voltage is held constant and its phase does not influence the SAR due to a lack of interfering signals.

Fig. 8: SAR_{10g} for SISO and MIMO systems with CSI at the transmitter. Constant transmit power $P_T = 20$ dBm.

Systems with beamforming-based MIMO

Beamforming-based MIMO uses only the best subchannel, i.e. there is only one data stream transmitted. Fig. 9 shows that in this case the lowest capacities are obtained. Due to beamforming at both ends, the capacity is still enhanced by increasing the number of antennas.

Fig. 9: Capacity for SISO and beamforming-based MIMO. Constant transmit power $P_T = 20$ dBm.

The results for the SAR_{10g} are given in Fig. 10. In systems where the minimum number of transmit and receive antennas equals one there exists only one subchannel. Therefore, there is no difference between MIMO with channel state information at the transmitter and beamforming-based MIMO in these cases and the SAR values are the same. For the MIMO 3x3 configuration the SAR values are quite similar, 0.88 W/kg with CSI and 0.86 W/kg for beamforming-based MIMO. For the MIMO 4x3 case, the SAR values are also similar.

Fig. 10: SAR_{10g} for SISO and beamforming-based MIMO. Constant transmit power $P_T = 20$ dBm.

Exposure Efficiency

The total transmit power has been kept constant for all MIMO schemes and all antenna configurations in the second approach. But the capacity differs remarkably for the different cases.

For a further evaluation of the MIMO schemes and antenna configurations the quotient of 10% outage capacity C and the specific absorption rate SAR is computed. The result is given as exposure efficiency EE of the system:

$$EE = \frac{\text{10\% outage capacity}}{\text{max. localized SAR averaged over 10g tissue}} = \frac{C}{\text{SAR}_{10g}}$$

An exposure-optimized system exhibits a high capacity and low SAR_{10g} . I.e. for an exposure-optimized system the value of EP is larger compared to a system with poorer exposure efficiency. The higher the value of EE the smaller is the exposure integrated over time experienced by the operator of the mobile to transmit a certain amount of information.

Fig. 11 shows the exposure efficiency EE for all antenna configurations and MIMO transmission schemes. No results are shown for the case of a system without CSI at the transmitter if the number of transmit antennas is larger than the number of receiving antennas since the receiver can't reconstruct the transmitted data streams without a channel knowledge.

The exposure efficiency EE for configurations where there is only one transmit antenna is the same for all MIMO schemes since the fixed transmit power is radiated by the single antenna. Adding antennas at the receiving or transmitting end will yield a higher EE. The MIMO 3x3 system without channel knowledge shows the best EE. If channel knowledge is available for this configuration the antenna weightings are adjusted to increase the capacity. However, this adjustment leads also to a higher SAR value. The increase in SAR is larger than the increase in capacity. The considered SISO systems show the worst exposure efficiency EE.

Fig. 12: Exposure efficiency for the investigated MIMO schemes.

Conclusion

It is shown that multiple antenna systems outperform classical single antenna systems by allowing higher capacities. To reach a demanded capacity the transmit power of a MIMO system can be clearly lowered compared to a SISO system. This leads to a tremendous decrease in exposure. Keeping the transmit power constant shows that MIMO systems with channel knowledge give the highest capacities. However, the exposure efficiency might be lower than in a system without channel knowledge. The MIMO scheme allowing the highest capacity is not necessarily optimized in terms of exposure.

THE EFFECT OF 1800 MHZ ELECTROMAGNETIC RADIATION EXPOSURE ON CORTICAL AND HIPPOCAMPAL ELECTROGENY IN NEURODEFECTIVE AND HEALTHY BRAIN

JAN BARCAL¹, JAN VRBA², FRANTIŠEK VOŽEH¹

²*Czech Technical University in Prague, Faculty of Electrical Engineering, Department of Electromagnetic Field; Czech Republic*

Abstract

In this study a simultaneous registration of the brain cortical and hippocampal activity during a high-frequency electromagnetic field (HF EMF) exposure was performed. All procedures were done under urethane anaesthesia (20%, 2g/kg i.p.) in Lurcher mutant mice (LMM) which serve as an excellent model of neurodegeneration. Healthy wild type mice (WTM) were used as controls. The animals were exposed to 1800 MHz HF EMF corresponding with the mobile phone frequency. We used gel electrodes (silicon tubes or glass microcapillaries filled with agar) where the connection with metallic electrodes is located out of HF EMF space. The evaluation of electrocorticograms and spontaneous hippocampal rhythmicity showed a distinct shift in main components of frequency spectra but clear effect has been observed only in WTM. Mice with inborn neurodegeneration (LMM) exhibited only gentle differences. The comparison of cortical and hippocampal electrogeny suggest an opposite effect of HF EMF on the brain cortex and hippocampal neuronal circuits. These findings support ideas about possible influencing the central nervous system by HF EMF exposure and support also some recent results about hidden health risks resulting from the mobile phones use.

Introduction

Each electromagnetic source localized near the biological object produces electromagnetic field which may cause **both thermal and non-thermal biological effects**.

A basic principle of **thermal effects** is the rise of temperature produced by the energy absorbed from oscillating electric fields. The force produced by an electric field on charged objects, such as the mobile ions present in the body, causes them to move, resulting in electric currents, and the electrical resistance of the material in which the currents are flowing results in heating. This heat input causes the temperature to rise and it continues to do so until the heat input is balanced by the rate at which it is removed, mostly by blood flowing to and from other parts of the body. Theoretical studies are focussed to the computation of specific absorption rate (SAR). The relationship between the SAR and the resulting temperature rise is complex, and significantly dependent on antenna configuration, location and frequency. The most problematic feature of a temperature calculation is modelling the effect of blood flow on heat transfer. Van Leeuwen et al. [1] published that heat deposition within the head was computed by coupling a finite difference time domain model for SAR with a new thermal model. The thermal model includes the convective effects of discrete blood vessels, whose anatomy was determined using magnetic resonance angiography of a healthy volunteer. For a 915 MHz dipole antenna with a time-averaged power output of 0.25 W (equivalent to a typical mobile phone), this study results in an SAR of about 1.6 W/kg and predicts a maximum brain temperature rise of 0.11 °C in the steady state.

An explanation of **non-thermal effects** seems to be more complicated and also controversial. The energy quanta of radiation at 0.9 and 1.8 GHz equal 4 and 7 µeV, respectively. Both these values are extremely small compared with the energy of around 1 eV needed to break the weakest chemical bonds in genetic molecules (DNA). Detectable changes can arise only if the effect of the electric field within the biological system exposed to RF fields is not masked by thermal noise. Thermal noise or random motion, also known as Brownian motion, is due to the thermal energy that all objects possess at temperatures above absolute zero. In solids, the atoms vibrate and in gases and liquids they move erratically to and fro following very frequent collisions with other atoms. So all components of biological tissue - ions, molecules and cells - are in

THE EFFECT OF 1800 MHZ ELECTROMAGNETIC RADIATION EXPOSURE ON CORTICAL AND HIPPOCAMPAL ELECTROGENY IN NEURODEFFECTIVE AND HEALTHY BRAIN

constant motion. Another mechanism involving cells concerns the attraction between them in the presence of an electric field [2], [3]. The electric field polarises the cell, that is to say charges in the cell move so that one side of it becomes positive with respect to the other. The cell is then an electric dipole (like a tiny torch battery) and attracts similarly polarised cells. For typical cells and frequencies below about 100 MHz, the energies involved are calculated to become comparable to thermal noise in electric fields of $E=300$ V/m. The energies are calculated to become appreciably less for RF fields, but Adair [3] suggests that, since these values would depend on the detailed structure of the biological elements involved, the possibility of biological effects for fields of this size cannot be excluded. Other possible biological effects are associated with cell membranes and the movement of currents through the membrane in either direction. Membranes are known to have strongly non-linear electric properties [4]. When a voltage is applied across the membrane, the current that flows is not always proportional to the voltage. Part of this non-linearity may, in fact, be due to the effect of the electric field on the proteins in the membrane or nearby, which assist the flow of the product currents through the membrane. The membrane also acts as a rectifier. If a voltage is connected across the ends of a wire, the size of the current that flows depends solely on the magnitude of the voltage: if the polarity of the voltage is reversed, the current changes direction but its size is unchanged. However, if the polarity of the voltage applied across a rectifier is reversed, the current changes direction but now its size also changes. So, if an oscillating voltage (electric field) is applied across a rectifier, the total current that flows when the field is in one direction is not balanced by the current when the field is in the other: an AC field produces a net DC current and hence a net flow of products through the membrane. However, the response times of the ion gates are very much slower than the period of microwave frequencies and, using data obtained from measurements on membranes [4], it has been shown that, for electric fields of 200 V/m, the relative change in the membrane potential is very small [3]. Another hypothesis is that the interaction with biological tissue depends on the coherence of the electromagnetic fields [5].

Possible effects on the brain and behaviour during acute exposure to RF fields are permanently discussed - mobile phones are conventionally held close to the head. Many results are about effects of RF fields on isolated nerve cells (neurons), on cultured nervous tissue, on living brain slices, on brain function in experimental animals, on the blood-brain barrier and on behavioural measures of brain function [6,7,8,9]. The behaviour of animals can be a very sensitive indicator of adverse health consequences. Early signs of potential insult are often behavioural rather than anatomical [10].

RF fields, continuous or pulsed, can affect membrane channels [11]. Experiments of Cleary [12,13] suggest that the flux of positively charged sodium and potassium ions across cell membranes can also be affected by RF exposure, over a wide range of frequencies (27 MHz to 10 GHz). Philippova [14] found that 900 MHz radiation, at SARs of 1 and 100 W/kg, specifically affects the binding of odorant molecules to receptor protein in the membranes of olfactory receptor neurons in the rat. Liburdy and Vanek [15] have also reported protein shedding from membranes as a result of RF exposure. A radiation at very low power can affect the ion channels associated with transmitter receptors: experiments of D'Inzeo et al. [16] suggest decrease in the frequency of opening of sodium channels associated with acetylcholine receptors in muscle membranes as a result of exposure to 9.75 GHz radiation at only 10-20 $\mu\text{W}/\text{m}^2$, which might cause a decrease in the excitability of the muscle. An increase in membrane conductance and a decrease in the spontaneous firing of impulses in neurons of the snail *Helix aspersa* when exposed for an hour to continuous and amplitude modulated 2.45 GHz radiation was described by Arber and Lin [17,18]. The effects were abolished by the application of ethylenediamine tetraacetic acid (EDTA), which chelates calcium. Another studies also described a decrease in the electrical amplitude of impulses and a reduction in the excitability of the frog sciatic nerve when exposed to 2.45 GHz radiation [19], and a decrease in spontaneous activity of neurons isolated from the marine gastropod *Aplysia* at relatively high intensities [20, 21].

The main aim of the presented study was a electrophysiological investigation of an influence of high-frequency electromagnetic field (HF EMF) on brain functions in Lurcher mutant mice, which represent an excellent model of neurodegenerative disease, and healthy animals.

Animals and Methods

Lurcher mutant mice (Lurchers) represent a natural model of genetically determined olivocerebellar degeneration [22]. Heterozygote individuals (+/Lc) are characterized by the postnatal complete loss of cerebellar Purkinje cells (excitotoxic apoptosis) and by the decreased number of granule cells and inferior olivary neurons (secondary to the loss of Purkinje cells). Affected homozygotes (Lc/Lc) are not viable. Unaffected homozygotes, wild type mice (+/+) are completely healthy and serve as controls. Our previous results suggest that in Lurchers some cognitive functions are changed - in series of experiments studying the development of spatial learning in Lc/+ and +/+ during the first month of life using the standard Morris water maze [23, 24]. Some neurons of Lurchers are more sensitive to neurotoxic substances [25] and other experiments discovered a higher degree of the CNS excitability in Lc/+ when compared with +/+ using a method of audiogenic epilepsy [26]. Similar

findings were obtained in experiments which measured brain cortical activity after previous electrical and drug stimulation [27, 28]. Also significant changes of hippocampal activity (LTP) were found in anesthetized Lc/+ in comparison with +/+ [29].

We expect that some brain structures in Lurchers would be more sensitive (i.e. with lower threshold) to different kind of stimulation and neuronal injury. It is possible to assume a higher effect of other types of stimulation on such neurons, including HF EMF. A direct registration of brain cortical and hippocampal activity during exposure to high-frequency electromagnetic field (HF EMF) and a depiction of possible changes in the hippocampal rhythmicity were performed. All experimental procedures were done under urethane anaesthesia (20%, 2g/kg i.p.) in adult (10-12 weeks) Lurcher mutant mice (n=20) and wild-type (healthy littermates) which served as controls (n=20). Experimental animals were exposed to HF EMF with frequency of 1800 MHz, similar to the range used by mobile phones. As a source of the HF EMF a high-frequency generator was used; the power output was approximately 1 W. The radiation was directed by a waveguide to a space with the animals placed (modified stereotaxic frame in the Faraday's chamber). The area of the orifice was 150 cm².

An important problem in the use of classical EEG technology is the presence of conductive (contact) electrodes in brain tissue resulting to discontinuity of HF EMF and possible electrolytical processes caused by the nonhomogeneity on the boundary line of metal-tissue. Our original method [30] is based on the use of gel electrodes (silicon or glass capillary tubes filled with agar). The corresponding conductivity is achieved by supplementation of saline and final biophysical quality is adequate to the brain tissue. The connection with classical (wire) electrodes is performed out of HF EMF space. Spontaneous electrocorticogram (ECoG) was measured as 2 min segments from continuously recorded activity either without HF EMF exposure or with it. Final calculation with Fourier analysis and averaging were performed off-line on DISYS-system (Software for data acquisition and analysis). Hippocampal activity was recorded by glass capillary filled with agar (used as a registration electrode), grounding electrode was a silicon tube filled with agar located on the neck. Stereotactic coordinates [31] - ref. point bregma: AP: 2.0; L: 1.5; V: 1.3 (CA1) – 2.0 (hilus DG). DISYS-system for a final averaging according to Fourier analysis with emphasis on a theta-oscillation especially was used.

Results

The experiments confirmed a possibility of direct EEG registration during exposure to HF EMF. Recording time for each experimental animal was approximately 30 minutes and DISYS system was able to describe spontaneous activity either before influencing by the HF EMF or during it. Examples of five seconds recording in wild type mouse (Fig. 1, 2) and in Lurcher mutant mouse (Fig. 3, 4) are shown below.

Fig. 1 – Spontaneous brain cortical activity (ECoG) in wild type mouse without HF EMF exposure

THE EFFECT OF 1800 MHZ ELECTROMAGNETIC RADIATION EXPOSURE ON CORTICAL AND HIPPOCAMPAL ELECTROGENY IN NEURODEFECTIVE AND HEALTHY BRAIN

Fig. 2 – Spontaneous ECoG in wild type mouse during exposure to HF EMF

Fig. 3 – Spontaneous brain cortical activity (ECoG) in Lurcher mutant mouse without HF EMF exposure

Fig. 4 – Spontaneous ECoG in Lurcher mutant mouse during exposure to HF EMF

The final evaluation and averaging of cortical activity showed a distinct shift to lower frequency components. These findings are in accordance with older and recent results but clear effect only in wild type

(healthy littermates) was observed (Fig. 5) whereas in Lurcher mutant mice only gentle differences between frequency spectra were found (Fig. 6).

Fig. 5 – Fourier analysis of ECoG in wild type mice group before (blue line) and during (red line) exposure to HF EMF

Fig. 6 – Fourier analysis of ECoG in Lurcher mutant mice group mice before (blue line) and during (red line) exposure to HF EMF

On the other hand, changes of hippocampal activity and shift towards higher frequencies in both types of animals (healthy and mutant) were observed (Fig. 7, 8).

Fig. 7 – Hippocampal activity in wild type mouse before exposure to HF EMF

Fig. 8 - Hippocampal activity in wild type mouse during exposure to HF EMF

The serious problem is depiction of SAR which is generally accepted as a indicator of the energy absorption by different kinds of living tissue. In our experiments we used mathematical modelling of SAR calculation. In the figures 9 and 10 examples of SAR calculation were shown (both using 900 MHz HF generator, where power output was approximately 10 W). We expect a similar distribution of SAR corresponding to the lower power output at one side but higher concentration of HF EMF resulting from less area of waveguide orifice.

Figs 9 and 10 – mathematical model of SAR in two different mice position

Discussion

An artificial source of HF EMF used in our experimental paradigm influenced spontaneous cortical activity. A shift towards lower frequencies was observed with gentle differences between Lurcher mutant mice and wild type mice. Our main working hypothesis was that some brain structures in Lurchers should be more sensitive (i.e. they have lower threshold) to different kind of stimulation and neuronal injury. We suppose that thermal gradient arising between lipo- and hydrophilic structures influences ion movement through membranes of neurons and/or glial cells. However, possible delicate changes were identified rather in the brain of healthy animals. These relatively ambiguous findings support our idea about a different vulnerability of the CNS in mice with neurodefective brain to some physical and chemical factors in comparison with controls. The higher CNS excitability in Lurcher mutant mice and its possible suppression or masking effect on the HF EMF influence may be used as an explanation of insignificant differences between healthy and mice with inborn neurodegeneration. Nevertheless, our general findings are in accordance with previously published investigations of Bawin et al. [32, 33] that exposed cats, which had been previously conditioned to produce selected EEG rhythms in response to a light flash, to low level RF fields. The changes were reported in the performance of the conditioned EEG response task and in various other behavioural parameters. It was argued that the fields acted directly on brain tissue causing a minute release of calcium, resulting in changes in membrane excitability, which could possibly affect EEG rhythms. Takashima et al. [34] reported changes in EEG of rabbits following exposure to a modulated RF field of 1-10 MHz, a frequency range outside the main interest but Shandala et al.[35]; Thuroczky et al.[36] reported about subtle effects on the EEG in rats and rabbits exposed to RF fields within the frequency range of interest. McRee et al. [37] described experiments performed by Rosensteig of the US Environmental Protection Agency, who exposed rats to RF from late fetal life until adult. He saw no changes in either the spontaneous EEG or the electrical responses evoked by flashes of light (visual evoked responses). Mitchell et al. [38] reported the findings of a joint project on the same subject carried out in the USA and the former Soviet Union. Both groups exposed rats to fairly intense continuous-wave RF fields for seven hours. Interestingly, both

THE EFFECT OF 1800 MHZ ELECTROMAGNETIC RADIATION EXPOSURE ON CORTICAL AND HIPPOCAMPAL ELECTROGENY IN NEURODEFECTIVE AND HEALTHY BRAIN

teams found small but statistically significant reduction of power in the EEG, but in different parts of the frequency spectrum.

Laboratory studies investigating the effects of mobile phone signals on the spontaneous EEG in awake subjects have produced somewhat mixed results. Reiser et al. [39] reported that exposure to GSM signals was associated with increases some 15 minutes later in the power of EEG frequencies of about 10 Hz and higher, Roschke and Mann [40] were unable to detect any differences in EEG spectra related to exposure to GSM signals. A similar inconsistency appears to hold for the study of sleep EEG. Mann and Roschke [41] reported that exposure to GSM-like signals reduced latency to sleep onset, and altered spectral characteristics of REM sleep, although a subsequent study by the same group [42] failed to replicate these findings. In other study [43], exposure to a "pseudo-GSM signal" (15 minute on/off cycles, 900 MHz, duty cycle of 87.5 % rather than the 12.5 % used in phone signals, and an estimated whole-body SAR of 1 W/kg) was associated with reduced waking after sleep onset and changes in EEG power spectra during the first of the night's episodes of non-REM sleep. In three studies „event-related potentials“ (ERPs) were investigated during exposure to GSM-like signals. In the first [44] visual sensory responses to checkerboard reversal were found to be unaffected during exposure. In two other studies [45, 46] positive effects were reported. In a recent study in Czech Republic, Jech and colleagues [47] also found changes of visual event related potentials during exposure to HF EMF.

Taken together, main importance of this study was that neurodefective animals and their healthy littermates (as ideal controls) were used. Despite our experimental paradigm (i.e. whole-body HF EMF exposure characterised by lower amount of absorbed energy in comparison with human brain during cellular phone use), presented results suggest that some neuronal populations (cortical and subcortical) react on this type of radiation. Current WHO recommendation published by Repacholi [48] consists of basic principles of safety for individuals. The limiting of the lenght of calls or using „hands-free“ device has probably higher importance in children in which possible thermal effect on the developing brain may be connected with higher healthy risks.

Abstract

- Objectives:

This work aims to provide evidence of an inductive electromagnetic bio-effect on the human brain, which is independent from sound waves and produced by mobile phones, in proximal field, through correlating the EEG data obtained from electrodes placed on both normal and cochlear deaf individuals.

- Methods

Two groups of four subjects are placed under controlled electromagnetic conditions inside a Faraday chamber, (two healthy and another two suffering from cochlear deafness). Each is sitting on a chair, fitted with additional support, and holding a cellular phone 2 cm away from the right auricular, in order to avoid a thermal effect as much as possible. All of them, relaxed and with their eyes closed, are EEG recorded in a basal state with their mobile phones off.

Then, each of them is again recorded under the same conditions but with the mobile on and listening to the same conversation. In order to assess the EEG changes so observed, a statistical analysis by means of the FFT (Fast Fourier Transform) was carried out.

- Results

For both, healthy and cochlear deaf, assimilation or integration of the mobile phone signal by some electrodes is to be found. This is due to the increase of amplitudes for alpha and theta waves, whereas the signal is not integrated in other electrodes. By correlating the spectra of frequencies of corresponding EEG records for the same brain areas, we have not observed significative differences for both groups.

- Conclusion

A possible electromagnetic direct inductive, non-thermal, bio-effect on the human brain is observed. This effect is produced by the use of mobile phones and it bears no relation to the sound waves.

Keywords: electromagnetic field, bio-effects, electroencephalogram, mobile phone, cochlear deaf.

Introduction

Recent technological advances in telecommunications have led to the use of electromagnetic fields (EMF) to man's own convenience, such as in Telemedicine, in the field of Medicine (Ramos and Monteagudo, 2006) or for diagnosis and treatment as well, within the field of medical specialities (Bardasano and Elorrieta, 2000, Rosch and Markov, 2004).

Nevertheless, electromagnetic fields from GSM mobile phones (Global System Mobile Communication) and from their base stations can have an effect on living beings and man, in particular, in different ways. More and more often we find proof from different fields of knowledge of this environmental electromagnetic pollution, which might involve the health of human and other living beings, (Navarro *et al.*, 2003, Santini *et al.*, 2003, Balmori, 2004, 2005, Hutter *et al.*, 2006).

Neurons can respond to electromagnetic fields, (Beasond and Semm, 2002) and different degrees of neurological and other kinds of alterations, which may change the physiology of the brain, can also be found and are associated to mobile phone radiofrequencies, (Hossmann and Hermann, 2003, Westerman *et al.*, 2004, Huber *et al.*, 2005, Maby *et al.*, 2005, Szykowska *et al.*, 2005, Papageorgiou *et al.*, 2006).

Evidence of alterations in the permeability of the hematoencephalic barrier in rats from mobile phones has been presented (Fritze *et al.*, 1997) as well as histological changes due to neural damage in the cortex, hippocampus and basal ganglia in the brain of exposed rats (Salford *et al.*, 2003) and changes in the EEG of the rabbit (Marino *et al.*, 2003).

We also have evidence of alterations in the brain of rats not only at the biochemical level but also at that of the glial cells. There is evidence of molecular alterations in the rat's brain due to GSM mobile phones after an acute exposure to high power 900 MHz micro waves. (Mausset-Bonnefont *et al.*, 2004).

Also, the effects of 900 MHz electromagnetic exposure on cochlear cell functionality in rats are evaluated as a distortion product due to otoacoustic emissions by Galloni *et al.*, 2005. In this work, in order to evaluate the influence of mobile phones on the human brain, we give the EEG recording an essential role as a working tool, (Krause *et al.*, 2004, Lin, 2004, Curcio *et al.*, 2005, Loughran *et al.*, 2006).

The EEG is a representative signal containing information about the condition of the brain. The shape of the wave may contain useful information, hence Croft *et al.*, 2002, found that EMF exposure decreased 1 Hz – 4 Hz activity in right hemisphere sites, and was associated with increasing 8 Hz – 12 Hz activity as a function of exposure duration in the midline posterior sites.

Along the same lines, Kramarenko *et al.*, 2003, used a telemetric EEG, and found that within 20 s – .40 s of exposure to a 900 MHz phone signal subjects showed slow-wave activity in the contralateral, frontal and temporal areas. They lasted for one second and were repeated every 15 s – 20 s. When the signal stopped the slow waves progressively disappeared in the next 10 minutes.

Furthermore, Cook *et al.*, 2004, suggested that 30% of the variation in alpha activity seen in their study were due to the pulsed magnetic field exposure and also, Papageorgiou *et al.*, 2004, found that baseline EEG energy was greater in males, while exposure to EMF decreased EEG energy of males and increased that of females. There were not statistically significant differences in memory performance between men and women, nor was there any difference between exposed and non-exposed states.

Additionally, in a small pilot study, Hamblin, *et al.*, 2004, found some evidence of neural activity as a result of mobile phone exposure during an auditory task.

Moreover, the effects of EMF emitted by mobile phones on human EEG were studied during an auditory memory task. The energy was found concentrated at the four basic bands. The results show evidence of a strong gender radiation interaction effect on the EEG energy and on the peak amplitudes within each of the four rhythms (Nanou *et al.*, 2005).

The EEG analysis performed with three different methods showed that statistically significant changes occur in the EEG rhythms, energy and dynamics between 12% and 30% of subjects. The results suggest that microwave exposure affects part of the population and can have an impact on health. (Hinrikus *et al.*, 2006).

This research is aimed at providing evidence of electromagnetic induction from mobile phones, in proximal field, to the human brain by comparing the EEG of healthy normal individuals with that of cochlear deaf, regardless of sound stimulus (sound waves).

• Materials and Methods

We have followed the protocol (patterns), as in previous experiences in our laboratory, as to the subjects, procedures, materials (Faraday screen, mobile phones, electroencephalograph and recording), etc. For more details, see Bardasano *et al.*, 2005.

Subjects

We have carried out this study on four individuals in two groups, (two healthy individuals and two suffering from cochlear deafness).

Procedure

Each subject is placed inside the Faraday chamber and comfortably seated on a plastic chair. The mobile phone is held over the right ear by an insulated device 2 cm from the auricular to avoid a thermal effect as much as possible. By means of the EEG, we tested the effects of the mobile phone on the subjects as follows: basal EEG activity, with eyes closed, for 5 min; each subject was recorded while listening to a five minute conversation with the phone placed on the right ear.

Materials

Mobile phone

Technical specifications: Global System Mobile Communication (GSM) class 4 (2 W), 880 MHz –960 MHz frequency band, which is a proximal field in relation to the subject. Specific Absorption Rate (SAR), highest value, 0.955 W/kg.

Electroencephalograph and recording

A digital EEG, with system plus software, model: SAM 32 FOFC I (latest version) by Micromed[®], which incorporates amplitude and frequency maps, was employed. EEG signals were collected from 18 channels and filtered with a band filter.

Statistical Analysis

In order to assess our EEG results, we have applied the FFT (Fast Fourier Transform) mathematical analysis.

• Results

In healthy and cochlear deaf individuals, we find assimilation or integration of the mobile phone signal in some electrodes. This is due to the increase of the amplitudes of alpha and theta waves. By correlating the spectra of frequencies of corresponding EEG records for the same areas, significative differences for both groups are not observed (see Appendix, Fig. 1 and Fig. 2).

• Discussion

Our discussion focuses on physiological interpretation and on methodological observation.

Physiological interpretation

During transduction of external signals, FFT analysis shows that a healthy subject's brain behaves in two ways to the signal from the mobile phone. It rejects the incoming signal or integrates it by making it its own, and generates another signal as a response. This is done by increasing the spectral power density of the incoming signal which implies an increase of energy without altering the frequencies. This means that a larger number of neurons are being activated underneath than at the basal phase for the same activated frequencies.

In short, the brain responds by yielding signals which lead to the generation of alpha and theta rhythms. The EEG response of the cochlear deaf is similar to that of the healthy subject with the phones on. For both groups, the behaviour of the EEG towards the signal from the mobile shows that it can either be integrated in the brain or it appears in the spectrum of frequencies of the typical peaks of mobile phones which overwhelm the normal brain signal, on the same recording electrode and for the same subject at a given time.

Let us call *integration* the capacity for assimilating, processing an incoming signal, and for emitting another signal as a response. Given that, the sound waves do not seem to affect the integration of such a signal in the brain.

Methodological observation

Research on the harmful bioeffects of mobile phones on the brain faces one of its challenges; that is, to avoid suffering, lesion, and death of the neurons. Neuroprotection is a way of guarding neurons which, for different reasons, have their death scheduled. We find several programs in the central nervous system which schedule the death of mobiles, which are activated by internal alterations (genetic features of the patient) or external (biological, chemical, such as exposure to toxins, heavy metals in drinking water, pesticides, and others, and physical elements such as artificial and uncontrolled electromagnetic fields. (Bardasano *et al.*, 2005)

The EEG shows the influence of mobile phones on man. In the field of Biomedical Engineering, research should contemplate at least the following aspects:

a. The General Adaptation Syndrome to changes in the state of matter and energy. Those changes take place in the environment of living beings, bearing in mind the threesome 'oppressor, depressor, stressor', adverse hypersensitive reactions and the microwave syndrome.

b. Electromagnetic Compatibility. In the field of the modern theory of the signal, the task is to observe machines or systems in good working condition and the human body, itself as a system, (the inductive influence of electromagnetism from a mobile phone and the bioelectromagnetism of the human brain).

c. The Physiology of Regulatory Systems and Chronobiology. To avoid alterations in the permeability of the hematoencephalic barrier or chronopathologies due to alteration of circadian rhythms, (waking and sleeping states), among others, due to this inductive influence.

Summary

By comparing the EEG data from mobile phones, independent from sound, through the electrodes glued onto normal and cochlear deaf subjects, we have tried to find evidence of an inductive electromagnetic bio-effect on the human brain.

We found that the signal is not integrated in some electrodes and we have not found significant differences for either group of healthy and cochlear deaf subjects, which, on the other hand, show assimilation or integration of the mobile phone in other electrodes because of the increase of amplitude of the alpha and theta waves. By comparing the spectrum of frequencies of the corresponding EEG for the same areas, we have not observed significant differences in both groups, either.

The effect, observed in the brain, is produced by the mobile phones.

Abstract

• Objectives.

We aim to obtain a model or pattern among normal subjects. Thus, we are subsuming a diagnostic method (digital EEG) and a therapeutic one, which is the physiological TMS (Transcranial Magnetic Stimulation), into a new technique, pending validation. This new technique will be able to obtain an electroencephalographic response and to quantitatively evaluate the alteration of cerebral rhythms in healthy subjects, (pattern for normality), employing physiological TMS at 10 pT (picotesla) and 8 Hz, simulating the alpha rhythm. The study is single blind and the subjects do not know when they are being stimulated.

• Material and Methods

We have employed digital EEG, mod. SAM 32 FOFC 1, with System PLUS Software by Micromed, latest version, and spectral analysis by FFT (Fast Fourier Transform). The sample was made up of 16 healthy subjects with their eyes open, half males and half females. The recording cap, which is elastic has twenty Ag/AgCl electrodes (SIEMENS) placed bilaterally and is electrode-glued onto the scalp of the subject. The 10/20 IS (International System) of electrode placement is used. EEG signals are collected from 18 channels, filtered through a 0.5 Hz – 70.0 Hz band filter and sampled at 128 Hz. We have also used a TMS prototype stimulator, mod. MG28TR10, which incorporates a timer for the EEG recorder to control the stimulation periods and pauses (1.5 min followed by a 1 min pause). Twenty magnetic stimulation coils are placed on the EEG recording elastic cap at a distance of 2 cm between them and the recording electrodes. This way, stimulation and recording can be carried out without interference.

• Results

A global increase in the alpha and beta rhythms has been observed as well as a decrease in delta and theta. Alpha and delta register the highest increase and decrease, respectively. A 17.5% increase in alpha rhythm and a 4.5 % in beta are performed at the expense of a decrease in delta and theta rhythms.

The most relevant increase in alpha rhythm, as the stimulation was going on, was registered at the Fp1, Fp2, F3 and F4 frontal electrodes, as well as at the central Cz.

• Conclusions

By means of the TMS at 10 pT and 8 Hz, we obtain a mimetic global bioelectrical neuronal response, as the alpha rhythm magnetic field is simulated and the brain is timed to it. We also find an alpha rhythm displacement towards frontal and central areas of the brain.

Keywords: magnetic stimulation, EEG, brain rhythms.

Introduction

Research on 500 μ T weak magnetic fields, extremely low frequencies (ELF) (between 0 Hz and 300 Hz), and their exposure to humans has yielded incomplete and contradictory evidence, (stemming mainly from clinical results) (Sandyk, 1992, Sandyk and Derpapas, 1993, Bardasano *et al.*, 1997a, Ramírez *et al.*, 1997, Anninos *et al.*, 2003).

This may be due to the scarce number of studies conducted under EEG, MEG (Magnetoencephalography) examination conditions or evoked potentials and how they affect the perceptual and cognitive processes in human beings. It must also be added that most bioelectromagnetic results in the different studies have been inconsistent with one another. The most important explanations, which may account for those inconsistencies are those aimed to clarify how different the features of the applied field may be (different intensity and frequency, waveform, and duration of exposure). We also find differences among the disparate protocols employed, which can be more or less precise regarding the elimination of artefacts or elements that bring about confusion in the electrophysiological recording (Cook *et al.*, 2002).

Most studies on low-power fields carried out inside Helmholtz coils generate a homogenous and continuous field, (Lyskov *et al.*, 1993, Marino *et al.*, 1996 and Heusser *et al.*, 1997), in which the subject has electrodes placed on both his first and second fingers of his non-dominant hand and on his scalp. The former measures skin conductance and the latter cerebral electric activity. A computer controlled system allows us to change the type of field generated by the coils at desired intervals, in either a random or pre-determined pattern and to register the ongoing physiological changes.

Most EEG studies so far, which observe the effects after applying a weak magnetic field, have been using this magnetic fields generation model and have been comparing the differences so obtained.

As regards to physiological stimulation, the simultaneous registry between stimulator and EEG does not allow us to categorically state the effect it has on the brain because a signal under possible electromagnetic pollution leads to doubtful interpretations. To sort out that problem a new biomedical engineered prototype must be designed. That prototype will allow for evaluation of the electrical response of the brain, as a response to an electromagnetic stimulus, under the best conditions, free of pollution and interference.

We have studied and evaluated the physiological low field TMS (Transcranial Magnetic Stimulation) at pT (picotesla) with a new stimulation system whereas other authors used a high field TMS (Pascual-Leone *et al.*, 1998, Iramina, *et al.*, 2002). This technique also applies to the treatment of neurodegenerative diseases, (Parkinson's disease, Alzheimer's, multiple sclerosis), psychiatric, etc. (Bardasano *et al.*, 1997a, b, Ramírez *et al.*, 1997, Wassermann and Lisanby, 2001, Bardasano *et al.*, 2005a, b, Bardasano *et al.*, 2006).

Material and Methods

• Subjects

The sample is made up of sixteen healthy voluntary subjects, (an average of 35 years of age; 8 male and 8 female), properly and ethically informed, and the readings are registered inside a Faraday chamber (For details, see Bardasano *et al.*, 2005c).

• Electroencephalograph and recording

We have employed digital EEG, mod. SAM 32 FOFC 1, with System PLUS Software by Micromed, latest version, and spectral analysis by FFT (Fast Fourier Transform). An elastic recording cap, glued to the scalp on both sides, holds twenty Ag /Ag Cl electrodes (SIEMENS) which are placed on both sides of the cap. The 10/20 IS (International System) of electrode placement is used and the actual placement has a common reference electrode placed at the frontotemporal intersection point and is grounded to the ear lobules. EEG signals are collected from 18 channels, filtered through a 0.5 Hz –70.0 Hz band filter and sampled at 128 Hz.

• Stimulator

Stimulating and recording can be carried out without interference using a TMS prototype mod. MG28TR10 at 10 pT and 8 Hz, which has a timer for the EEG recorder to control stimulation periods and pauses (1.5 min followed by a 1 min pause). Twenty magnetic stimulation coils are placed on the EEG recording elastic cap at a distance of 2 cm between them and the recording electrodes (Bardasano *et al.*, 2006) (Fig.1).

Fig. 1. TMS stimulator, mod. MG28TR10 (left). Subject sitting inside the Faraday chamber. Recording cap and amplifier are also shown here, (right).

Fig 2. Beginning of the stimulation process. We can see a lower channel designed to observe the morphology and frequency of the stimulus. The stimulus-pause sequence allows for both the ulterior elimination of traces of stimulus and analysis of the pause tracks as though it had been done with a non-stop recording.

• Procedure

The subjects are comfortably seated (Fig 1) with their eyes open and without outside stimulation. A basal EEG is first done for 5 min and then a long 10 min sequence stimulation (Fig 2). The subjects are single blind, as they do not know when they are being stimulated.

• Statistical analysis

The data have been computed, analysed and interpreted by means of the statistical set SAS System Release 8.02 by SAS Institute Inc. Cary, N.C., USA.

In the frequency tables, (in ASCII format for the 19 electrodes applied), the comparison between groups was evaluated by differential pairing and contrast with the paired T-Student. The p-values are given for up to 4 decimal figures.

• Results

An important increase in the alpha and beta rhythms has been observed as well as a decrease in delta and theta. alpha and delta record the highest increase and decrease, respectively, (a 17.5% increase in alpha rhythm and a 4.5 % in beta rhythms, repeatedly, at the expense of a decrease in delta and theta (see Fig 3 and Appendix, Fig. 4).

The most significant increase in alpha rhythm, at the same time as the stimulation was being carried out, was registered at the Fp1, Fp2, F3 and F4 frontal electrodes and at the central Cz.

This leads us to believe that there is a displacement towards anterior brain areas of the physiological alpha rhythm, under stimulation.

Below, find bar graphs of mentioned electrodes where the basal state is the first bar, the second bar stands for stimulation and the third for the difference.

As soon as the recording was over, each subject was asked how he felt as a whole; 84% mentioned they experienced a pleasing and soothing sensation; the remaining did not mention any particular feeling, (indifference) and 3 cases felt their hands going numb.

Fig 3. Comparison of frequency-percentage histogram. Redistribution of brain rhythms (alpha, beta, delta and theta), mean value of all the electrodes.

• Discussion

The systems usually employed for TMS have high intensity field-generating coils with a current peak of between 2 kA and 8 kA. This way, the different resulting potential, which is needed to induce functional stimulation or inhibition in the cortical area, can be achieved and it can be done with a 600 ms single-pulse field or with a 200 ms – 300 ms double-pulse field. These field intensities induce currents a lot higher than needed to obtain a selective effect. Furthermore, they expand over too large areas of the cortex to stimulate a target area round a few square millimetres. There is no reliable evidence found as yet to prove that the way to standardise the useful stimulation intensity may be based on the evoked muscular potentials obtained after stimulation. However, the fact that low intensity does not yield evoked muscular potentials does not imply there is not any effect. There are other effects, yet subclinical, that can be more relevant than the evoked motor responses.

Therefore, localization and selective stimulation objectives are not guaranteed with the high-power field systems which, additionally, provide undesirable thermal effects, preventing stimulation for long periods of time. The stimulated cerebral areas selected as objectives are not the only ones receiving this induced current. Besides the target area, there are stimulations in subcortical areas where their effect is yet unknown, or where undesirable effects are found, with hard to control collateral consequences.

Conversely, the intensity that flows through our coils is in μA , which allows for stimulations for as long a duration as desired without adverse effects on the patient. We should bear in mind that the intensity of the current is so high as it flows through the high-power field coils that there is a noise to be taken into consideration as we interpret the results (Nikouline *et al.*, 1999). However, our subject can not hear a thing and, therefore, does not know whether the current is flowing; it is a single blind experiment.

High-power field stimulation is not physiological which is conceptually different from low-power field stimulation. The latter tries to simulate neuronal biophysics in that it works within the same ranks of frequency

and intensity, whereas a high-power field is quite a few ranks more intense than natural bioelectromagnetism and works with antiphysiological frequencies (Gutiérrez, 2004).

After a decade of experimentation, high-power field transcranial magnetic stimulation has not yet come up with a treatment for relief from any illnesses (Wassermann and Lisanby, 2001). However, studies on low-power field research have been fewer, isolated, inhomogenous, and contradictory. If we only focus on the physiological transcranial stimulation (at pT rank), the Sandyk, Anninos's team stands out alone in the world in the field of therapeutics as they aim to simulate the physiological cerebral magnetic field during stimulation (Sandyk *et al.*, 1993, Anninos *et al.*, 2003).

We must remark that all the studies we have analysed use the same methodology; firstly, they carry out a basal registry, then they stimulate a given field and, finally, they record EEG post-stimulation; the results are then compared and the "before-after" differences are observed. We, on the other hand, apply the stimulation and pause it serially. This allows us to see what goes on at consecutive moments, immediately after the moment of stimulation. This way, we do not need to observe a given effect much later. Furthermore, we use direct application coils on the skull, which generate small fields round it and does not require surrounding the subject with a large field.

By using pT magnetic field, the rank of physiological stimulation is never reached as opposed to those other studies which usually work at the μ T rank.

Summary

We aim to obtain a model or pattern among normal subjects. We have used a new technique, the physiological TMS, (validation pending), which is a therapeutic method and a digital EEG, a diagnostic method. Thus, we are subsuming two methods. This new technique allows us to obtain an electroencephalographic response and also to measure changes in the rhythms of a healthy subject's brain, (pattern for normality). Physiological TMS at 10 pT and 8 Hz, simulating the alpha rhythm, were employed. The subject does not know when stimulation is taking place, so this study is single blind.

This way, we obtain a mimetic global bioelectrical neuronal response, as the alpha rhythm magnetic field is stimulated and the brain is timed to it. An alpha rhythm displacement towards frontal and central areas of the brain was also observed.

ABSTRACT

Background: Numerous studies have demonstrated the utility of extremely low frequencies (ELF) electromagnetic fields in the treatment of pain. Moreover, the effects of these fields seems to depend on their respective codes (frequency, intensity, waveform).

Purpose of the study: In our study we want to value the effects of the TAMMEF (Therapeutic Application of a Musically Modulated Electromagnetic Field) system, which field is piloted by a musical signal and its parameters (frequency, intensity, waveform) are modified in time, randomly varying within the respective ranges, so that all possible codes can occur during a single application.

Ninety subjects, affected by chronic low back pain, were enrolled in the study and randomly divided into three groups of 30 patients each: A exposed to TAMMEF, B exposed to ELF, C exposed to a simulated field. All subjects underwent a cycle of 15 daily sessions of 30 minutes each and a clinical examination upon enrolment, after 7 days of therapy, at the end of the cycle and at a follow-up 30 days later.

Results: All the patients of groups A and B completed the therapy without the appearance of side effects: they presented a significant improvement of the subjective pain and the functional limitation, which remained stable at the follow-up examination. In group C, there was no improvement of the pain symptoms or articular functionality.

Conclusions: This study suggests that the TAMMEF system is efficacious in the control of pain symptoms and in the reduction of functional limitation in patients with chronic low back pain. Moreover, the effects of the TAMMEF system cover those produced by the ELF field.

Key words: electromagnetic fields, therapy, low back pain, TAMMEF.

INTRODUCTION

The effects of the various types of low frequency electromagnetic fields used in clinical practice depend on their codes (frequency, intensity, waveform, the number of impulses per train and the interval between one train and another). The electromotor forces induced at a given point of a biological system act on the electric charges present which respond, causing functional modifications in the cellular microenvironment (1-3).

The overall biophysical effect can be appreciated only by observation, since the level of complexity of the system does not allow one to predict what mechanisms of action will predominate. However, it is possible to

compare the effects of a certain field with those of an all-inclusive reference field whose parameters continually change in time so that all possible codes can occur in a single application.

Our group has already shown the efficacy and tolerability of the extremely low frequency (ELF) field in patients affected by osteoporosis (4), rheumatoid arthritis (5) and osteoarthritis (6,7). Recently to evaluate the utility of applying the widest possible magnetic field, we introduced the new TAMMEF (Therapeutic Application of a Musically Modulated Electromagnetic Field) system. The field is obtained from recorded musical passages; thus its parameters (frequency, intensity, waveform) are modified in time, randomly varying within the respective ranges, so that all possible codes can occur during a single application (6,7).

The aim of this study is to evaluate the efficacy of the TAMMEF system in the treatment of chronic low back pain. In particular, we wished to ascertain if the effects of the field piloted by a musical signal are comparable with those of field with frequency of 100 Hz and a sinusoidal waveform. Both fields are generated by an opposing pair of heteronomous polar expansions and thus present the characteristic spatial conformation.

METHODS AND PATIENTS

Methods

The instruments used to generate the ELF and TAMMEF fields are similar.

An audiotape player sends the relative monochannel-microphone signal to two low frequency amplifiers A and B, both with adjustable gain. The current from amplifier A, modulated according to the recorded signal, feeds two electromagnets with iron-silicon cores joined posteriorly by a ferromagnetic arc. The anatomical region to be treated is placed between the opposing faces (3x4 cm) of the polar expansions. The current from amplifier B feeds a loudspeaker that plays the pilot musical passage. The music can also be heard through headphones, with automatic exclusion of the loudspeaker. The gain of amplifier A is regulated so that when the audiotape contains a sinusoidal signal with frequency of 100 Hz, the electromagnetic field is equal to the ELF field used (about 3 gauss midway between the poles when this distance is 30 cm). This set-up is then left unchanged whatever the contents of the audiotape used subsequently. The patient is allowed to regulate the gain of amplifier B, with the volume preferred, whether the music is being transmitted over a loudspeaker or into a headset.

Patients

Ninety subjects (63 females and 27 males), between 59 and 76 years old, affected by chronic low back pain, were enrolled in the study (table 1a) and randomly divided into three groups: A = 30 patients subjected to TAMMEF, B = 30 patients subjected to ELF and C = 30 patients subjected to a simulated field. Group C was introduced because of the possibility that the TAMMEF effects would be indistinguishable from those of the ELF, and thus to test for the presence of a substantial placebo effect. All the patients including in group C listened to the music. Evaluation of the stage of the disease was based on the radiographic system of Kellegren and Lawrence (8). The clinical examination was based on the Million Instrument test (9), a validated questionnaire specific for back pain. On the basis of the point of the score of the test, the patients were divided into three subgroups, as shown in Table 1b.

All the subjects were out-patients and, correctly informed of the experimental plan, gave their written consent. All the patients underwent a cycle of 15 daily sessions of 30 minutes each, with application of the magnets in contact with the lumbar spine. In the past, all the patients had been treated occasionally or cyclically with analgesic (paracetamol) or non-steroidal anti-inflammatory drugs (diclofenac, or piroxicam, or celecoxib, or rofecoxib), but they had suspended any drug at least 15 days before the beginning of the cycle. The clinical examination was performed when the patients were enrolled in the study, after 7 days of therapy, at the end of the cycle and at a follow-up, 30 days later (10).

The evaluation of the possible therapeutic effects has been effectuated using the Million Instrument test as modified by the authors: we have divided the evaluation of pain from the evaluation of articular function because of the well-known subjectivity of pain to the placebo effect (11).

Statistical analysis

The differences between the means of the various parameters at 0, 15 and 45 days were tested by Student's t test or Mann-Whitney-U test as appropriate.

RESULTS

Above all, we specified that no significant differences were found between the three groups of patients, concerning private data and their degree of disease. All the patients of group A and B completed the therapeutic cycle, without side-effects that might have required suspension of the treatment. With regard to the efficacy of the therapy, it should be underlined that none of these patients had to take analgesic-

antiinflammatory drugs during the cycle and that all the patients presented a significant improvement of both subjective pain and regional functional limitation. In particular, in the TAMMEF group, the subjective pain progressively decreased in all subjects even after the first week and regressed completely at the end of treatment in 24 (80%) of the 30 patients. In the remaining 6 patients (20%), the pain symptoms, albeit not totally regressed, decreased significantly with respect to the basal values and to those recorded after the first week (Figure 1a). In the ELF group, the time course of subjective pain was equivalent to that of the TAMMEF group, with complete regression in 23 patients (76.6%) and a significant reduction in the remaining 7 patients (23.4%) (Figure 1b). With regard to the evaluation of articular functionality, there was a significant partial recovery of mobility in all patients, starting from the first week (thus concomitant with the improvement of subjective pain). At the end of the cycle, in the TAMMEF group, 21 patients (70%) manifested a total recovery of the partially compromised articular functionality, while 9 patients (30%) showed a significant further improvement with respect to the already positive trend recorded after the first week of therapy, although they did not achieve a total functional recovery (Figure 2a). In the ELF group, there was a total functional recovery in 19 patients (63.3%), while in 11 patients (36.7%) the change was similar to that of the TAMMEF group (Figure 2b). The clinical follow-up, one month after the end of the cycle, revealed that in 28 group A patients (93.3%), there was no appreciable variation in the regression or improvement of pain symptoms from what was recorded at the end of the magnetotherapy; in the other 2 subjects (6.7%), there was a clear relapse of pain. However, this was not accompanied by a concomitant worsening of articular functionality, which continued to show the same recovery as recorded at the end of the therapy one month previously. There was a very similar pattern in group B: in 27 patients (90%), there was no change from the situation at the end of therapy, whereas 3 subjects (10%) reported a relapse of the pain symptoms. The time course of the articular pathology was clearly different in the 30 subjects of group C. Only 3 of them (10%) presented a slight subjective improvement of the symptoms in the first 5 days of the cycle, while the other 27 patients (90%) reported no significant pain reduction. After the first week, application of the simulated magnetic field had to be suspended in 12 group C patients (40%) because of its ineffectiveness, while the remaining 18 patients (60%) completed the cycle. At the end of treatment and at the clinical follow-up one month later, all the patients who completed the cycle reported no improvement of pain symptoms or articular functionality; indeed, there was a slight worsening of pain (Figures 1c-2c).

DISCUSSION

All the patients treated with TAMMEF or ELF completed the therapeutic cycle and manifested a significant improvement of the clinical picture. The two electromagnetic fields had equivalent effects and produced a so-called "tail effect", continuing after the suspension of therapy, as if the biophysical action interfered with the pathogenetic mechanisms of the disease, probably by inhibition of the inflammatory process (4,5). The lack of efficacy in the group C patients confirms the therapeutic effects of the two fields. Indeed, considering the known relationship between the pain pathways and the psychic habitus of the patient (12-14), only the slight improvement of pain symptoms initially shown by the group C subjects could be attributed to the placebo effect. It should be mentioned that all the patients subjected to TAMMEF applications stated that they enjoyed listening to the music and they manifested a psychological attitude of trust and satisfaction. It also seems that these patients showed more evident and quicker responses, although this was not statistically significant and is reported only as an impression and a possible topic for future research. Our results confirm the efficacy and tolerability of low frequency magnetic fields as previously reported (4-7,10,15), also support the hypothesis that the effects of magnetic fields with parameters that change in time, like those produced by the music-piloted TAMMEF system, are equivalent to the effects of the ELF field (6,7). Moreover, in relation to current studies on interactions between the nervous, endocrine and immune systems (16,17), it may be possible to combine the electromagnetic stimulus with the corresponding acoustic stimulus, i.e. listening to the pilot musical passage. In fact, the two mechanisms, triggered in different sites and acting by different but simultaneous and coherent channels, might produce responses that reinforce one another (18).

Abstract

A great experience of investigation of the EMF influence on the personal computers users' health has been accumulated. Carried out long-term observations of the health condition of the VDT users have shown that stress of their main life support systems: central nervous, cardiovascular, immune has been observed. Clinical-laboratory data have been obtained by the results of the profound medical examination of 1052 investigated users; from them 467 men and 585 women. The total number of factors, which have been put into database, is about 150000. Statistical processing of multivariate data was used for revealing early signs of negative influence of the factors of professional activity amongst VDT users. It is shown that reduction of the adaptation capacities of an organism is noted already in the first years of work at VDT. It causes breaches of the adaptation processes: decline of the functional activity of the antioxidant systems and activation of the processes free radicals oxidations, oppression of the immunological reactivity. Modification of the immunological and biochemical indices were considered and analysed with regard of the professional seniority and age. Such approach has allowed revealing the symptoms of fore-pathology of some part of working with VDT and referring them to the defined group of risk.

MODELING AND GIS SOFTWARE APPLICATIONS FOR EMF ENVIRONMENTAL MONITORING IN SICILY

S. CALDARA, P. COSTANZA, G. LISCIANDRELLO

**REGIONAL AGENCY FOR ENVIRONMENTAL PROTECTION OF SICILY
(ARPA SICILIA)**

Via U. La Malfa, 169 90146 Palermo Italy

scaldara@arpa.sicilia.it, piero.costanza@gmail.it, glisciandrello@arpa.sicilia.it

Abstract

Regional Agency for Environmental Protection has been operating for 5 years in Sicily to ensure environment and consequently public health protection from EMF exposure.

This paper deals with EMF monitoring in all county territory.

In order to increase the knowledge of sources and their impact on environment, a register of telecommunication devices has been implemented; technical items have been used as inputs for modeling tools and simulation outcomes are compared with measurement results.

All these data are collected in GIS software.

In particular mobile phone networks and broadcasting systems have been studied. A complex site for TV and Radio broadcasting is reported as an example.

Moreover some comparison between two different simulation software has been developed.

GIS register show that whole Sicilian territory is covered by mobile phone base stations with high concentration in big cities (Palermo and Catania). Simulations have been used to determine measurements and monitoring policy according to particular needs related to special places like schools, hospital, etc.

Introduction

The development of new telecommunication systems, as mobile phone base stations and broadcasting antennas, as well as electric power plants and power delivery lines, even if has contributed to improve life quality, is also responsible of the increasing human exposure to electromagnetic fields (EMF) from manmade sources which are to be added to natural electromagnetic irradiation.

Italian national law n. 36 of 2001, separately regulates both extremely low-frequency (ELF) and radio-frequency (RF) electromagnetics fields and makes a difference between acute (thermal) and chronic (non thermal) adverse health consequences.

Acute exposures are associated with thermal hazards and are characterized by threshold exposures below which no health effects occur.

In case of long term exposure to low (non thermal) levels of EMF there are no threshold exposures significant for human health. In this case health risk is thought to be of probabilistic nature: if the time exposure increases not the magnitude of adverse health consequence but the probability to have consequences increases.

According to the A.L.A.R.A. caution principle of keeping the exposure to lower possible level, “attention values” and “quality aims” have been fixed; they are not safety threshold exposures but an operational reference for prevention and public health protection.

In particular, the Italian “DPCM July 8th 2003” law arranges “threshold exposures” (Tab. 1) and “attention values” (Tab. 2) to prevent short term and possible long term health effects due to exposure to EMF generated by RF fixed source in the range 100 kHz up to 300 GHz; it also arranges “quality aims” to minimize, in a progressive way, people exposure to EMF and measurement standards.

The Regional Agency for Environmental Protection of Sicily has been operating for 5 years in Sicily to ensure environment and consequently public health protection from EMF exposure.

The Agency has an important role of technical support to local councils by giving preventive opinions about the installation of new TLC systems based on existing systems emission evaluation compared with threshold exposures and attention values.

Table 1 – Threshold exposures (DPCM July 8th 2003)

Frequency range (MHz)	RMS e. f. E (V/m)	RMS m. f. H (A/m)	Power density S (W/m ²)
0,1 - 3	60	0,20	-
>3 – 3.000	20	0,05	1
>3.000 – 300.000	40	0,10	4

Table 2 – Attention values (DPCM July 8th 2003)

Frequency range (MHz)	RMS e. f. E (V/m)	RMS m. f. H (A/m)	Power density S (W/m ²)
0,1 – 300.000	6	0,016	0,10

Register of TLC fixed EMF sources**Mobile phone base stations**

In order to carry out the register of TLC fixed EMF sources, which complies with the Italian law n. 36/2001, the Regional Agency for Environmental Protection of Sicily, in February 2003, has stipulated an agreement with the TLC Companies which periodically transfer data about their system.

All mobile phone base stations of the regional area have been then geo-mapped (Fig. 1 and 2). In particular, each point of the chart represents a site with several antennas of base stations. Of each site Gauss-Boaga co-ordinate, number and model of the antennas, the power (W), the gain (dB), the frequency and the eight of the electrical center are known.

As we can see from figures 1 and 2 and from table 3 the overall regional area is covered by mobile phone base stations. The highest concentrations are specially in big cities (Palermo and Catania) and near the coastline. Table 4 highlights the lower specific power of 3G (UMTS) systems compared with GSM technology based ones.

Table 3 – Base stations distribution

<i>Town</i>	n. of sites	n. of antennas	Total power (W)
Palermo	442	1960	46189
Catania	239	1044	22691
Messina	179	650	13696
Trapani	66	264	7735

Enna	12	36	835

Table 4 – Base stations characteristics

<i>Frequency</i>	n. of antennas	Power (W)	Specific power (W)
GSM - 900	4110	134925	32,82
GSM - 1800	2233	52482	23,50
UMTS	2878	55712	19,35

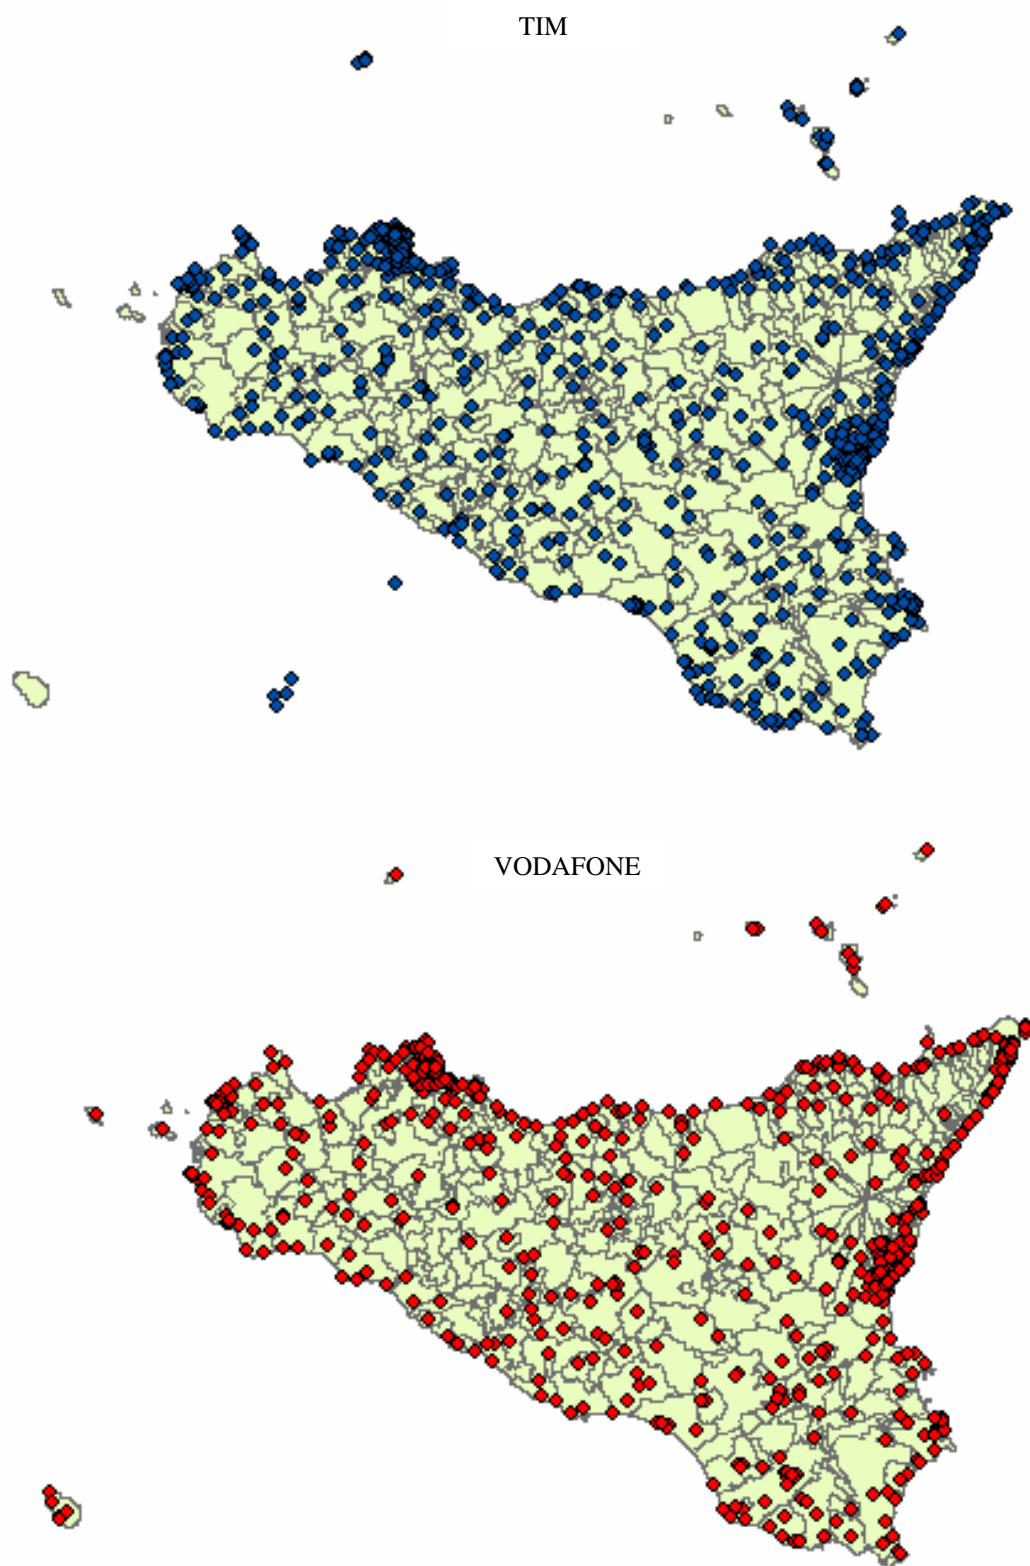

Figure 1 – GIS representation of mobile phone base stations distinguished per company

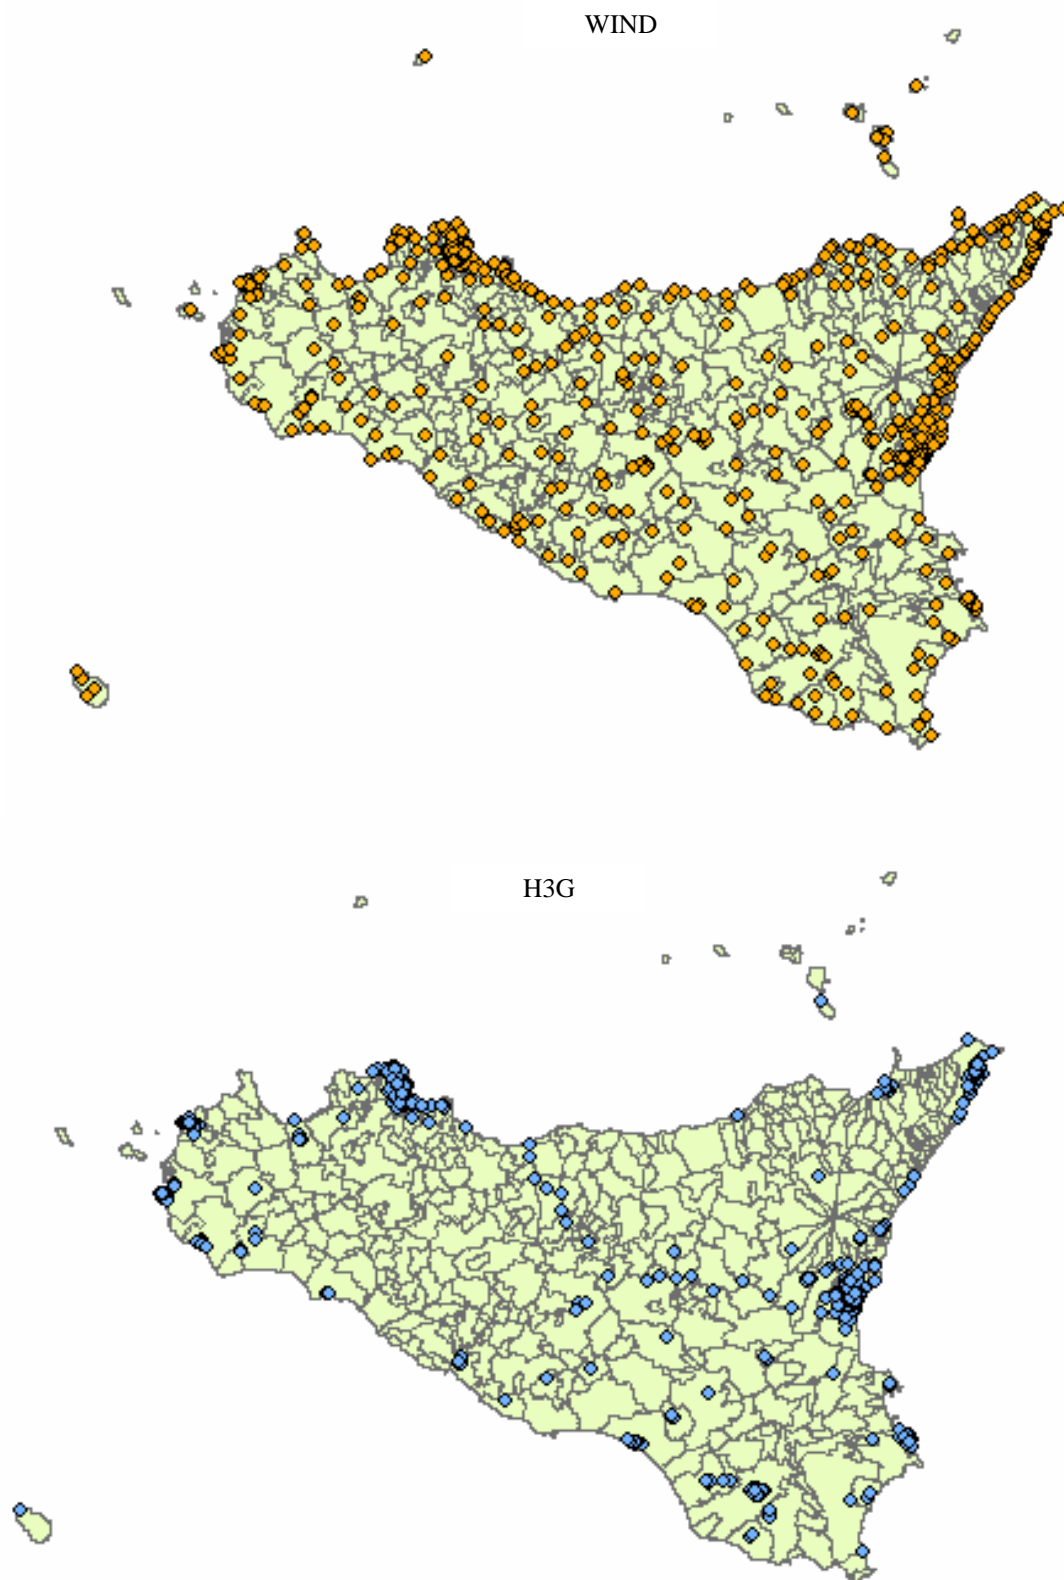

Figure 2 – GIS representation of mobile phone base stations distinguished per company

TV and Radio broadcasting

Data concerning Radio and TV supplied by the Telcommunication Regional Department were not complete so that all Radio and TV company in the regional area were directly asked to transfer information about broadcasting systems.

Such action brought to identify eleven crowded multiple antenna sites in the regional area (Fig. 3)

Figure 3 – RTV crowded multiple antenna sites

In particular, the features of broadcasting multiple antenna site of Caltanissetta are listed below:

Mount S. Anna

- Total power 20950 W
- Intersted Area 1,8 km²
- Specific power 11 mW/m²
- N. of antennas 9 RTV antennas (one of which with a power of 20000W)

Mount S. Giuliano

- Total power 6160 W
- Intersted Area 1,25 km²
- Specific power 5 mW/m²
- N. of antennas 19 RTV antennas (one of which with a power of 2000W)

Modeling and GIS software

The Geographical Information System (GIS) is based on a relational database containing all technical information of EMF sources, a cartography managing software and a model based software which, starting from geo-mapped and technical information, is able to simulate the EMF distribution in a given area.

The GIS returns the following informations:

1. number and positioning of geo-mapped sistems (Fig 1 e 2)
2. technical data-sheets
3. photographic documentation (Fig. 4)
4. EMF simulation based on “Radmap 8.0” 2D modelling software (Fig. 5).
5. EMF simulation based on “VICREM” 2D and 3D modelling software (Fig. 6).

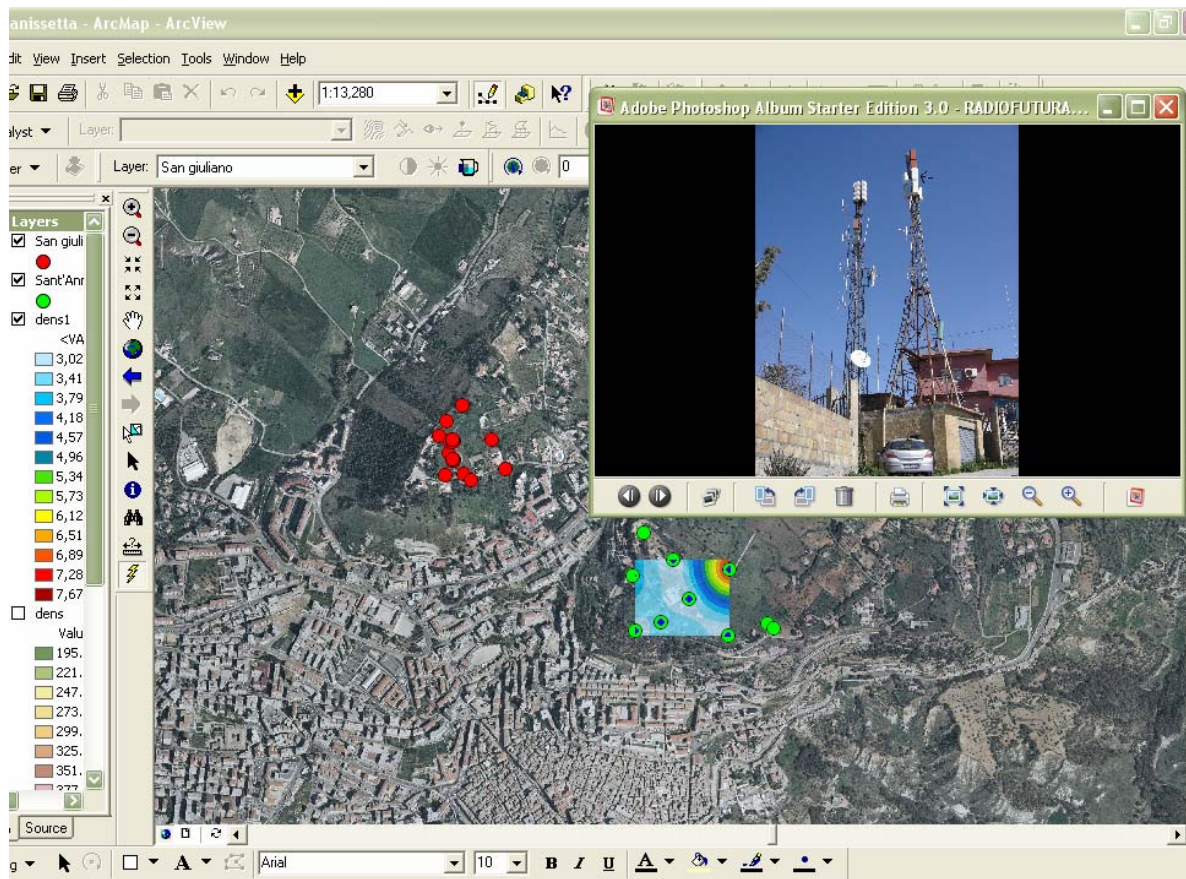

Figure 4 – Example of GIS informations (Caltanissetta)

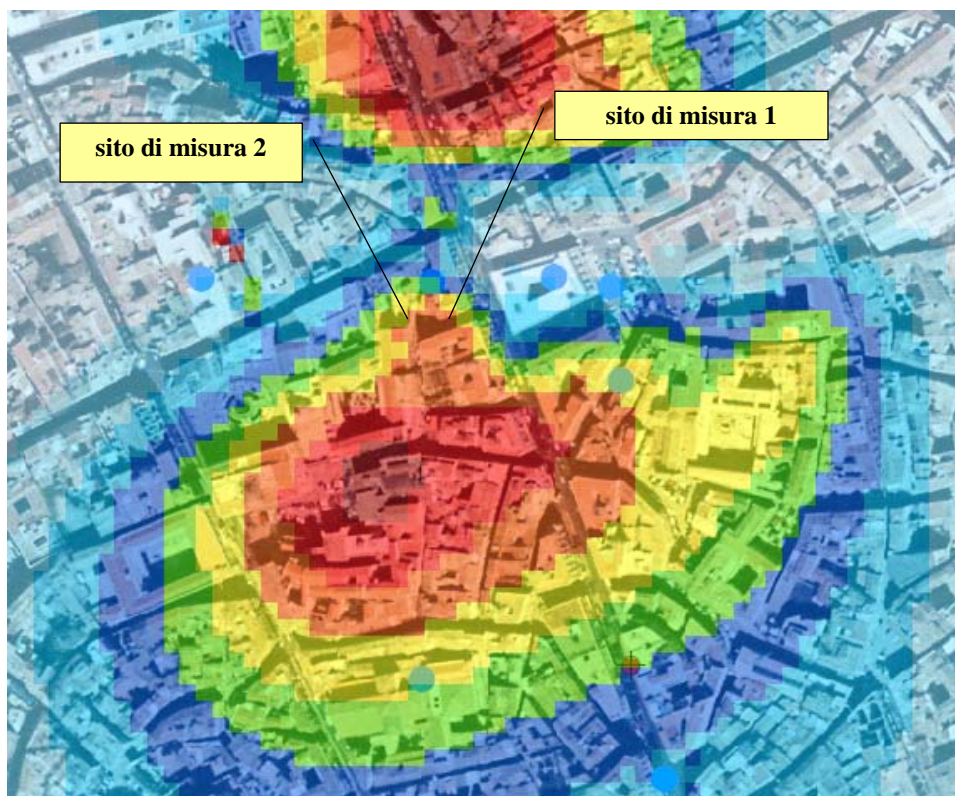

Figure 5 – Example of Radmap 2D simulation in Palermo

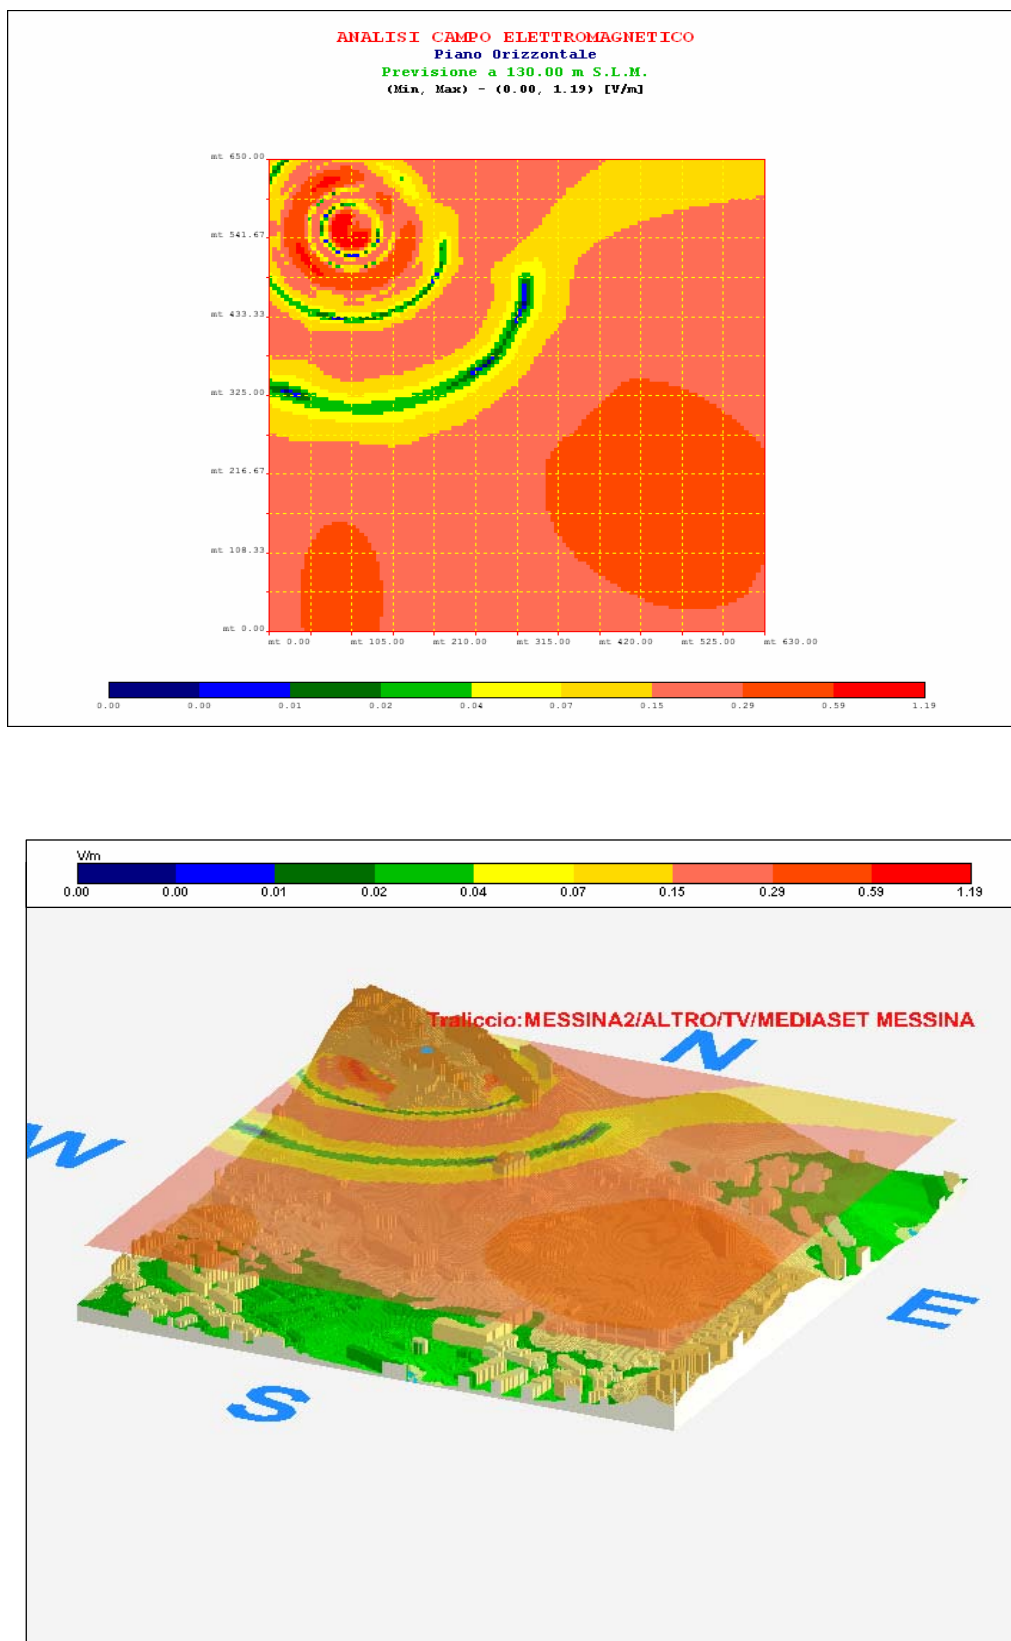

Figure 6 – Example of VICREM 2D and 3D simulation in Messina

Monitoring network

Continuous EMF monitoring is thought to be a suitable answer to the strong citizens' expectations of environmental controls which could give warranty threshold exposures respect 24 hours a day.

This measurement method is particularly significant because it takes into account the time history of the EMF level.

The ARPA Sicilia EMF monitoring network is based on 182 mobile monitoring devices, 102 of which have been supplied by the Ugo Bordoni Foundation for a national monitoring project.

The selection of monitoring sites has been based upon the following criterions:

- Analysis of already known sources generating EMF levels higher than threshold exposures;
- Analysis of particular sites in order to deal with the public concerns about potential health effects (schools, hospitals, etc.);
- Specific claims by local councils or citizens.

In Tab. 5 RF EMF (100 kHz – 3 GHz) monitoring results in Sicily in 2004 and 2005 are reported.

Table 5 – Continuous EMF monitoring results (2004-2005)

Monitoring results can be collected in the GIS. In Fig. 8 the GIS representation of monitoring activity in the city of Palermo is shown.

Monitoring results have been compared with the simulation software outcomes in order to setup the models and, at the same time, to check measurement procedures. The correlation between measurement results and simulations is good (Fig. 7 and Tab. 6) although simulations are lower than measurements.

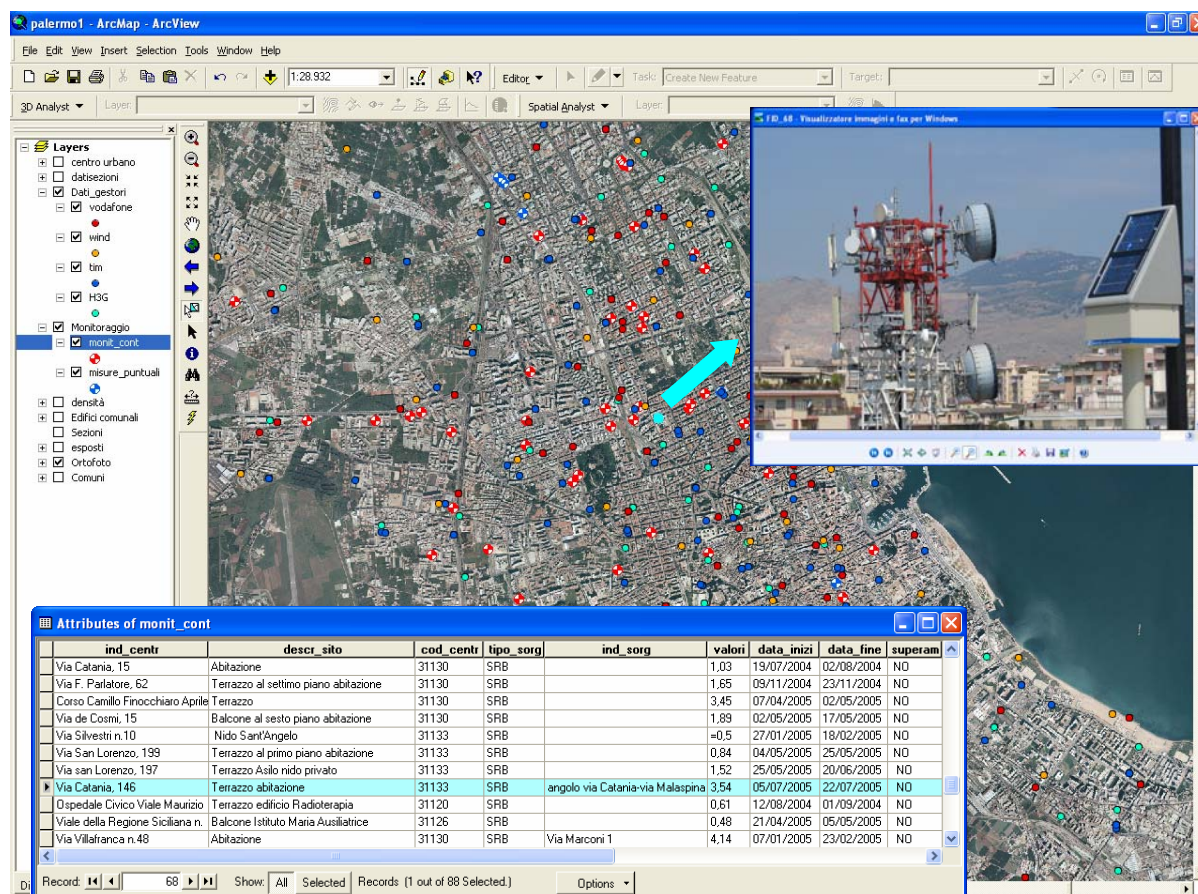

Figure 8 – EMF Monitoring metadata in Palermo

Summary

In this paper ARPA Sicilia register of TLC fixed EMF sources is presented. The Geographical Information System (GIS) which all these data are collected in is presented as well. In particular mobile phone networks and broadcasting systems have been studied and a complex site for TV and Radio broadcasting is reported as an example.

Register data contain the technical items which have been used as inputs for modeling tools; simulation outcomes have been compared with measurement results showing a high correlation.

GIS register shows that whole Sicilian territory is covered by mobile phone base stations with high concentration in big cities (Palermo and Catania).

Moreover the results of RF EMF continuous monitoring in Sicily and, in particular, graphical GIS data of Palermo have been reported.

Acknowledgments

The authors want to acknowledge the support from the “Ugo Bordoni Foundation” for the continuous monitoring devices availability.

Abstract

Regional Agency for Environmental Protection has been operating for 5 years in Sicily to ensure environment and consequently public health protection from EMF exposure.

Another task of ARPA Sicilia is the correct EMF exposure risk communication to citizens.

ARPA Sicilia is already partner of a national monitoring program which gives information by web only for mobile phone b.s. generated emf.

This paper deals with the use of EMF modeling and GIS software results as possible tools for a clear risk communication.

In order to increase the knowledge of sources and their impact on environment, a register of telecommunication devices has been implemented; technical items have been used as inputs for modeling tools and simulation outcomes are compared with measurement results.

All these data are collected in GIS software and processed to generate charts which gives graphical information about base stations, TV and Radio broadcasting systems and power lines territorial distribution, simulations of EMF level, monitoring activity results and petitions. These charts, published in the Agency web site, can be a user-friendly instrument which allows people to get a correct perception of risk better than tables or numbers.

Introduction

In the societies with a high rate of industrialization Citizens' restlessness is increasing for the possible consequences of technological development. Such worries derive also from the changed image of science, than in general terms, it is not anylonger more perceived as caretaker of "sure knowledge", also because of the inability demonstrated by the scientific world in the last few decades to preview, to manage and to interpret some catastrophic events.

The risk is diffusely perceived and it invests multiple aspects of our life, the fear of unexpected events, of personal or collectives risks is so intense that it has made our society defined as "the society of risk". Particularly, regarding electromagnetic fields, the worries are magnified by the electromagnetic fields potential risks evaluation uncertainty.

The majority of the papers written on the topic have often been of dubious interpretation, moreover, some of them present methodological inaccuracies and it is quite difficult to make comparisons between different studies as the data seem to be strictly related to the various methodologies applied.

In ICNIRP's 1998 guidelines we read that: the results of epidemiological studies on exposure to electromagnetic fields and neoplastic pathologies do not allow the creation of a scientific base on which basing the guidelines for the exposure.

Even the definition of possible cancerogenous for the 50 - 60 Hz EMF, given from IARC, takes into consideration the fact that epidemiological tests so far carried out are limited and the tests on animals limited or inadequate. In this situation of uncertainty, mass media's tendency of emphasising such kind of news, surely contributes to instil worries to citizen up to the point of transforming such worries in a real society issue

In the past, these worries were looked at as irrational and due to people's inability to understand scientific data

that, through probability theory, demonstrated how the risk related to a given technology (for example in terms of human life losses) was insignificant.

They have been later on analyzed, in a comprehensive way, the complex interactions between the factors that contribute to create in the citizen the perception of the risk and the consequent behaviours.

In particular, fears and worries on the risk deriving electromagnetic fields are inexplicable if the risk is only defined through statistical calculation.

The results of such studies have highlighted some persisting aspects which contribute to expand risks' perception from electromagnetic fields. Such aspects can be summarized as follows:

- Lack of confidence, the risk is more feared as it is caused by an immaterial and imperceptible physical agent;
- Uncontrollability, the subject exposed to the risk by not being able to control exposure feels incapable of dealing with the risk;
- Uncertainty, there are no reliable evidences about consequences, the apprehension is augmented by the fact that the risk could actually be greater for children and that the possible effects could manifest themselves even after a long period;

The World Health Organisation launched in 1996 an international programme on electromagnetic fields, suggesting the evaluation of health and environment risks with the aim of defining research protocols to be carried out following standards compatible and comparable among them. This project will be ended by 2006.

In July 2003, when the first block of activities was over, ARPA Sicilia organised a conference on the topic which marked the beginning of a new path. All the stakeholders, which are involved, in the field, have been invited to participate from TLC companies to environmental association not forgetting the institutional stakeholders involved in the overall managing of the problem.

Such occasion has been useful in order to start a dialogue, an essential premise to establish a climate of mutual confidence needed to be able to manage the problem effectively.

Risk communication

ARPA Sicilia's plan for the communication of the risk due to electromagnetic fields exposure previews two articulations: on one hand, the essential "usual" communication, even if accompanied by the use of the Internet, on the other hand, the new approach of communicating the results of monitoring activities aimed at encouraging and promoting citizens' involvement.

Taking into account these premise, a study on health implications deriving from the exposure to the electromagnetic fields has been commissioned the Department of Biotechnologies of the Medicine Faculty of the University of Palermo. The results of this research are available on the Internet (www.arpa.sicilia.it).

Starting from a preliminary analysis of potential users' characteristics, the documents have been drawn up modelling the type of information to the different targets.

The preferred approach was based on divulgation, in fact, the adoption of a winning graphic and animated images, allowed not only to render basic concepts of physics easily comprehensible (an example could be the difference between an electric field, a magnetic field and electromagnetic field or between direct current and alternating current), but also epidemiology fundamental principles and base terminology.

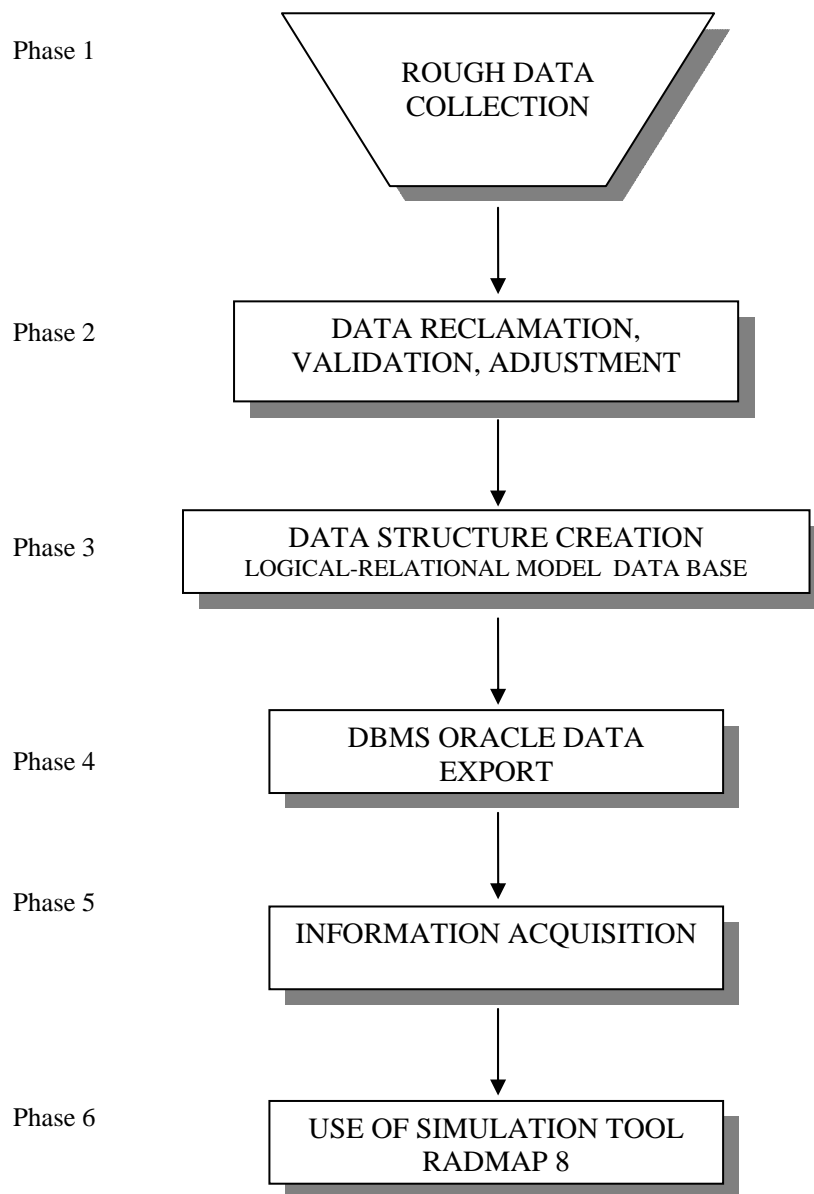

The opportunity of getting deeper on the subject has also been guaranteed (links to specialized sites and a list of downloadable epidemiological studies)

Beside the communication of "usual" type, the plan currently being developed aims at the diminution of "uncontrollability of the risk" feeling and at responding adequately to the citizen steadily increasing need of involvement through the adoption of GIS.

The GIS software

The system, in ArcMap environment, allows the geo-mapping of electromagnetic fields sources of all types, from radio frequency (RF) and low frequency (ELF) collecting all the data in a database containing all the physical parameter that allow, by using ad-hoc models of calculation, to make forecasts about the distribution of a electric or magnetic field in a given area. Such simulations can be carried out on horizontal and vertical plans and to be overlapped to the cartography (orthophotographs and/or technical charts) for a correct understanding of the results in their context. It is also possible to relate the distribution of field with the buildings's height in order to characterize possible critical situation.

In order to obtain a structured and versatile communication a multi-steps and multi-phases procedural approach needs to be followed. The different phases are summarized in the following diagram:

Phase 1

In this phase the elementary information is received in the form of a electronic sheet in a classic tabular structure.

Phase 2

The rough data (radioelectric parameters, geographic coordinates, etc) are carefully examined, corrected if imprecise or incongruous, and once validated, manipulated in order to take the most suitable format for the successive elaborations (e.g. a file text information containing the attenuations in dB of the diagram of radiation of a given antenna , needs to be converted in a numerical format, or still it is necessary to execute the conversion of co-ordinates for a corrected geo-mapping). This often is the most laborious phase due to the various kinds of adjustments needed.

Phase 3

In this phase the data are organized, subdivided and correlated among them in order to reflect the logical relational model of the date base (already pre-existing) on which the tool of simulation is based. Congruency controls are carried out and the original electronic sheet format is abandoned in favour of a most suitable one such as MsAccess.

Phase 4

At this point, usually by means of specific queries, data are exported into DBMS Oracle as implied by the simulation tool and essential for its correct functioning.

Phase 5

To complete the supply of input data and to improve the output data, it can be useful to collect additional information such as cartography, orthofotographies, raster images. Particular attention needs to be paid to cartographic data nearly always subordinate to procedures of adaptation (e.g poly-lines in polygons, creation of shapefiles, etc) and of conversion of coordinates.

Phase 6

The epilogue of this sequence of activities is the creation of a visual environment rich of details, able of producing visual and analytical reliable results for an immediate perception of the informative message derived from the analyses.

The informative system also allows to geo-map, by collecting the relevant information (meta data), not only the control activity carried out by ARPA's Provincial Laboratories but also the continuous monitoring activities and the state of claims and demands of the population resident on the territory.

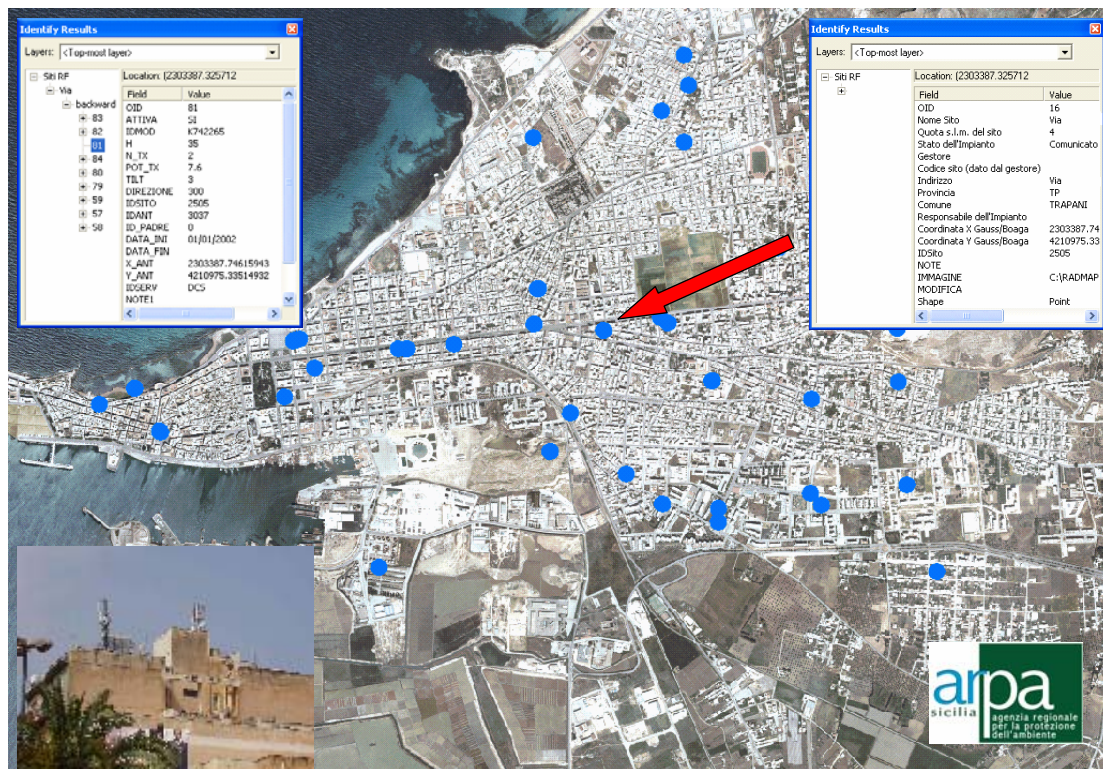

Fig. 1 GeoMapping of Mobile Phones Basic Radio Station in the City of Trapani

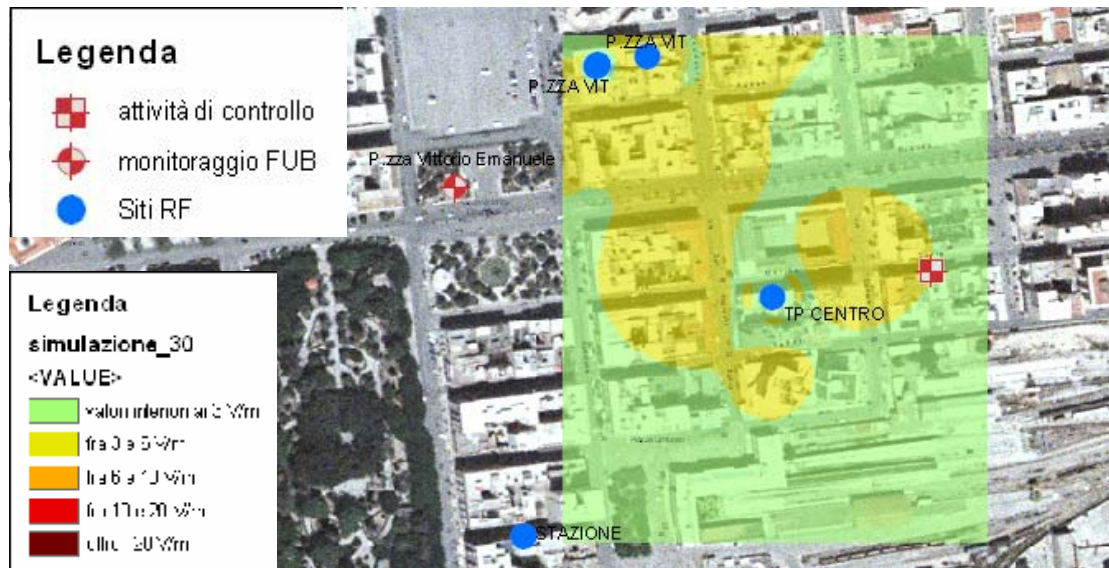

Fig. 2 Example of simulation of the distribution of electromagnetic field from RF source

Fig. 3 Example of simulation of the distribution of electromagnetic field from ELF source

In this way, the Agency monitoring activities will be available on the Internet.

The customer will be able to interact with the digital thematic chart obtained through the elaboration of the data already supplied by the companies; such elaborations, even with the approximations tied to the intrinsic simplifications of every model, will concur, intercrossed with the data of 'citizens' demands, to spot on the

territory the situations on which the worries of the population are mainly concentrated. Following the identification of such areas, it will be possible to define “the sensitive” areas from the point of view of the emotional impact on the population, even if in such zones an overcoming of the limits of exposure or the values of attention (as defined in Italian law) is not found or expectable.

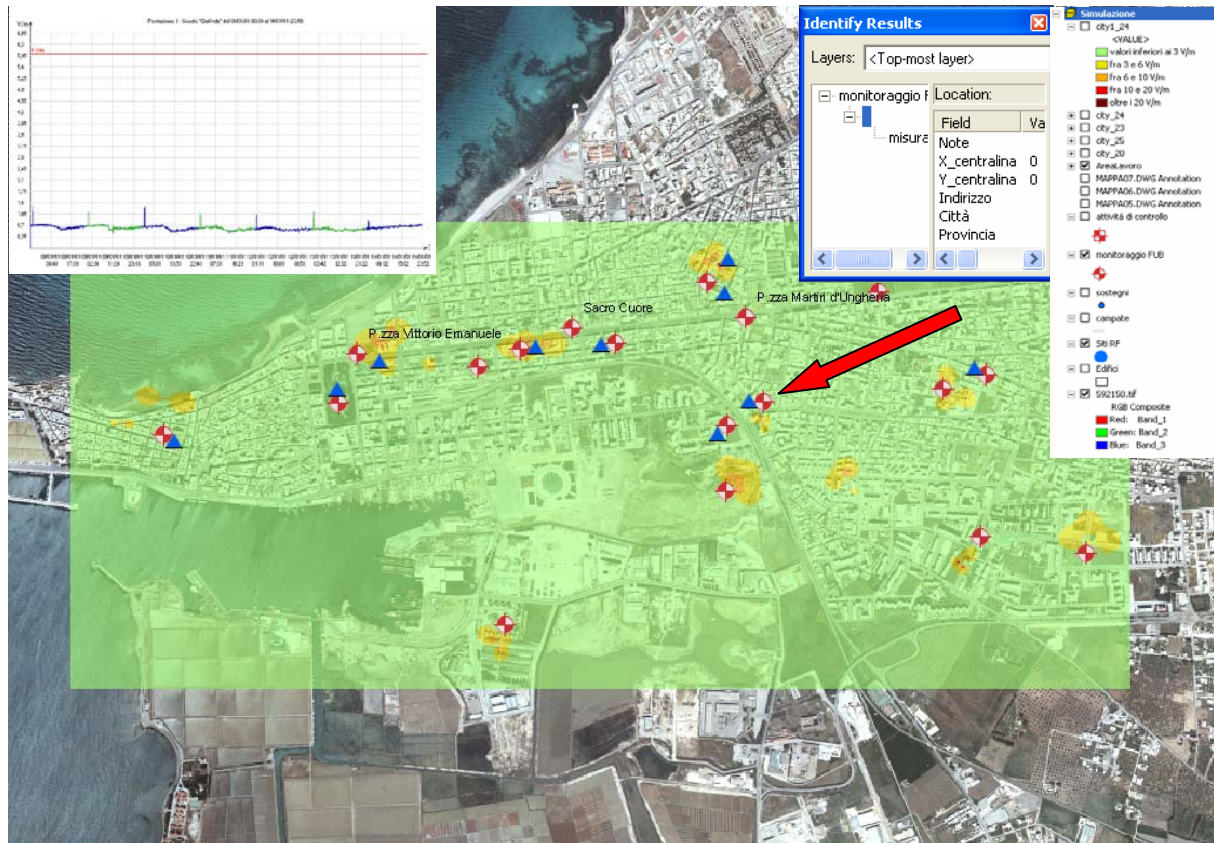

Fig. 3 Example of simulation chart, citizens' claims and demands theme and monitoring results.

The graphical representation, containing all the themes synthesizing all the informational elements used, will contribute to plan the monitoring activity let alone to communicate such programming by taking into account two elements: the quantitative data (the estimated value of the levels of electromagnetic field) and the population's perception level towards the problem manifested through claims, petitions, activity of civil society association etc.. In such identified areas, by applying a priority order determined through the analysis of the quantitative element (outcomes of measures or provisional calculations) monitoring devices will be put in place and the collected data will be made available directly to the customer on the net.

The addressee of the information, will be able to interact with the thematic charts, on which they will be highlighted: the forecasted distribution of the levels of electromagnetic field, the claims, the monitoring-devices position. Connected to the theme of monitoring-devices, measure outcomes and graphs on the monitoring activity will also be displayed.

Conclusions

With such procedure that does not have a conclusion, but it is under continuous update, it will be possible for the citizen to follow the monitoring in all its phases, from the planning to the communication of the validated data. It is believed that this way of transmitting the information, which supplies contextualized data on the territory which the customer can interact with, can be more effective as compared to a sterile communication of numbers or diagrams of difficult reading and comprehension and that it can contribute to clear the legitimate doubts of people and to supply to citizens the instruments needed to acquire an effective knowledge of the problem.

GENOMIC INSTABILITY IN BLOOD SAMPLES SUBMITTED TO CONTROLLED CELL PHONE RADIATION LEVELS

ABSTRACT

Genomic instability is characterized by genetic alterations such as chromosomal rearrangements, aneuploidy, micronuclei frequency increase, microsatellite instability, mutations, gene amplification, gene transcription changes, transformation and cell death in the first and following generations of cells after the first insult. We have investigated the effect of AMPS and CDMA radiation in cultured blood samples from 10 donors in 200 replicates after 72hs exposure in a specially designed exposition set up (TEM CELL) at SAR levels from 0,8 to 10W/kg. The genome was investigated for structural chromosomal abnormalities, micronuclei frequency and aneuploidy of chromosomes 8 and 17 through both conventional and molecular cytogenetics (FISH) techniques. Genomic changes such as chromosomal breaks, translocations, marker chromosomes and aneuploidy, when compared to the controls, were detected in SAR levels above 5W/kg as well as the increase of micronuclei frequency above 10W/kg. As genomic instability and chromosome damage are frequently related to tumorigenesis, our findings support the hypothesis of a positive effect of RF radiation on the genome of cultured blood cells and also give further evidence to suggest continuous cytogenetic investigation of occupationally exposed individuals to SAR levels above the accepted international limits.

INTRODUCTION

In vitro studies are important to delineate possible damage mechanisms caused by non-ionizing radiation or radiofrequency (RF) fields and its interaction with biological systems such as cells, tissues and organisms. The main advantage of these studies are the possibility to control almost all variables and test conditions to discard interferences and also to delineate investigation targets to be explored through *in vivo* and clinical-epidemiological studies.

Genomic instability (GI) has been identified mostly in tumor cells and is characterized by the accumulation of multiple changes that converts the genome of a normal cell into an instable genome [1]. This instability is characterized by genetic alterations such as chromosomal rearrangements, aneuploidy, micronuclei frequency increase, microsatellite instability, mutations, gene amplification, gene transcription changes, transformation and cell death in the first and following generations of cells after the first insult [2].

In vitro investigations in different cell systems have shown both a positive and negative association of cell damage leading to GI after RF exposure although most of them were attributed to thermal effects. These groups suggested that RF is not mutagenic by itself and that the adverse effects of such exposition would be due to hyperthermia caused by cell exposition in high frequencies or high intensity fields [3,4,5,6].

Genomic instability and cell phone radiation

By the other hand, aneuploidy of chromosome 17 was observed in a dose-dependent way along with alterations related to chromosome segregation suggesting that RF can interfere in the cell cycle and cause chromosome damage and genomic instability in temperature controlled exposition environments [7]. Other events were observed and associated with RF dose-dependent exposition such as transmembrane efflux of molecules, transcription errors, cell transformation, enzyme activity changes, fosforilation of hsp27 (heat shock protein 27) and increase of mRNA levels of the FOS gene [8,9,10,11,12].

Since there is a major concern regarding the association of RF exposition and tumorigenesis and as genomic instability is one of the first events for tumor onset we investigated the frequency of chromosome damage, micronuclei formation and aneuploidy in lymphocytes submitted to RF fields in a controlled and highly monitored exposition set-up.

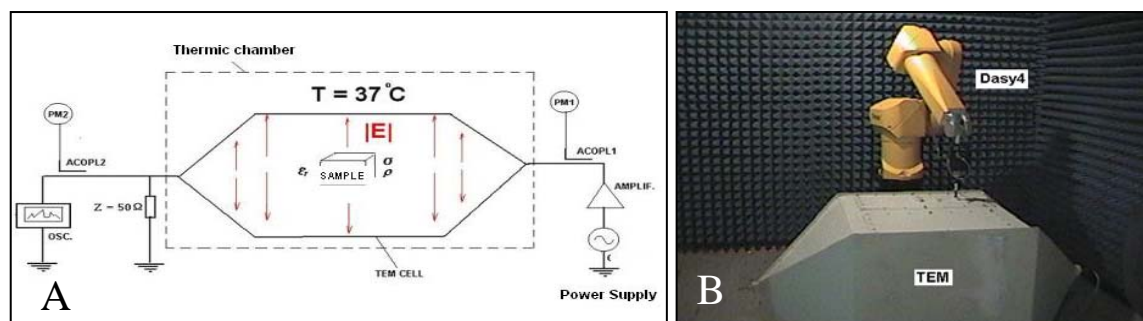

MATERIALS AND METHODS

The study population consisted of 10 healthy, non-smokers male and female subjects that were not X-rayed in the last 12 months. The study was approved by the University's and by the National Ethical Committee (CONEP). Participants were informed of the study aims and asked to sign consent. Venous blood samples were collected in coded heparinized tubes and divided to be used in different assay as both test, sham-exposed and control samples.

1. Cytogenetics: short-term lymphocytes cultures were established using 0,5 ml of blood added to HAM F-10 medium (NUTRICELL) supplemented with phytohaemagglutinin (INVITROGEN) and 10% of fetal bovine serum (NUTRICELL). Cells were harvested after 72 hours of stimulation and colcemid (INVITROGEN) was added 1 hour before harvesting. Cultures were submitted to hypotonic shock for 10 min with 0,075 M KCl at 37°C and then fixed in methanol-acetic acid (3:1) washes 3 times. For conventional cytogenetics analysis, after being air-dried and dropped onto glass slides in a humidified chamber, lymphocytes were stained with 5% Giemsa-Wright solution for 6 minutes. Structural aberrations such as chromatid and chromosome gaps and breaks, acentric and dicentric fragments, double minutes, satellite increase were evaluated. Each abnormality was scored as an event. Mean frequencies were obtained for each exposition type. For each donor, 200 cells were analyzed. For aneuploidy analysis, centromere probes for chromosomes 8 and 17 (QBIOTEST) were hybridized through mini-preps FISH assays according to the manufacturer's instructions. Mini-preps were obtained dropping 10 µl of cell suspension onto glass slides. For each probe, 200 cells were analyzed, per donor. Cells containing less and more than 2 hybridization signals were scored as aneuploidy. Mean frequencies were obtained for each exposition type.
2. Micronuclei: lymphocytes cultures were established as described previously for the cytogenetics assays but Cytochalasin B (SIGMA) was added after 44 h of stimulation. Cells were also submitted to hypotony but fixed only in methanol, 3 times. Cells were stained with 5% Giemsa-Wright solution for 6 minutes. For each donor, 1000 cells were analyzed and the mean frequencies for each exposition type were obtained. Micronuclei were evaluated only with SAR values of 0,8 and 10W/kg using AMPS technology.

The exposition set up was especially designed for this project. A transverse electromagnetic cell (TEM CELL) was used to irradiate the samples inside an incubator at 37°C (Figure 1A) for 72 hours that is the current standard time to obtain metaphases for cytogenetic analysis. Temperature was corrected by air insufflations, when necessary, especially in high SAR levels. All exposition parameters were controlled and the conditions to obtain the desired SAR levels were measured and established before the experiments through the robotic device DASY4 (Figure 1B). Cell cultures were submitted to 0,8; 2,0; 5,0 and 10,0 W/kg SAR levels in AMPS and CDMA technologies. Sham exposed (all transportation conditions and no exposition) and control samples (patient control, no transportation conditions, no exposition) were also analyzed.

Figure 1: Exposition set up. A. Diagram of the exposition system. B. DASY4 robotic device for set up characterization and calibration.

RESULTS

The results for chromosome abnormalities, aneuploidy of chromosomes 8 and 17 and micronuclei frequency are summarized in Table 1.

Table 1. Summarized results of the genomic imbalances

Type	SAR	Chromosome Ab.		Aneup 17		Aneup 8		Micronuclei Freq (%)	
		Mean	Range	Mean	Range	Mean	Range	Mean	Range
CDMA	2	0,019	0-0,058	0,48	0,96-1,92	0	0-0		
	5	0,021	0-0,070	0,13	0-0,95	2,15	1,96-6,14		
	10	0,039	0-0,079	2,91	0-5,56	4,44	4,0-9,84		
AMPS	0,8							8,93	(7,39-10,76)
	2	0,006	0-0,035	0,53	0,97-1,79	1,26	0,98-2,91		
	5	0,016	0-0,043	0,54	0,94-1,92	2,4	0,81-4,50		
	10	0,025	0-0,055	6,1	3,17-10,62	4,19	1,47-7,38	13,36	(6,06-19,44)
Control		0	0-0	1,04	0,65-2,80	0,375	0-1	4,07	(2,30-6,56)
SHAM		0,006	0-0,035	1,31	0,99-1,96	0,492	0-1,96	8,74	(7,50-11,24)

A dose dependent effect was clearly noted for all the evaluated patterns as the abnormalities were shown to be more frequent as higher were the SAR levels of exposition despite of CDMA and AMPS technologies.

The most frequent observed chromosome abnormalities were chromosome and chromatid breaks although other events such as fragment deletions and amplifications as well as ring chromosomes were also found as shown in Figure 2.

Figure 2: Chromosome Abnormalities A. Satellite length increase. B/C. Chromosome breaks. D. Chromatid gap. E. Deletion. F. Ring Chromosome G. Acentric Fragment. H. Amplification

The micronuclei frequency has increased with SAR levels of 10W/kg and the results obtained with a SAR level of 0,8 W/kg, which is close to what a person might be exposed realistically, was very similar to the frequency obtained in the sham-exposed samples. Aneuploidy of chromosome 17 was considered relevant only with SAR levels of 10W/kg, when compared to the mean frequencies of the control and sham exposed samples. Aneuploidy of chromosome 8 was considered relevant, when compared to the controls only with SAR levels of 5 and 10W/kg.

DISCUSSION

A general concern for people that are exposed to RF fields, especially with the increasing number of cell phone users, is the connection between radiation and cancer. Genomic instability is largely found in tumor cells and there is a strong evidence that high SAR levels, above the international regulation limits, may have a genotoxic effect and induce DNA damage at some level.

It is interesting to note that aneuploidy and chromosome damage have been considered two of the most notorious transformation-related events in tumorigenesis because it precedes malignant transformation in many tumors. Cancer aneuploidy and other imbalances affect gene dosage and a large number of proteins including those involved in the mitotic spindle apparatus resulting in a self-perpetuating chromosomal instability [13]. As we detect genomic imbalances in blood cells submitted to increasing SAR levels we remain to understand if these instable cells are still capable to escape to an apoptotic via in order to exterminate the imbalanced clones and preserve tissue integrity. We have observed much more translocations and marker chromosomes, yet to be identified through SKY (spectral karyotyping) than dicentrics, acentrics and rings which are considered much more unstable aberrations with fast disappearance *in vivo* [14,15].

In response to genotoxic such as RF, various chemicals and reactive cellular metabolites, cell cycle checkpoints that slow down or arrest cell cycle progression can be activated, allowing the cell to repair or prevent the transmission of damaged or incompletely replicated chromosomes. The balance between cell cycle arrest, damage repair and initiation of cell death could determine if cellular or DNA damage is compatible with cell survival or requires cell elimination by apoptosis. Defects in these processes may lead to hypersensitivity to cellular stress, and susceptibility to DNA damage, genomic defects, and resistance to apoptosis, which characterize cancer cells. This is the main issue to justify chromosomal studies in *in vitro* models [16]. Molecular chromosome techniques such as CGH – Comparative Genomic Hybridization [17] and SKY – Spectral Karyotyping [18] can add more information to conventional cytogenetics reports and indicate hot spots for chromosome structural abnormalities.

When individuals exposed to RF in a work environment were evaluated it was shown that other factors might potentiate the clastogenic effects of RF radiation such as light deprivation resulting in a disturbance of melatonin secretion [19]. Such observations may explain the fact that our sham-exposed samples have always shown higher mean frequencies of abnormalities when compared with the controls alone. It is necessary to consider that epigenetic and environmental factors may play an important role to potentiate the radiation effect on the DNA.

Our findings support other groups' results as we were able to demonstrate a dose-dependent effect against the genome particularly with SAR levels above 5W/kg [20].

The set up system used for the expositions was carefully designed to meet the needs described at the WHO'S EMF International Project. Parameters such as temperature, power input and output, TEM CELL characterization prior to the experiments and experimental dosimetry tests were developed and taken into account to achieve reliable results in isothermal conditions.

Our results have shown the importance of genomic analysis especially through conventional and molecular cytogenetics techniques and suggest the use of continuous cytogenetics analysis especially for occupationally exposed professionals who are the ones that might be exposed to higher SAR levels [15].

We are yet to describe the effect of RF in different systems and exposition parameters specially with regard to an intermittent mode of radiation exposure.

ACKNOWLEDGEMENTS

The authors would like to thank Mauro Lins, M.Sc for the initial technical support for the exposition set up. This research was supported by FUNTTEL.

Abstract

An exact, analytical solution has been used to calculate the electromagnetic (EM) radiation emitted by an active implant within an eccentric-spheres, human head model and variations thereof. The EM field is determined by use of Green's dyadic for a lossy, dielectric sphere containing any number of lossy, dielectric, spherical inclusions. The inclusions can be placed anywhere within the host sphere. The source is a point dipole encapsulated within a tiny, lossless, dielectric sphere. In theory, this implant can be placed anywhere within the head model; calculations have been made with the implant inside the skull, either at the side, near a temple, or at the side of the jaw. Numerical results have been obtained for frequencies ranging from 400 MHz to 4 GHz. The effect of the orientation of the dipole source has been investigated. The radiation absorbed by the head model has been studied by use of plots of the total absorbed power per tissue against the frequency as well as by use of maps of the Specific Absorption Rate (SAR) on cross sections of the head.

I. Introduction

The growing interest of the scientific community in the implantation of active antennas inside the human body has been related to communication and monitoring purposes. In this paper the operation of an active implant, which radiates in the RF or microwave band, from within the human head has been examined. Applications of this study may include (a) comparisons of SAR calculations with the guidelines of international standards, (b) controlled absorption, aimed at therapeutic interventions, and (c) diagnosis of anatomical abnormalities through measurements of near- or far-field radiation escaping from the head.

The analytical solutions that have been made available over the years treat the human head as a multilayered, lossy, dielectric sphere [1]-[3]. Herein, an eccentric-spheres model of the human head and two simplified versions thereof have been considered. The implanted antenna is an infinitesimal, electric dipole encapsulated within an acrylic sphere, which immunizes the source dipole from the surrounding tissue, which may be conductive.

From the point of view of eventual health hazards of communication devices, the focus is on the power absorbed by the brain, the appearance of hot spots, and the peak SAR values. Furthermore, the characteristics of the implant are investigated by calculations of the delivered power, maps of the electric-field intensity around the head, and far-field radiation diagrams.

II. Head Model and Implant

All three head models, which are of interest in this paper, can be obtained from the geometry shown in Fig. 1. Model 1 comprises a spherical bone shell (host sphere), which represents the skull, and three inclusions; the latter are a major, spherical core, representing the brain and a pair of small eyeballs, all properly placed within the bone shell. The (outer) radius of the skull is $\alpha_0 = 9\text{ cm}$, the radius of the brain is $\alpha_1 = 7\text{ cm}$ and those of the eyes are $\alpha_2 = \alpha_3 = 1\text{ cm}$. The center of the brain, O_1 , is vertically displaced by $d_{01} = 1.5\text{ cm}$ from the center of the skull, O_0 . The eyes are centered at O_2, O_3 , which are horizontally displaced by $d_{02} = d_{03} = 7.95\text{ cm}$ from O_0 ; the left-hand eye is in the meridian plane $\varphi = 23^\circ$ (Fig. 1a), whereas the right-hand eye is in the meridian plane $\varphi = (360 - 23)^\circ = 337^\circ$. Thus, the eyes are symmetrically placed with respect to the coordinate plane

xO_0z . Model 2 is obtained from model 1 by omission of the eyeballs and model 3 is obtained from model 2 by the substitution $d_{01} = 0$. The brain volume is 1436.75 cm^3 , this value being in the range $[1400 - 1500 \text{ cm}^3]$ of normal, human brain volumes. The electrical properties assigned to bone, brain, and eye tissue as well as the corresponding density of each tissue, are shown in Table I for two frequencies which are of special interest [4].

The active implant is an infinitesimal, electric dipole, placed at the center of an acrylic sphere of radius $a_4 = 0.5 \text{ cm}$ and refractive index $n_4 = n_{acr} = 1.61 + j0$. The lossless capsule immunizes the source from the conductive bony shell [5]. The implant is positioned at distance $d_{04} = 8 \text{ cm}$ from O_0 , either on the y -axis (position 1) or on the yO_0z plane at $\theta = 145^\circ$ declination from the z -axis (position 2). The first position of the source is supposed to be inside the left auricular and the second in the mouth, where the lower left, 3rd molar (tooth #38) is found.

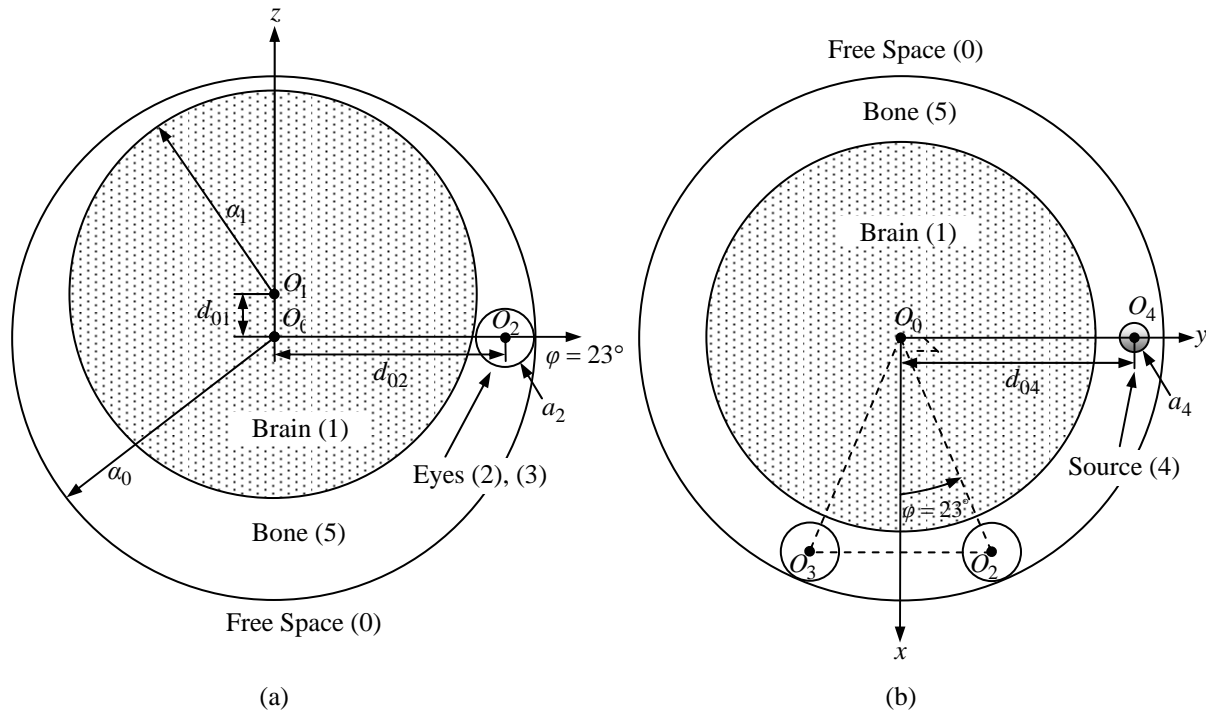

Figure 1. (a) Vertical ($\varphi = 23^\circ$) and (b) horizontal ($\theta = 90^\circ$) cross-sections of head model 1; the point source, encapsulated in an acrylic sphere of radius a_4 , is shown in position 1 (left auricular); position 2 is also in the meridian plane $\varphi = 90^\circ$, but below the xO_0y plane, at $\theta = 145^\circ$.

Table I. Relative, dielectric constant ϵ_r , conductivity σ (mhos/m), and density ρ (kg/m^3) of human head tissue layers

Frequency (MHz)	Bone (1850 kg/m^3)		Brain (1030 kg/m^3)		Eyes (1010 kg/m^3)	
	ϵ_r	σ	ϵ_r	σ	ϵ_r	σ
1500	11.98	0.22	45.99	1.12	68.70	1.87
2400	11.41	0.38	44.33	1.62	68.24	2.44

III. Analytical Determination of the Electric-Field Intensity

The electric-field intensity anywhere within, as well as outside, the aforesaid head model is determined by use of the dyadic Green's function (dGf) $\overline{\overline{G_e}}(\vec{r}, \vec{r}')$ of a dielectric sphere with several, eccentric, spherical, dielectric inclusions; all dielectrics may be lossy. The position vectors \vec{r} , \vec{r}' correspond to the field and source points. The point source can be placed anywhere, but, in this study it has been placed in the bone shell, which is denoted as region 5 (Fig. 1); the generality of the analysis is not impaired otherwise. The analytical determination of $\overline{\overline{G_e}}(\vec{r}, \vec{r}')$ is an intricate task which has been undertaken by the authors elsewhere [6]. Still, it

might be convenient to state that the analysis begins by consideration of the dGf of an unbounded space with electrical properties identical to those of the acrylic inclusion; that dGf is given by [7]

$$\begin{aligned} \bar{\bar{G}}_{e0}(\vec{r}, \vec{r}') = & -\frac{1}{k_4^2} \hat{r} \hat{r}' \delta(\vec{r} - \vec{r}') + \\ & + j \frac{k_4}{4\pi} \sum_{mn} (-1)^m \frac{2n+1}{n(n+1)} \begin{cases} \left[\bar{M}_{mn}^{(1)}(k_4 \vec{r}) \bar{M}_{-mn}^{(3)}(k_4 \vec{r}') + \bar{N}_{mn}^{(1)}(k_4 \vec{r}) \bar{N}_{-mn}^{(3)}(k_4 \vec{r}') \right] & r < r' \\ \left[\bar{M}_{mn}^{(3)}(k_4 \vec{r}) \bar{M}_{-mn}^{(1)}(k_4 \vec{r}') + \bar{N}_{mn}^{(3)}(k_4 \vec{r}) \bar{N}_{-mn}^{(1)}(k_4 \vec{r}') \right] & r > r' \end{cases} \end{aligned} \quad (1)$$

where $k_4 = k_0 \sqrt{\varepsilon_{r,4}}$ is the wavenumber within region 4 of the nonspherical body, which accommodates the source; $k_0 = \omega/c_0$ is the wavenumber of free-space, i.e. region 0, and $\varepsilon_{r,4}$ is the relative permittivity of the acrylic sphere; $\bar{M}_{mn}^{(1)}$, $\bar{N}_{mn}^{(1)}$ and $\bar{M}_{mn}^{(3)}$, $\bar{N}_{mn}^{(3)}$ are vector, spherical harmonics of an unbounded acrylic medium; the former pair comprises wavefunctions that remain bounded at the origin of coordinates, whereas the latter pair of wavefunctions are bounded at infinity. By application of the boundary conditions on every spherical interface of the nonspherical body, $\bar{\bar{G}}_e(\vec{r}, \vec{r}')$ is ultimately obtained, but neither further details about that analytical formulation nor the resulting, cumbersome expression for $\bar{\bar{G}}_e(\vec{r}, \vec{r}')$ are needed in this paper, which is focused on numerical results. The validity of the solution has been checked numerically through reciprocity and energy-conservation checks as well as analytically by simplifying the geometry and comparing the resulting solution to those of articles published before [8], [9].

The point source is represented by the current distribution

$$J(\vec{r}') = I_0 l \frac{\delta(r' - r_0) \delta(\theta' - \theta_0) \delta(\phi' - \phi_0)}{r' \sin \theta} \hat{e}, \quad (2)$$

wherein $I_0 l$ is the dipole moment and \hat{e} is the orientation, i.e. polarization, vector. The electric-field intensity due to this dipole source can be determined anywhere in space by integration of the posterior scalar product of $\bar{\bar{G}}_e(\vec{r}, \vec{r}')$ with the aforesaid current [10]:

$$\vec{E}(\vec{r}) = j\omega\mu_0 \int_{\vec{r}'} \bar{\bar{G}}_e(\vec{r}, \vec{r}') \cdot \vec{J}(\vec{r}') d^3 \vec{r}' \quad (3)$$

IV. Numerical Results

The effect of the implant on the head has been investigated first by use of diagrams of the absorbed power versus the operating frequency of the implant, which is in the range 400MHz - 4GHz, for both positions of the implant. The aforesaid frequency range is associated with ISM, TETRA, GSM, UMTS, WLAN, and Bluetooth devices. Moreover, these diagrams display lucidly which fraction of the radiated power is absorbed by each tissue at anyone of those frequencies. Absorption by the brain and the bone is shown in Figs. 2 and 3 as percentage of the total radiated power, respectively, for head models 1, 2 and 3. The dipole orientation is in every case along the z-axis.

The first remark yielding from the aforementioned diagrams is that the brain absorption is maximized at about 1500MHz when the dipole is placed in the ear and at 1700MHz when the implant is placed at the tooth. At the very same frequencies absorption by the bone shell is minimal.

When the eccentric-brain, head model, i.e. model 1 or 2, is under consideration it is obvious that there is strong dependence of the absorbed power on the dipole position. Absorption by the brain with the implant in the ear exceeds that with the implant in the tooth, and the opposite is true for absorption by the skull. This outcome can be justified by the different distance of the source from the brain in the aforesaid positions.

The remark made above does not apply to the concentric-brain, head model, i.e. model 3, because the source is equidistant from the brain for both the positions examined. In that model, the difference in the frequency, whereby absorption is maximized, can be justified by the different angle by which the dipole is aimed at the brain.

The overall absorption by the left eye, which in every case is closer to the implanted antenna, in model 1, is less than 0.05% and it is not shown. Finally, for all three models, a very small percentage of the radiated power escapes from the head into the free-space surrounding. That percentage is less than 3% for position 1 of the implant, with the maximum value occurring at 2700MHz, and it does not exceed 1% of the radiated power for position 2, the maximum value being at 2200MHz.

Next, the effect of the dipole orientation on the power absorbed by the brain, the bone and the eyes is investigated. In Figs. 4 and 5 the overall absorbed power by the brain and the bone, respectively, is plotted against the declination angle θ of the polarization vector of the point dipole; θ is measured from the z -axis. The operating frequency is 1500MHz .

Figure 2. Absorption by the brain vs. frequency for head models 1, 2 and 3.

Figure 3. Absorption by the bone vs. frequency for head models 1, 2 and 3.

It is clear that absorption by the brain and the bone is practically unaffected by the orientation of the dipole when the latter is placed inside the ear. A slight increase in the absorption by the brain and a corresponding decrease in the absorption by the bone are observed when the dipole is placed at the tooth for all three head models.

The effect of dipole orientation on the absorption by the eyes is far more significant. As shown in Fig. 6, absorption by the left eye, which is closer to the radiating implant, increases as the main radiation lobe of the dipole rotates so as to include the eye, and decreases as that lobe points elsewhere. However, the overall power absorbed by the eyes remains a small percentage of the total radiated power

Subsequently, numerical results are shown for the SAR anywhere within the nonspherical head model; the SAR has been determined by use of the definition

$$SAR = \frac{\sigma |E|^2}{2\rho}, \quad (4)$$

wherein σ is the conductivity and ρ is the density of tissue.

Figure 4. Absorption by the brain vs. dipole orientation (i.e. declination angle) for head models 1, 2 and 3

Figure 5. Absorption by the bone vs. dipole orientation (i.e. declination angle) for head models 1, 2 and 3

Figure 6. Absorption by the eyes vs. dipole orientation (i.e. declination angle) for head model 1

SAR maps are shown for characteristic cross-sections of the human head. The SAR maps of Figs. 7 and 8 correspond (a) to a horizontal cross section of the head through the centers of the skull and the eyes and (b) to a vertical cross section of the head through the centers of the skull, the brain and the acrylic capsule. The brain core in Figs. 7(a) and 8(a) seems smaller because it is somewhat raised above that cross section, i.e. the xO_0y plane. The active implant is inside the left ear and the operating frequency is 1500MHz in Fig. 7 and 2400MHz in Fig. 8. The radiated power is 1W for all the cases examined.

Figure 7. SAR maps on (a) xO_0y and (b) yO_0z planes; the implant is inside the left ear and the frequency is 1500MHz .

Figure 8. As Fig. 7 at 2400MHz .

A cursory look at the above SAR maps suggests that the higher the frequency the more superficial is the penetration of the EM radiation inside the brain and the eyes. The maximum SAR in the brain is found at the cortex, directly in front of the implant, where the radiation is most intense. The maximum SAR in the brain is 10.8W/kg , when the frequency is 1500MHz , and it reaches 21.0W/kg at 2400MHz .

Finally, local SAR evaluations have been made with the implant inside the tooth. Figs. 9 and 10 are SAR maps for the same cross-sections of the eccentric-brain head model as Figs. 7,8 and for the same frequencies. The aforesaid remark about the dependence of the penetration depth of the EM radiation on the operating frequency of the implant is reconfirmed. However, the importance of the distance of the implant from the brain is now made evident, since the maximum local SAR in the brain in these cases is 1.6W/kg at 1500MHz and 2.4W/kg at 2400MHz .

Figure 9. SAR maps on (a) xO_0y and (b) yO_0z planes; the implant is inside a tooth and the frequency is 1500 MHz .

Figure 10. As Fig. 9 at 2400 MHz .

When the implant is intended for telecommunication or monitoring purposes the field outside the head is important for the appliance that receives the transmitted data. The EM field outside the head is shown in Figs. 11 and 12 as maps of the amplitude of the electric-field intensity up to distance 90 cm from the center of the head. Those maps correspond to the coordinate plane xO_0y with the implant inside the ear or in a tooth. The operating frequency is either 1500 MHz or 2400 MHz and the power radiated by the implant power is 1 W . It is clear from those maps that the presence of the head orients the EM radiation in directions opposite to the head and this effect is stronger at the higher frequency, i.e. at 2400 MHz , for both positions of the implant examined. Finally, it is noted that, the average electric-field intensity on that plane is stronger with the implant in the ear than with the implant in the tooth. This, last remark holds even when the electric-field intensity is mapped on a horizontal plane through the tooth.

The study of the EM field outside the head model is completed by the radiation patterns shown in Figs. 13-16. Radiation patterns are plotted on all three coordinate planes, i.e. xO_0z (a), yO_0z (b), and xO_0y (c). The electric-field intensity in all those patterns has been normalized with respect to the maximum value of the electric-field intensity generated by the encapsulated dipole in free space. The comments incited by Figs. 11 and 12 about the re-orientation of the EM radiation due to the presence of the head and about the dependence of the electric-field intensity on the frequency and the position of the implant are compatible with Figs. 13-16.

Figure 11. Field maps around head model 1; the implant is in the left ear and the frequency is (a) 1500 MHz, (b) 2400 MHz

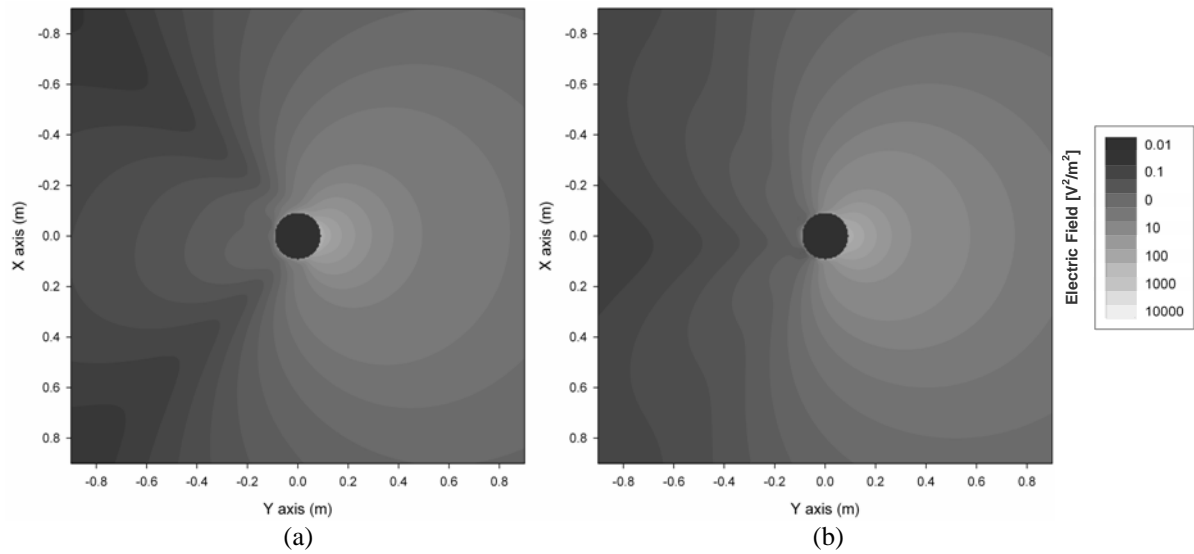

Figure 12. As Fig. 11 with the implant in a tooth

The radiation characteristics of the dipole itself are strongly affected by the electrical and geometrical features of the head model. Comparisons with radiation patterns corresponding to models 2 and 3 suggest that the position of the brain in the skull strongly affects the radiation patterns, whereas the effect of the eyes can hardly be noticed.

The final part of this investigation on the effect of the human head on the radiation characteristics of the implant, concerns the variation of the radiated power crossing the surface of the acrylic capsule with the operating frequency; that plot is shown in Fig. 17 across the frequency range 400MHz–4GHz. Since the acrylic medium has been considered lossless, the aforesaid radiated power is equal to power delivered by a tiny transmitter to the dipole, provided that matching between them is possible even though the current flowing along the dipole is modified by the presence of the head. The continuous line in Fig. 17 corresponds to power radiated by the dipole from within the acrylic sphere in free space; that power has been normalized with respect to the power radiated by the very same dipole in free space at every frequency; the dashed line corresponds to the power radiated by the implanted antenna and it has been normalized by the power radiated by the encapsulated dipole in free space. It can easily be seen from Fig. 17 that when the radius of the acrylic capsule is greater than 40 wavelengths, i.e. for frequencies above 1500MHz, the power radiated by the implanted antenna varies periodically with the frequency and the effect of the head is minimal.

V. Summary

The effects of an infinitesimal electric dipole placed at the centre of an acrylic sphere and implanted inside the human head have been studied by use of three head models. On the one hand, the absorbed power and the SAR in any part of the head models, have been evaluated and the importance of the operating frequency, the position and the orientation of the dipole have been established; the EM radiation escaping the head as well as the effects of the head on the characteristics of the implant have been examined. On the other hand, the importance of some anatomical details of the head models, within the framework of analytical methods, has been assessed, thus allowing for the appropriate head model to be used for the application at hand.

ABSTRACT

Experimental evidence exists suggesting that Extremely Low Frequency Magnetic Fields (ELF-MF) and Melatonin (MEL) can exert antagonistic effects on different cellular responses. However, the nature of such an interaction remains unknown. Our previous studies have shown that MEL significantly reduces proliferation and stimulates cytodifferentiation in HepG2 human hepatocarcinoma cells, these effects being antagonized by the exposure to 50 Hz, 10 μ T MF. Conversely, the MF increases the growth rate of HepG2 when administered alone, but not in the presence of MEL. The present work investigates whether gap junctional intercellular communication (GJIC) could be involved in the described MF/MEL responses. Connexin32 (Cx32) expression (Immunocytochemistry - Image analysis) and functional GJIC (Parachute technique) have been analyzed in cultures exposed to the following conditions: Control, MEL (10 nM), MF (50 Hz, 10 μ T) and MEL + MF. The results show that MEL stimulates dye transfer and induces expression of Cx32. Both effects are inhibited by the simultaneous exposure to MF. Therefore, the results suggest that previously reported antagonistic effects of MEL/MF in the proliferation and/or differentiation of HepG2 could be mediated by modulation of Cx32 expression and functional GJIC.

INTRODUCTION

There is mounting evidence that the pineal gland's hormone melatonin (MEL) intervenes in the control of neoplastic processes in cells, animals and humans (Blask *et al.*, 1993; Stevens, 2005). Melatonin has been reported to inhibit cell proliferation in different tumor types, such as hepatoma and colon cancer from rodents (She *et al.*, 2004; Dakshayani *et al.*, 2005; Mei *et al.*, 2005) and to reduce the incidence and growth of chemically induced mammary tumors (Melancon *et al.*, 2005; Cos *et al.*, 2006a). Also, several studies addressing oncostatic effects of MEL in the human breast cancer cell line MCF-7 have shown that MEL can inhibit proliferation and the metastatic behavior in these cells (Cos *et al.*, 2006b). Although different mechanisms have been proposed to explain the potential ability of MEL to suppress tumor promotion and progression, the actual mechanisms responsible for the oncostatic capacities of this hormone remain unidentified. Recent experimental evidence suggests that MEL could also influence proliferative processes due to its oxidative function and free radical scavenging properties (reviewed by Vijayalaxmi *et al.*, 2004). In addition, MEL has been reported to affect processes involved in cell differentiation (Radio *et al.*, 2006), including the establishment of cell adhesion and cell contacts, (Cos and Fernández 2000). In previous works we have reported that MEL enhances junctional transfer in normal C3H/10t1/2 cells and in primary cultures of mouse hepatocytes (Úbeda *et al.*, 1995a; Blackman *et al.*, 2001a). These results suggest that melatonin could exert its antitumoral action, at least in part, by modulating the levels of gap junctional intercellular communication (GJIC).

On the other hand, a number of *in vivo* studies have shown that extremely low frequency (ELF) magnetic fields (MF) can influence the development of tumor-promoting processes (reviewed by Loscher and Mevissen, 1994; Fedrowitz *et al.*, 2004) and alter MEL secretion by the pineal gland (reviewed by Reiter, 1994; Henshaw and Reiter 2005). The results of different studies suggest that ELF MF-induced reduction of MEL levels in the circulating blood could be determinant to the tumor promoting action of these fields. *In vitro*, 60/50 Hz MF have been reported to block Melatonin-induced inhibition of cell proliferation in human breast cancer MCF-7 cells (Liburdy 1993; Blackman *et al.*, 2001b; Ishido *et al.*, 2001). The HepG2 cell line has been extensively used for studying the mechanisms of action of a wide spectrum of potential carcinogens including ELF MF, which have been shown to promote proliferation in these cells (Trillo *et al.*, 2001). Moreover, previous studies by our group have shown that MEL significantly reduces proliferation and stimulates cytodifferentiation in HepG2 cells, these effects being antagonized by the exposure to 50 Hz, 10 μ T MF. Conversely, when administered alone, the MF increased the growth rate in HepG2, whereas the presence of

MEL in the medium blocked such a cellular response (Cid *et al.*, 2004; Cid *et al.*, 2005). The present work investigates whether gap junctional intercellular communication could be involved in the previously described MF/MEL antagonistic responses on the proliferation or differentiation of HepG2. For that purpose the functionality of GJIC and the expression of connexin32 (Cx32) were analyzed on samples exposed to 50 Hz, 10 μ T MF and/or treated with 10 nM MEL.

MATERIAL AND METHODS

Cell culture

HepG2 human hepatocarcinoma cells (ECACC, TDI S. A., Madrid) were cultured in Dulbecco's-Eagle modified medium (DMEM; Bio-Whittaker) supplemented with 5% heat-inactivated Fetal Bovine Serum (FBS, GIBCO), 10% Glutamine, and 10% penicillin/streptomycin (GIBCO), in water-jacket incubators (Forma Scientific) at 5% CO₂, 37 °C and 100% RH atmosphere.

MF exposure

The exposure set-up used in these experiments was reproduced from that described by Blackman *et al.*, (1993). Each exposure system consisted of two identical sets of two 1000-turn, 20-cm-diameter coils of enameled wire, aligned coaxially 10 cm apart, in a Helmholtz configuration, and oriented to produce vertically polarized magnetic fields. Each set of coils was kept inside a magnetically shielded chamber (co-netic metal; Amuneal Corp., Philadelphia, PA) placed inside a CO₂ incubator (Forma Scientific). The generating (Newtronic Model 200MSTPC, Madrid, Spain) and monitoring (Hewlett Packard, 974A, Loveland CO) equipment was connected to the coils. The flux density and electromagnetic background in the exposure area were measured and recorded before and after the experiment with a fluxgate magnetometer (EFA-3, Wandel & Goltermann GMW & Co. Germany). The background MF inside the shielded chambers was AC: 0.04 ± 0.03 μ T, DC: 0.05 ± 0.04 . In each experimental run only one of the two sets of coils was energized. The samples in the unenergized set were considered sham-exposed controls. Both incubators were used, in a random sequence, alternatively for MF exposure and sham-exposure. The MF exposure parameters were chosen on the basis of our previous observations (Trillo *et al.*, 2001; Trillo *et al.*, 2003; Martínez *et al.*, 2006), which revealed that a 42-h exposure to a sinus wave 50 Hz intermittent (3-h On/3-h Off) MF at 10 μ T significantly stimulates cell growth in both, the HepG2 human hepatocarcinoma cell line and the NB69 human neuroblastoma cell line.

GJIC assay: Parachute and Flow cytometry techniques

The GJIC was examined through a two-dye method based on the parachute technique, previously described by Goldberg *et al.* (1995). This technique is currently used to detect and quantify GJIC functionality in different cellular systems (Czyz *et al.*, 2000; reviewed by Fonseca *et al.*, 2006). The high sensitivity of this method allows for detection of small changes in functionality of GJIC by examining a large number of cells in a single experimental run. In our experiments, the samples were seeded at a density of 10×10^4 cells/ml. After allowing for cell attachment (4 hours post-plating) the dishes were distributed in two groups and an initial dose of Melatonin (N-acetyl-5-methoxy-tryptamine, Sigma) was added to one of the two groups. At the end of day 3 postplating the medium was renewed and a second dose of MEL was administered to the previously treated group. At this time both groups, with or without MEL, were divided in sham-exposed and MF-exposed samples. The cells were subjected to: a) no treatment: controls, b) treatment with MEL, c) exposure to MF, and d) MF exposure imposed upon MEL treatment. The MF-exposed samples were treated intermittently, 3h On/3h Off, with a 50 Hz, 10 μ T MF for 24 h. At the end of day 4, when cells were close to confluence, all the samples were distributed into two groups: the recipient and the donor group. The group of recipient cells was pre-stained with a permanent, non-toxic lipophilic dye that binds to membranes irreversibly, DiI (1-1'-dioctadecyl-3,3',3'-tetramethylindocarbocyanine perchlorate; Molecular Probes). The donor population was treated with a gap junction-permeable dye Calcein, a derivative of Calcein acetoxymethyl ester (Calcein-AM, Molecular Probes). After seeding the donor cells on the corresponding recipient samples under conditions promoting gap junction (GJ) formation, the four experimental groups were exposed and/or incubated for an additional 18 h lapse. At the end of this period the samples, two per experimental condition: Control, MEL, MF and MEL + MF, were analyzed by flow cytometry (Cell Quest software) and the percent of cells showing both dyes (Cal+ / DiI+ events) vs. the total Cal+ events, were determined. A total of 20,000 events per sample were recorded. Two additional samples were used to establish the basal level of fluorescence.

Cx32 expression assay

The Cx32 expression was estimated as the percent of Cx32 positive cells by immunocytochemistry and Computer-Assisted Image-Analysis. The methodology used for treatments with MEL and/or MF has been described previously by Cid *et al.* (2004). In short, cells were seeded at a density of 9.5×10^4 cells/ml on 12 mm \varnothing

coverslips sited into the Petri dishes. Additional Petri dishes were used to test viability and cell proliferation. A total of 12 or 20 dishes, to obtain 3 or 5 plates, per experimental condition: Control, Melatonin, MF and Melatonin + MF, were assayed. After allowing for cell attachment to the coverslips (4 hours post-plating) the dishes were distributed in two groups and an initial dose of Melatonin was added to one of the two groups. At day 3 post-plating the medium was renewed, and a second treatment with MEL was administered in the previously treated group. Each of the two groups, treated with MEL or untreated, was distributed in sham-exposed and MF-exposed samples. The MF-exposed samples were treated intermittently, 3h On/3h Off, with a 50 Hz, 10 μ T MF for 42 h. At the end of this period the cells were tested for appropriate viability and cell proliferation before being processed for analysis of connexin32. Cells on coverslips were fixed with periodate-lysine-paraformaldehyde (PLP). After washing with PBS, cells were permeabilized, (acetone 50%) and the endogen peroxidase was inactivated (H_2O_2 3%). The non-reactive sites were blocked (FCSi 10%, Triton X-100 0.05% in PBS) for 1 h at room temperature. Then, the samples were incubated for 24 h at 4 °C with a monoclonal antibody against the central cytoplasmic loop of human Cx32 (IgG clone M12.13; Chemicon Int.), dilution 1:200, in FCSi 5% / Triton X-100, 0.15% / PBS. Immunostaining was enhanced through the ABC method (Vectastain ABC Elite kit, Vector Laboratory, Burlingame CA), and revealed with the peroxidase substrate, diaminobenzidine tetrahydrochloride (DAB). The nuclei were counterstained with Hematoxyline. Background controls without the primary antibody were also included in the study. The samples were visualized and evaluated through a photomicroscope. Two coverslips per experimental condition were randomly chosen and a total of 20 microscope fields per coverslip were analyzed. The quantification of the immunolabeling was carried out through Computer Assisted Image-Analysis (IPWin and AnalySIS software). The ratio of Cx32 positive cells vs. total cells per microscope field was determined. Additional analysis taking into account the total immunostaining area of Cx32 vs. total cells per microscope field was carried out.

RESULTS

GJIC functionality in samples exposed to MF in the presence or the absence of MEL

Previous studies by our group showed that a dose of 10 nM MEL was effective inducing decreases in cell proliferation and in the promotion of differentiation in HepG2. These effects were antagonized by the exposure to 50 Hz, 10 μ T MF (Cid *et al.*, 2004; Cid *et al.*, 2005). On that basis, in the present study the concentration 10 nM MEL was assayed to study the functional GJIC in cells exposed to 50 Hz 10 μ T MF in the presence or absence of MEL. The parachute technique revealed that untreated HepG2 cells (control condition) exhibit a low degree of junctional activity. However, the presence of 10 nM MEL in the medium increases significantly the coupling rate (17.7 ± 0.4 % over controls $p < 0.01$) in these cells (Fig. 1). In contrast, the coupling response to the MF exposure did not differ significantly from that in controls, both in the presence and in the absence of MEL; which reveals that the 10 μ T MF, per se, does not change the functional GJIC in HepG2, but can block the MEL-induced coupling in these cells.

Fig. 1. The functional GJIC was measured as the percent of cells showing both dyes (Cal+ / DiI+ events) over the total Cal+ events. Coupling rate in the different conditions tested, Control, MEL, MF and the combined treatment, MEL + MF. The MEL-induced coupling was antagonized by the exposure to MF. Data normalized over controls N = 4 experiments. Mean \pm SEM *, $p < 0.05$ (ANOVA followed by Student's T test).

Cx 32 expression in samples exposed to MF in the presence or the absence of MEL

The effect of the treatments with MEL and/or MF on the Cx32 expression and on its subcellular distribution was determined through Computer Assisted Image-Analysis. The analysis was focused on the expression of Cx32 because changes in both, the amount and distribution of this connexin have been suggested to be implicated in human hepatocarcinogenesis (Nakashima *et al.*, 2004), and increases in Cx32 expression induce phenotypic normalization in HepG2 (Yang *et al.*, 2003), whereas decreases in Cx32 seem to be linked to cell proliferation and progression in rodent hepatocarcinomas (Temme *et al.*, 1997). In the untreated cells the Cx32 expression presents an abnormal localization and distribution when compared to normal hepatocytes (data not shown). This abnormal pattern of expression consists on an increased cytoplasmic accumulation, either distributed in vesicular structures or presenting a diffuse appearance located generally in the perinuclear zone. The cytoplasmic membrane presents little expression of Cx32, with no immunoreactive gap junctional plaques. This aberrant pattern of Cx32 expression in HepG2 cells was not modified by the exposure to MF or by the MEL treatment. However, in MEL treated samples a significant increase (32.9 ± 0.9 % over controls, $p < 0.05$) in the percent of cells expressing cytoplasmic Cx32 immunostaining was observed at day 5 of treatment (Fig 2). In contrast, the response to MF alone or to the combined treatment (Mel + MF) was similar to that observed in controls. These data reveal that, when applied alone, the MF did not exert significant effects on Cx32 expression or on functional GJIC. However, when applied on MEL treated samples, the MF exposure antagonized the MEL-induced responses. Preliminary data (not shown) on immunoblot for Cx32 confirm these results.

Fig. 2. Percent of Cx32 positive cells, quantified by the Image Analysis software IPWin, in the different experimental conditions tested. The treatment with 10 nM MEL increased significantly the percent of cells expressing Cx32. This response was counteracted by the exposure to 50 Hz, 10 μ T MF. Data normalized over controls, Mean \pm SEM of 4 experimental replicates; *, $p < 0.05$ (ANOVA followed by Student's T test.)

DISCUSSION

Previously reported results by our group have shown that MEL significantly reduces proliferation and stimulates cytodifferentiation in HepG2 human hepatocarcinoma cells; these effects being antagonized by the exposure to sinusoidal 50 Hz, 10 μ T MF. Conversely, the MF increases the growth rate of HepG2 when administered alone, but not when in the presence of MEL (Cid *et al.*, 2004; Cid *et al.*, 2005). It is currently believed that a tight regulation of gap junctional intercellular communication mediated by connexins may contribute to cell growth and differentiation by keeping important signals, such as those involved in growth control, at equilibrium among gap junction-connected cells. The present work investigates whether gap junctional intercellular communication could be involved in the MF/MEL responses described before. The results of the present work show that untreated, control HepG2 cells have a low degree of junctional activity and an aberrant expression of Cx32. However, the treatment with MEL increases the functional GJIC and the percent of cells that express the gap-junctional protein Cx32 in HepG2. On the other hand, although the exposure to MF alone does not exert any significant influence on these junctional processes, when applied on MEL-treated cells the MEL-induced responses on the functionality of GJIC and on Cx32 expression were abolished.

The stimulating effect of MEL on GJIC functionality has been well described in a variety of cell lines. Úbeda *et al.* (1995a) reported that physiological concentrations of MEL between 0.01 and 0.1 nM, induce significant increases in the junctional transfer of mouse normal fibroblast C3H/10T1/2. Blackman *et al.* (2001a)

found similar results in primary cultures of mouse hepatocytes treated with MEL at the physiological doses of 0.2 and 0.4 nM. In the present study, the HepG2 human hepatocarcinoma line also responded with significant increases of the coupling rate (parachute technique) when treated with a concentration (10 nM) higher than the above described as effective in normal, non-cancer cells. Even higher, pharmacological concentrations of MEL (10 μ M) have been reported to efficiently increase GJIC functionality in the breast cancer cell line MCF-7 (Cos and Fernandez 2000). Taken together, these results are consistent with the hypothesis that cancer lines are, in general terms, less sensitive to MEL than normal cells.

It has been well established that the restoration of connexin expression in tumor cells often leads to a partial reversion of the tumoral phenotypes and to increased growth control (King and Lampe 2004). Like reported by other authors working with poorly differentiated hepatocarcinomas (Krutovskikh *et al.*, 1994), an aberrant pattern of Cx32, mainly cytoplasmic and diffuse, was observed in the present study in the HepG2 line. This may represent a general pattern in hepatocarcinoma cells, potentially due to the presence of abnormalities in the intracellular transport of Cx32, in the exportation of this connexin to the cell membrane, in the process of formation of GJIC plaques or in the recycling of the connexons. All these alterations would provoke the retention of the Cx32 in compartments of the endoplasmic reticulum, Golgi or lysosomes (Segretain and Falk 2004). In the present study, the MEL treatment stimulated the Cx32 expression. However, the connexin remained in the cytoplasm and did not stimulate the formation of GJ plaques in cell membranes. Moreover, growing experimental evidence supports the hypothesis that connexins can exert by themselves anti-proliferative effects that are independent of their functionality in intercellular communication. Such effects have been observed in a number cellular types including, glioma C6 (Bond *et al.*, 1994), bladder carcinoma BC31, (Krutovskikh *et al.*, 2000) and the breast cancer line MDA-MB-231 (Qin *et al.*, 2002). Although the mechanism responsible for the described effect remains unknown, some authors have suggested that interactions with transcription factors and regulation of gene expression of specific proteins, like the cell cycle regulator p27 could be involved in the effect (review, Jiang and Gu 2005). Consequently, the effects of MEL in the GJIC functionality and in the expression of Cx32 observed in the present work could be responsible, at least in part, for the antiproliferative and differentiating actions exerted by MEL in the same, HepG2 cell line (Cid *et al.*, 2004; Cid *et al.*, 2005.)

Although a number of in vivo and in vitro studies have described MEL/MF interactions on the growth and/or differentiation, the mechanisms responsible for these interactions remain unknown. In the present study, the exposure to a 50 Hz, 10 μ T MF did not influence significantly the functionality of the GJIC or the Cx32 expression in the absence of MEL. However, in MEL-treated samples, the exposure to the MF abolished the stimulating effect of MEL on the gap junctional activity and on the expression of Cx32. These results are consistent with those previously reported by our group (Úbeda *et al.*, 1995b) showing that a 30-minute exposure to a 50 Hz, 1.6 mT MF blocks MEL-induced increase in GJIC in C3H/10T1/2 cells. Úbeda and coworkers proposed that the MF could influence the regulation of the permeability of the GJ channels and/or the channels' renovation. Other authors have suggested that the MF could exert an influence on signal transduction pathways that regulate the cell cycle, through modifications in the functionality of cell membrane receptors, including the MEL receptors (Ishido *et al.*, 2001). Thus, in the present study, the antagonistic effects exerted by MF on the cellular responses to MEL could be due to a blocking of the MEL's stimulatory actions at different levels including GJIC regulation and signal transduction pathways that regulate the cell cycle.

SUMMARY

In the present work we studied the effects of a 50 Hz 10 μ T magnetic field on melatonin-induced responses on GJIC. The HepG2 human hepatocarcinoma cell line has been previously shown by our group to be responsive to a 50 Hz, 10 μ T MF, which acts on these cells as a promoter of proliferation when administered alone, but not in the presence of MEL. Conversely, MEL reduces the growth rate of HepG2 and the field antagonizes such a response. The present results show that at a 10 nM concentration the neurohormon melatonin stimulates GJIC and Cx32 expression in HepG2, a cell line that exhibit a low degree of functional GJIC and an aberrant expression of Cx32. On the other hand, the exposure to MF alone does not influence the GJIC parameters, but blocks the MEL-induced responses on GJIC. Consequently, the herein reported effects of MEL in the GJIC functionality and in the expression of Cx32 could be responsible, at least in part, for the antiproliferative and differentiating actions exerted by MEL in the same HepG2 cell line (Cid *et al.*, 2004; Cid *et al.*, 2005). Besides, the antagonistic effects exerted by MF on the cellular responses to MEL could be due to a blocking of the MEL's stimulatory actions at different levels including GJIC regulation and signal transduction pathways that regulate the cell cycle.

Abstract

Electro-permeabilization of biological cells has been proposed as a very efficient method in medicine for gene therapy, cancer chemotherapy, and drug delivery. Although the molecular processes involved in the permeabilization mechanisms are very complex, the formation of "pores" in the plasma membrane, under the influence of an electric field, is deemed responsible of the cellular responses. The model accuracy is crucial to understanding the behaviour of the cell. It must include the majority physical phenomena in order to obtain realistic results from the numerical scheme approximating the theoretical model (circuitual or field based). In this work an improved electrical model of the cellular membrane is presented taking into account the electro-permeabilization phenomena occurring under the action of electrical impulses. In particular, the presented model consists of a modified Hodgkin-Huxley-type non linear equivalent circuit for the cell membrane. The electroporation phenomena are considered by introducing a controlled current source in the basic model. The global cellular dynamics is examined for different characteristics (amplitudes, duration, rise and fall time) of the applied electrical pulses. The trans-membrane voltage and the conduction dynamics of the ionic channels are evaluated through an efficient simulation procedure.

Introduction

Since its introduction the conceptually simple model of the cell membrane behaviour, firstly proposed by Hodgkin and Huxley (HH) [1], has been widely studied in order to describe a wide class of biological phenomena associated to the transmission of information in excitable cells systems (see for example [2-3]). The HH approach has been employed to model electrical activation in a range of cell types including neurons [4], [5], ventricular myocytes [6], smooth muscles [7], etc. Although several studies have put in evidence that the HH model needs some improvements, its simplicity and efficiency in describing significant properties of the biological processes still motivate its use in medicine, biology, bioengineering etc.

The physical mechanisms allowing the development of excitable cell signal dynamics are based on the mutual interactions among ionic currents flowing through the membrane. The flux of the different ionic species taking place through channels across the cellular membrane is considered as a time continuous, deterministic and voltage-dependent phenomenon driven by the potential difference across the membrane (Trans-Membrane Voltage, TMV).

From an electrical point of view the cell membrane can be effectively modelled as a lumped parameter circuit, as shown in fig. 1. The membrane is represented by a capacitance, the ionic channels as linear or nonlinear conductances and the voltage generators are linked to the so called Nernst equilibrium potential, determined by the ratio of the specific ionic concentrations inside and outside the cell.

The TMV dynamics in response to electrical stimuli has been extensively analyzed in the literature on the basis of such a circuit model, thus allowing to infer or verify many interesting properties of the cell behaviour. In some cases the applied

electrical pulses are such that the number and dimensions of the pores on the membrane may be affected giving rise to the so called phenomenon electroporation [8-10]. The increased pore density on the cell surface determines an additional current path which has been traditionally modelled by a current generator characterised by a constant value. However, since the modification of the pores number and dimensions is dependent on the instantaneous value of the TMV, a more accurate model can be envisaged in which the current injection associated to electroporation is taken into account by considering a voltage dependent instead of a constant current generator.

Therefore, in this paper an accurate analysis of the electrical dynamics of the Hodgkin-Huxley cellular model is performed. The modifications induced by the voltage dependent electroporation generator is studied for different values of the amplitude, duration, rise and fall time of the applied electrical stimulus applied to a cell. The dynamics of trans-membrane voltage and conduction currents associated to the ionic channels are evaluated through an efficient simulation procedure. It is worth remarking that the aim of this first work is exclusively oriented to the numerical analysis of the modified HH circuit. The biological implications on the cell behaviour due to the obtained numerical results, which require complex and multidisciplinary research efforts, will be developed in future works.

Fig. 1 Cell membrane and associated Hodgkin-Huxley circuit model.

Proposed circuit model including electroporation

In the electric circuit of Fig. 1, the total ionic currents $i_{ions}(u, t)$ can be expressed as:

$$i_{ions}(u, t) = i_{Na}(u, t) + i_K(u, t) + i_L(u, t) = [g_{Na}^{max} \cdot m^3(u, t) \cdot h(u, t) \cdot (u - E_{Na})] + [g_K^{max} \cdot n^4(u, t) \cdot (u - E_K)] + [g_L^{max} \cdot (u - E_L)] \quad (1)$$

where g_c^{max} ($c=K, Na, L$) is the maximum value of the conductance corresponding to the largest aperture of the channel, m (or n) and h are two nonlinear variables describing the activation or inactivation of the channel and p and q are suitable exponents depending on the ion type, E_c is the Nernst voltage and $u(t)$ is the trans-membrane voltage. The Nernst voltage is linked to the ratio of the external and internal ionic concentrations $[C]$: $E_c \propto \ln \frac{[C]_{ext}}{[C]_{int}}$. In Tab. 1 the values of the typical parameters are reported.

It has to be noted that all voltages are referred to the value E_R assumed at rest across the membrane.

Tab. 1

C_m [$\mu F/cm^2$]	E_R [mV]	E_{Na} [mV]	E_K [mV]	E_L [mV]	g_{Na}^{max} [mS/cm ²]	g_K^{max} [mS/cm ²]	g_L [mS/cm ²]
1.0	-75.0	$E_R + 15.0$	$E_R - 2.0$	$E_R + 0.613$	120.0	36.0	0.3

In order to describe the electroporation phenomenon, a voltage controlled current generator is introduced through a branch in parallel as shown in Fig. 2. It accounts for the ions exchange between an external cleft space around the cell where charge build-up and depletion occurs, and the cell interior.

Its influence in the charge dynamics across the cell can be particularly remarkable when the TMV assumes high values and for quasi static variation.

A DETAILED ANALYSIS OF THE ELECTRICAL DYNAMICS OF THE HODGKIN-HUXLEY

The charge flow, governed by the ions concentration gradient, can be modelled by a current I_{ep} given by:

$$I_{ep} = N \cdot i_{ep} = N \cdot \left\{ \frac{\pi \cdot r_m^2 \cdot \sigma \cdot v_m \cdot R \cdot T}{F \cdot h} \cdot \frac{e^{v_m-1}}{\frac{w_0 \cdot e^{w_0 - n v_m} - n \cdot v_m}{w_0 - n \cdot v_m} e^{v_m} - \frac{w_0 \cdot e^{w_0 + n v_m} + n \cdot v_m}{w_0 + n \cdot v_m}} \right\} \quad (2)$$

where N is the pore density, r_m is the radius of the pore, σ is the conductivity of the fluid solution, F is the Faraday constant, R is the gas universal constant, T is the absolute temperature, h is the thickness of the cell membrane, w_0 and n are the energy gap and the length of the pore. $v_m = u(t) \left(\frac{F}{RT} \right)$ is the adimensional TMV. The pore density $N(t)$ is governed by a first order differential equation:

$$\frac{dN(t)}{dt} = \alpha e^{(u(t)/V_{ep})^2} \left(1 - \frac{N(t)}{N_0} e^{-q(u(t)/V_{ep})^2} \right) \quad (3)$$

where N_0 is the pore density for $u(t)=0$ and α , V_{ep} and q are suitable constants. In Tab. 2 the values adopted for the different quantities appearing in (2) and (3) are reported together with the initial condition considered for the integration of eq. (3).

Fig. 2 Proposed circuit model including the electroporation generator

Numerical experiments and results

Kirchhoff current law applied to the circuit of Fig. 2 gives:

$$C_m \frac{du(t)}{dt} = i_{ext} - [I_{ep} + i_L + i_{Na} + i_K]$$

The dynamic evolution of the TMV and the different current can be determined by evaluating at each time step the unknowns the 5 unknowns u , m , n , h , N :

$$\begin{aligned}
 \mathbf{Y} &= [m(u, t), h(u, t), n(u, t), u(t), N(t)]^T \\
 \left\{ \begin{aligned} \frac{d\mathbf{Y}}{dt} &= \mathbf{f}(t, m, n, h, u, N) = \mathbf{f}(t, \mathbf{Y}) \\ \mathbf{Y}|_{t=0} &= \mathbf{Y}_0 \end{aligned} \right. \quad (4)
 \end{aligned}$$

$$\mathbf{Y}|_{t=0} = \begin{bmatrix} m(u, 0) \\ h(u, 0) \\ n(u, 0) \\ u(0) \\ N(0) \end{bmatrix} \quad \mathbf{Y}_0 = \begin{bmatrix} m_\infty(E_r) \\ h_\infty(E_r) \\ n_\infty(E_r) \\ E_r \\ N(t=0) \end{bmatrix}$$

In order to solve the nonlinear equation system (4) a Runge-Kutta scheme has been implemented in a suitable numerical procedure written in C language. The effectiveness of such a numerical scheme has been proven in a previous work concerning a range analysis on a simpler circuit based on the HH model [11]

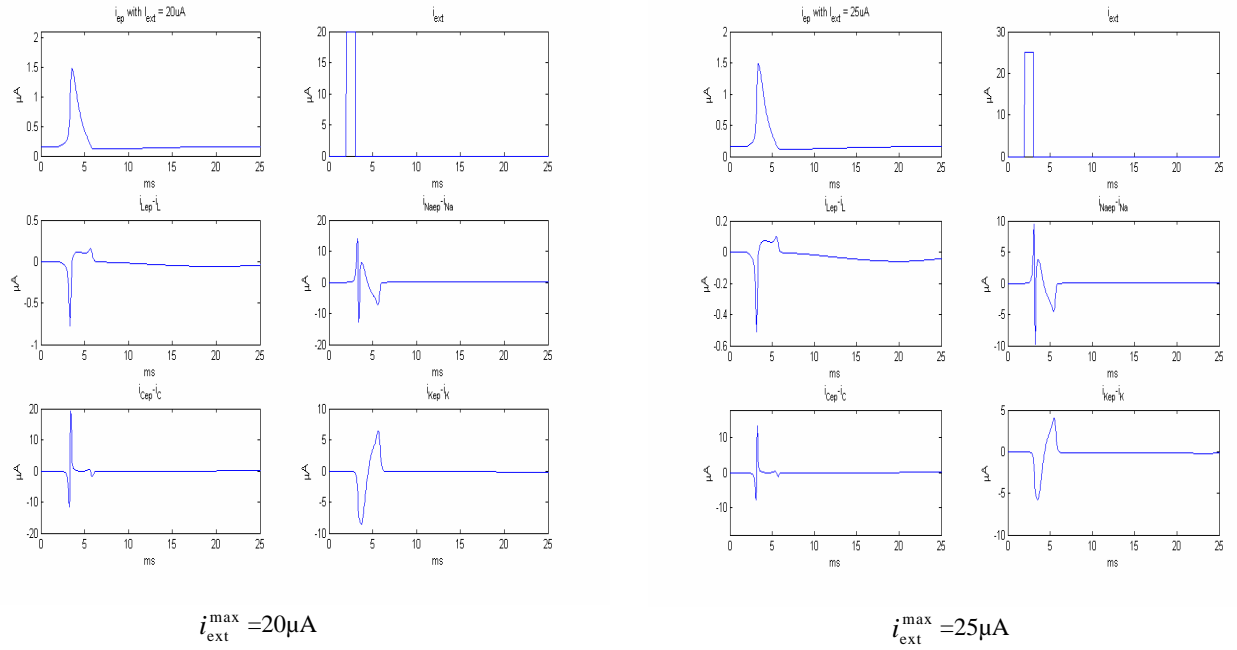

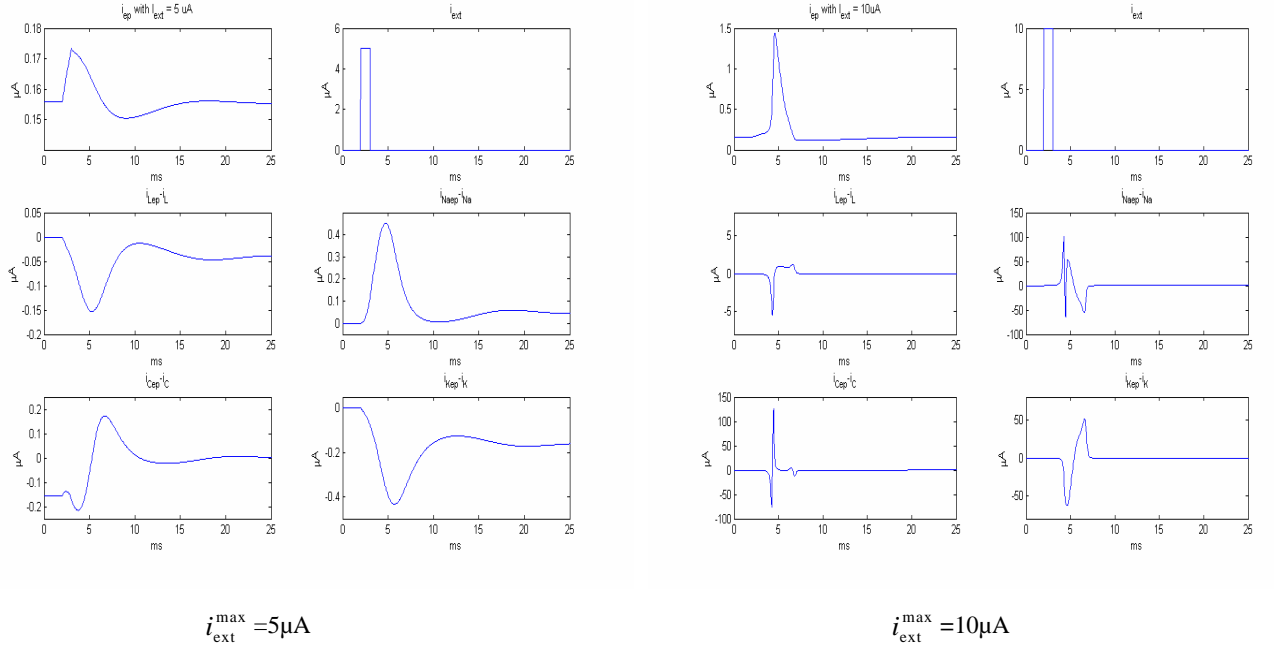

In order to envisage the influence of the electroporation generator on the TMV and different current components dynamics, the most relevant quantities appearing in the model have been calculated either with the classic HH model (i.e. the circuit of fig. 1) or with the modified one (i.e. the circuit of fig. 2). In particular, the different current components have been evaluated as a response to an applied external rectangular pulse i_{ext} characterised by a duration $\Delta t=1\text{ms}$ and by variable amplitudes ($I= 5, 7.5, 10, 15, 20, 25, 30, 40$ e $50\mu\text{A}$).

The effects of the electroporation generator is described by the plots of Figs 4, where the difference between the time evolution of the current components obtained in presence of such a generator (characterised by the suffix *ep*) or with the classic HH model are reported for the different values of the external current pulse.

As can be noted by the analysis of the presented simulation results, the greater influence of the electroporation generator is obtained for an applied pulse of $10\mu\text{A}$ where a very strong variation appears for ionic currents, especially those associated to Na and K channels, and for the displacement current i_{cm} through the membrane. For greater values of the external pulse amplitude the presence electroporation current becomes weaker as it concerns all the considered variables. In fact the pulse of about $100\mu\text{A}$ for i_{cm} and i_{Na} corresponding to an external pulse of $10\mu\text{A}$ reduces of about one tenth for an applied current of $50\mu\text{A}$. This findings are also summarised in Fig. 5, where the absolute value of the max discrepancies between the currents values obtained with or without the electroporation generator are presented.

A similar influence can also be noted for the TMV, as can be evinced from the results shown in Fig. 6. Even for this variable the more sensible effect of the presence of the electroporation is limited to applied current pulses of about $10\text{-}15\mu\text{A}$.

A DETAILED ANALYSIS OF THE ELECTRICAL DYNAMICS OF THE HODGKIN-HUXLEY

Conclusions

In this paper an analysis of the electrical dynamics of a modified Hodgkin-Huxley cellular model which takes into account the electroporation phenomenon has been performed. The modifications induced by a voltage dependent current generator emulating the electroporation has been studied for different values of the amplitude, of the applied electrical stimulus applied to a cell.

The dynamics of trans-membrane voltage and conduction currents associated to the ionic channels obtained by adopting an efficient simulation procedure put in evidence that the electroporation phenomenon is effective for moderate values of the applied current stimulus. The peak effect is obtained for an external pulse of about 10-15 μA . Greater values of the applied pulse induce a masking effect on the electroporation phenomenon: the dynamics of either the trans membrane voltage and the ionic currents become increasingly governed by the external pulse rather than the electroporation generator.

Abstract

A series of experiments was designed to determine the potential of EMF exposure to stimulate the immune system of chicken against infections that are common in farm practice.

In a first experiment 32 groups of six one-week old chicken were either (8) or not exposed (8) to *campylobacter* infection and exposed (16) to both infection and EMF treatment with an LF alternating field (Immument BV, 30 minutes per day, 6,5 μ T). Fresh excrement samples were taken on 6 different time points during the trial and were analyzed for the quantitative presence of *Campylobacter jejuni*. No difference in the course of this infection was observed between the non-treated and EMF treated groups.

Birds were weighed individually on day of arrival and subsequently on days 7, 14, 21, 28, 35 and 42. Feed intake is measured per cage on a weekly basis. A large and significant difference ($p < 0.0005$) in feed conversion (feed intake divided by growth) was observed between the EMF group (1.61) and the non treated group (1.75).

In a second and third experiment 32 groups of eight chickens were either (8+8) or not (8+8) exposed to infections with *Eimeria* parasite (coccidiosis) and either (8+8) or not (8+8) given the same EMF treatment as above. Thus all combinations of treatment and/or infection were given to 8 groups of eight chickens.

Feed conversion was determined as above. Infection course was determined by counting oocysts in excrement as above. Moreover intestinal lesions were scored (blind) as caused by the different *Eimeria* after the chickens were slaughtered after the growth period.

Feed conversion was equally good between the negative control and both EMF groups. For the EMF treated infected chicken feed conversion was better (1.52) than the non-treated infected chicken (1.62).

In both experiments a significant reduction ($p < 0.01$) in intestinal lesions caused by the different subspecies of the parasite was observed in the EMF treated group.

Introduction

For chicken farmers infectious disease poses the biggest problem both for animal welfare as economically.

Preventive antibiotics have been used as a growth promoter in animal production. These could eliminate infectious disease early, before the animals had to spend energy on the disease. In general up to 5% increase of growth could be achieved with preventive antibiotics. However, preventive antibiotics have been banned in Europe from animal feed since 2006, because of development of microbial resistance in humans.

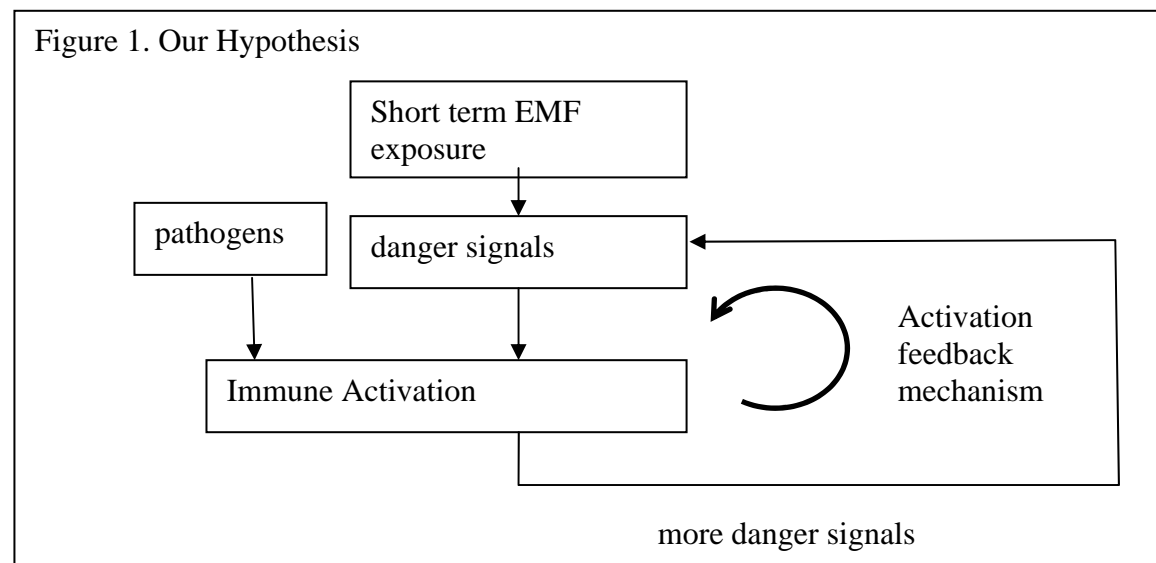

In chicken farming, hygiene and waiting periods between production cycles are measures that help against infectious disease for pathogens that cannot survive outside the host. However in particular *Coccidia* parasites with their long surviving spores are an infection that cannot in practice be avoided. Chemical/pharmaceutical agents against coccidia infection will be banned in the EU from 2012 onwards. This has led to a cessation of development of such agents. The farming community has the impression that the existing agents already increasingly lose their effectiveness due to development of resistance in the coccidia parasites.

Coccidiosis is a common infectious disease in poultry, causing major economic losses. The protozoan parasite of the genus *Eimeria* explosively multiplies in the intestinal tract of poultry and produces tissue damage, resulting in interruption of feeding and digestive process or nutrient absorption, reduced body-weight gain, dehydration and blood loss, and increase susceptibility to other diseases agents (McDougald, 2003) such as *Clostridium perfringens*, leading to necrotic enteritis (Helmond and Bryant, 1971; Maxy and Page, 1977; Shane et al., 1985).

Economically the damage due to coccidia infection is estimated at 10 points feed conversion (100 grammes more feed necessary for 1 kg weight growth), which translates into a result loss of 5 euro cts per chicken.

Immument has designed a technology in which low field strength (around 5 micro Tesla) LF EMF is applied for the treatment of chicken. In (Cuppen et al. 2006a), it is proposed that the working mechanism of this treatment is that LF EMF induces positive stress at cell level, which causes an increased production of cytokines (called

danger signals) that put the immune system in a higher state of alertness and activity.

This reduces the time that it takes for a self sustained immune reaction to pathogens to be established. Therefore pathogens have less time to multiply and damage is reduced.

Many studies have suggested that the immune response to *Eimeria* infection in part is mediated through the release of cytokines. Breed et al. (1997) reported that chicken peripheral blood leucocytes of *E. tenella* infected chickens produce interferon- γ after in vitro re-stimulation. Moreover, it has been shown that treatment of chickens with interferon- γ preceding infection with *E. acervulina* decrease the negative effect of infection on weight gain (Lowenthal et al., 1997).

The aim of this study is to determine the potential of the treatment with the Immune LF EMF signal as a weapon against infections in chicken that are common in practice.

Experiment design

Three experiments have been done, with 1) campylobacter infection, 2) coccidia infection with high infection pressure and 3) coccidia infection with lower, more practical infection pressure.

For the three subsequent experiments 192, 288 and 272 one-day old female broilers (Ross 308) are purchased from the hatchery. On day of arrival, they are wing-banded, weighed and randomly housed in wire-floor, suspended cages. Each cage is provided with thick foil and litter. Each test cage was provided with a 16 loop coil under the floor through which LF EMF treatment was administered for 30 minutes per day. No attempt was made to create a uniform field since in another experiment it was determined that effective field strengths lie between 0.1 and 50 micro Tesla. Moreover the practical application that is our goal will also not allow uniform field strengths. The field strength (rms) in the middle of the cage was set at 6,5 micro Tesla, measured with a F.W.Bell 5180 Tesla meter with sensitive probe. Dosimetry control during the experiment was ensured by constantly monitoring the (rms) current through the coil. The applied signal was designed by Immune, which contains several LF components with frequencies between 100 and 10.000 Hz.

Continuous lighting is provided throughout the experiment. The temperature in the cage at arrival is 32°C as required by one day chicken and is gradually decreased to ambient temperatures during the experiment.

Two different basal diets are produced for this experiment by Research Diet Services BV in Wijk bij Duurstede, The Netherlands: a starter diet (week 1 – 2) and a grower/finisher diet (week 3 – 6).

Feed and water were available ad libitum.

Treatment and control groups for the three experiments are indicated in Table 1.

IMMUNE STIMULATION IN CHICKEN BROILERS

Table 1. Test groups in 3 experiments.

-/+camp indicates without/with campylobacter infection; -/+cocc indicates without/with coccidia infection.

A	B	C	D
Experiment 1, 42 days, each replicate starts with 6 chicken, of which 2 are removed at random and analyzed on day 12. Infection pressure at day 6 with <i>Campylobacter jejuni</i> (indicated as +camp)			
Negative control, -camp 8 replicates	Positive control, +camp 8 replicates		EMF, +camp 16 replicates
Experiment 2, 35 days, each replicate starts with 8 chicken, 2 are removed and analyzed at day 21, 2 at day 28, 2 at day 36. Infection pressure (high) at day 15 with Coccidia (+cocc)			
Negative control, -cocc 8 replicates	Positive control, +cocc 8 replicates	EMF, -cocc 8 replicates	EMF, +cocc 8 replicates
Experiment 3, 35 days, each replicate starts with 8 chicken, 2 are removed and analyzed at day 21, 2 at day 28 and 2 at day 36. Infection pressure (low) at day 15 with Coccidia (+cocc)			
Negative control, -cocc 8 replicates	Positive control, +cocc 8 replicates	EMF, -cocc 8 replicates	EMF, +cocc 8 replicates

Measurements

Chickens are weighed individually on day of arrival and subsequently on days 7, 14, 21, 28, 35 and 42 in experiment 1, on day 13 in experiment 2 and day 8 in experiment 3, and on days 21, 29 and 36 in experiment 2 and 3. Feed intake is measured per cage on a weekly basis. Feed intake per broiler is calculated as feed intake per cage divided by number of broiler days. Mortality is registered on a daily basis, but rates are only calculated for the total period.

Statistical analysis

The oocyst values were logarithmically transformed ($\log_{10}(X + 1)$) to create a normal distribution before being analyzed, and lesion scores were transformed using multinomial transformation.

All performance data for each variable are subjected to an analysis of variance, in which the treatment (control vs. EMF) and infection (positive or negative) were the independent factors with the statistical program SAS.

The level of statistical significance is set at $P < 0.05$.

Infection with *Campylobacter jejuni* in experiment 1

On day 7, after collection of control excrement samples, water infected with *Campylobacter jejuni* C356 (ASG-Lelystad) ($\sim 1 \times 10^5$ per ml) is offered to the broilers in a separate drinking cup. For infection, broilers need to drink only 1 ml of this infected water. The birds had access to drinking water for 1 hour.

Collection of excrements in experiment 1

On days 7, 12, 19, 26, 33 and 40 plastic foil is placed on top of the litter in each cage in order to collect fresh excrements. After 2 hours, plastic is removed, fresh excrements are scraped of the foil and stored in plastic jars. Samples are sent to the laboratory the same day. Analysis of the excrements starts within 24 hours after collection according to the method of Jacobs-Reitsema et al. (1995).

Inocula and contamination procedure experiment 2

Sporulated oocysts of *E. acervulina* (W119, Weybridge), *E. maxima* (Weybridge), and *E. tenella* (Houghton) laboratory strains were obtained from the Animal Health Service, Poultry Health Centre (Deventer, The Netherlands). The number of oocysts per milliliter of suspension was counted with a hemocytometer (Fuchs-Rosenthal counting chamber). A volume containing sporulated oocysts (1.76×10^4 *E. acervulina*, 1.25×10^4 *E. maxima*, and 7.5×10^3 *E. tenella*) in K2Cr2O7 was transferred into a scaled plastic tube and the K2Cr2O7 was washed out by centrifugation. On day 15 of the experiment birds in 18 cages (144 birds) were individually infected. The sporulated oocysts were administered with 1 ml of tap water via a scaled 1-ml syringe directly into the crop.

Inocula and contamination procedure experiment 3

In this experiment a natural simulation of a coccidial infection within the broilers' test facility was developed. This was accomplished by seeding a portion of the litter with coccidial oocysts prior to broiler placement on new litter on day 15 of the trial. A similar dose of *Eimeria* species was used as in experiment 2, e.g. *E. acervulina*, *E. maxima* and *E. tenella*. Equal amounts of each species was mixed into the wood shaving and spread evenly across the back half of each contaminated group pens. The broilers picked up the oocysts from the seeded litter, mimicking a natural infection, as all birds do not pick up oocysts at the same time, which led to a progression of the infection as in the field. The non-infected broiler groups were reared in clean litter.

Infection measurements experiments 2 and 3Oocyst Count (OPG)

The oocyst per gram faeces (OPG) counting were performed on fresh faeces collected on days 15, 29, and 36 (days 6, 14, and 21 post infection). Oocyst shedding was assessed on one sample of homogenized faeces material collected from each cage. Modified MacMaster counting chamber techniques of Hodgson (1970) was used to determine the OPG in the homogenized faeces. A 10% (w/v) faeces suspension in a salt solution (1.1%) was made. After shaking vigorously, 1 ml of the suspension was pipetted into 9 ml-saturated sodium chloride (1.2%). After mixing again, a portion of the later suspension was run into the MacMaster chamber and the oocysts per gram faeces were counted.

Caecal lesions

Intestinal lesion scorings were performed blindly to the treatment modality on days 15, 29, and 36 (days 6, 14, and 21 PI). Two birds per cage (36 cages) were euthanized by cervical dislocation, dissected and different coccidial lesions were scored. The 0-4 scoring system described by Johnson and Reid (1970) was used. The scores for the individual birds of the same treatment group were summed up to arrive at a treatment value.

Results and discussionFeed intake and feed conversion

Daily feed intake per broiler is calculated as weekly feed intake per cage divided by so-called 'broiler days', which is the number of broilers per cage times the number of days corrected for drop outs. Data show that the feed intake of broilers of the EM group was significantly lower than the negative control group for all three experiments.

Feed conversion is calculated as the growth [g] divided by the feed intake [g] over the total period. The results of the feed conversion are shown in Table 2. Feed conversion of the broilers of the EM group with infection (as in practice) was significantly lower than controls for all three experiments.

Table 2: Feed conversion of broilers

Total period	Negative control	Positive control	EMF no infection	EMF w infection
Experiment 1	1.78 ± 0.02	1.73 ± 0.04		1.61 ± 0.03*
Experiment 2	1.58 ± 0.04	1.63 ± 0.04	1.57 ± 0.05	1.52 ± 0.06 *
Experiment 3	1.83 ± 0.03	1.84 ± 0.05	1.73 ± 0.03*	1.72 ± 0.03*

* significant (p<0.05)

Comparing negative control with EMF no infection, and positive control with EMF with infection results it turns out that in 4 out of 5 cases a significant and economically highly relevant improvement in feed conversion is achieved by EMF treatment. In chickens, one explanation for less feed uptake indicates could be less energy spent on developing infections. Given a certain amount of meat consumption this also translates in the corresponding 8% decrease in resource usage for meat production. Assuming that manure production is proportional to feed conversion minus 1 (the amount of feed *not* transformed into live weight) and assuming that digestion of phosphates in feed is 60%, this corresponds to a reduction in phosphate load, for equal end weight of the animals, to the environment of about 16%.

The calculation is as follows: Feed contains X per kg. The animal takes up $Y = X * 60\% * 1.84$. Excretion is $(X * 40\% * 1.84)$ without EMF and $(X * 1.72 - Y)$ in the second case. Reduction is $((X * 0.4 * 1.84 - (X * 1.72 - X * 0.6 * 1.84)) / (X * 0.4 * 1.84)) = 16\%$.

Moreover it should be noted that the reduction in feed conversion achieved rivals the best results achieved in comparable trials with preventive antibiotics (now illegal in animal feed in the EU). This indicates that EM treatment is as effective in suppressing infections and the resulting productive loss in chicken as preventive antibiotics were.

Microbiological analysis of excrements

Fresh excrement samples were taken on different time points during the trial and were analyzed for the quantitative presence of *Campylobacter jejuni* in experiment 1 and OPG count (oocyst shedding – parasite spores) in experiments 2 and 3.. The results are presented in Table 3.

Despite proper hygienic conditions the negative control group and negative EMF groups were also infected during the course of the experiment. Thus they became also infected groups, though there is no control of the level of infection.

Table 3:

	Negative control	Positive control	EM not infected	EM infected
Experiment 1, Amounts of colony forming units (cfu) of <i>Campylobacter jejuni</i> in excrements of broilers (expressed as 10 log CFU per g of excrement)				
Day 6	negative	negative		negative
Day 12	3.24 ± 0.61*	6.05 ± 0.15		5.78 ± 0.14
Day 19	5.71 ± 0.24	6.55 ± 0.08		6.37 ± 0.15
Day 26	5.25 ± 0.65	6.16 ± 0.23		6.60 ± 0.21
Day 33	4.58 ± 0.54	5.66 ± 0.24		5.88 ± 0.21
Day 40	6.20 ± 0.26	5.98 ± 0.17		5.53 ± 0.19
Experiment 2, OPG counts (oocysts per gram faeces, expressed as log ₁₀ (X+1))				
Day 21	0.00 ± 0.00	5.70 ± 0.35	0.00 ± 0.00	5.96 ± 0.06
Day 29	2.10 ± 0.69	4.02 ± 0.34	2.89 ± 0.66	3.86 ± 0.17
Day 36	4.10 ± 0.20	2.24 ± 0.52	3.87 ± 0.58	1.93 ± 0.59
Experiment 3, OPG counts (oocysts per gram faeces, expressed as log ₁₀ (X+1))				
Day 21	1.72 ± 0.87	4.03 ± 0.12	2.17 ± 0.83	4.11 ± 0.10
Day 29	3.26 ± 0.71	4.58 ± 0.18	2.05 ± 0.78	4.35 ± 0.27
Day 36	4.04 ± 0.27	3.82 ± 0.13	2.36 ± 0.71*	3.66 ± 0.23*

Results show that the infection with *Campylobacter* was significantly lower in the negative control group than in the other two groups on day 12. One week later, on day 19, infection with *Campylobacter jejuni* was similar for all three groups. Applying the EM field under the cages of the broilers had no effect on the infection rate of *Campylobacter* throughout the experiment in terms of bacteria excretion.

Also during experiments 2 and 3 cross-contamination occurred again in both uninfected groups despite proper hygienic conditions, which indicates that *Campylobacter* and *Coccidiosis* are both very infectious in practical circumstances.

OPG counts on day 29 and day 36 are numerically lower for infected EMF group compared to the infected control group and only in experiment 3 on day 36 this difference is statistically significant. More investigations are required to determine whether the EMF treatment can contribute to a diminished outbreak of a coccidiosis contamination.

Coccidial lesion scores in experiment 2 of intestines due to *E. acervulina* and *E. maxima* were significantly lower in the positive EMF group compared to the positive control group on day 21 (Table 4a). On day 14 of the experiment cross contamination was detected, but still lesion due to *E. maxima* of the EMF positive group was significantly lower than that of the positive control group. This might suggest that the EMF treatment counteracts the onset of a coccidiosis infection.

Table 4a: Mean lesion scores of intestines for experiment 2

	Control		EMF	
	- cocc	+ cocc	- cocc	+ cocc
<i>E. acervulina</i>				
Day 21	0.00 ± 0.00	1.95 ± 0.15	0.00 ± 0.00	1.19 ± 0.10*
Day 29	0.30 ± 0.11	0.90 ± 0.10	0.50 ± 0.13	0.63 ± 0.13*
<i>E. maxima</i>				
Day 21	0.00 ± 0.00	2.30 ± 0.15	0.00 ± 0.00	1.50 ± 0.13*
Day 29	0.45 ± 0.17	1.55 ± 0.20	0.63 ± 0.18	0.81 ± 0.19*
<i>E. tenella</i>				
Day 21	0.00 ± 0.00	2.65 ± 0.13	0.00 ± 0.00	2.00 ± 0.20*
Day 29	0.30 ± 0.12	1.00 ± 0.16	0.56 ± 0.18	0.69 ± 0.15*

During experiment 3 lesions scores of intestines were also determined (see Table 4b) due to the same *Eimeria* spp. These results show that the EMF treatment caused significantly lower lesions scores for all species investigated during the whole trial for both infected as well as uninfected groups, except for *E. acervulina* and *E. tenella* on day 21 (numerically lower).

Lesions scores of both infected groups in experiment 1 started at a similar level compared to the individual contamination of experiment 2, although lesions due *E. acervulina* were higher and lesions due to *E. tenella* were lower. Results further show that lesions scores decreased during the trial for both infected groups, which showed that the contamination by seeded litter is a good contamination method in order to study immunity against coccidiosis during natural contamination. Lesion scoring of both uninfected (control and EMF) groups increased during the trial, which shows that these broilers did not yet reach immunity against coccidiosis.

Table 4b: Mean lesion scores of intestines for experiment 3

It is unlikely that there is a direct effect of EMF on the *Eimeria* parasites. In literature there are no indications that organisms are directly and seriously damaged by EMF without an extremely high energy content. In our experiments, the energy levels are extremely low. On the other hand, cytokine production has been reported, as well as oxygen burst, both of which are instrumental in immune activation. It is therefore not unlikely that the reduction in pathology found is caused by a more effective immune reaction in the animal.

Mortality was almost equal between EMF and corresponding control groups in all experiments (11 vs. 12%, 7 vs. 7% and 16 vs. 14% total mortality respectively for experiments 1, 2 and 3).

Conclusions

The study indicates that

- LF EMF treatment does not seem to reduce a *Campylobacter* infection in broilers, which is in agreement with our hypothesis since this bacteria is a commensal for chicken and an enhanced immune system cannot be expected to fight it.
- LF EMF treatment reduces the damage, in terms of intestinal lesions of Coccidiosis infection in broilers. This supports the hypothesis that LF EMF can enhance the immune response.
- LF EMF treatment was shown in 4 out of 5 measurements to improve feed conversion up to 12 points. This is highly interesting to farmers economically, but also to society as a whole since it represents a decrease in resource usage of 8% and a decrease in phosphate load on the environment of 16%.
- Since feed conversion improvement is not restricted to the experiments where the chickens were actually suffering from (for them) relevant infections it seems that LF EMF improves the immune competence of the animals, independent of one particular infection.

IMMUNE STIMULATION EFFECTS IN FISH AND FISH IMMUNE CELLS THROUGH WEAK LOW FREQUENCY ELECTROMAGNETIC FIELDS WITH VARIABLE FIELD STRENGTH

Abstract

A series of experiments (n=14) was designed to determine the potential of LF EMF exposure to stimulate the immune system of fish.

Common carp head kidney-derived phagocytes were used to determine respiratory burst activity as a measure for immune activation. Exposure to the Immune LF EMF signal at 5 μ T or 1,5 mT led to 42% or 33% increase in immune activity, respectively, compared to negative control values. EMF could also additionally stimulate chemically pre-stimulated samples up to 18% (5 μ T) or 22% (1,5 mT). Statistical analysis was carried out with SAS via a meta-analysis of the 14 datasets. A significant ($p < 0.0001$) increase on the response of the EMF exposed cells was found.

Subsequently, a series of experiments were performed using live goldfish. During transport from the grower commercial goldfish suffer from heavy parasitic and microbial infections to such an extent that without treatment high mortality will be observed over a period of a few weeks.

Groups of fish were housed under equal conditions in at least 4 control tanks and 8 to 16 EMF-exposed tanks. Exposure was done at field strengths between 0,15 and 50 μ T by coils positioned around the outside of the fish tanks, creating a predominantly vertical field.

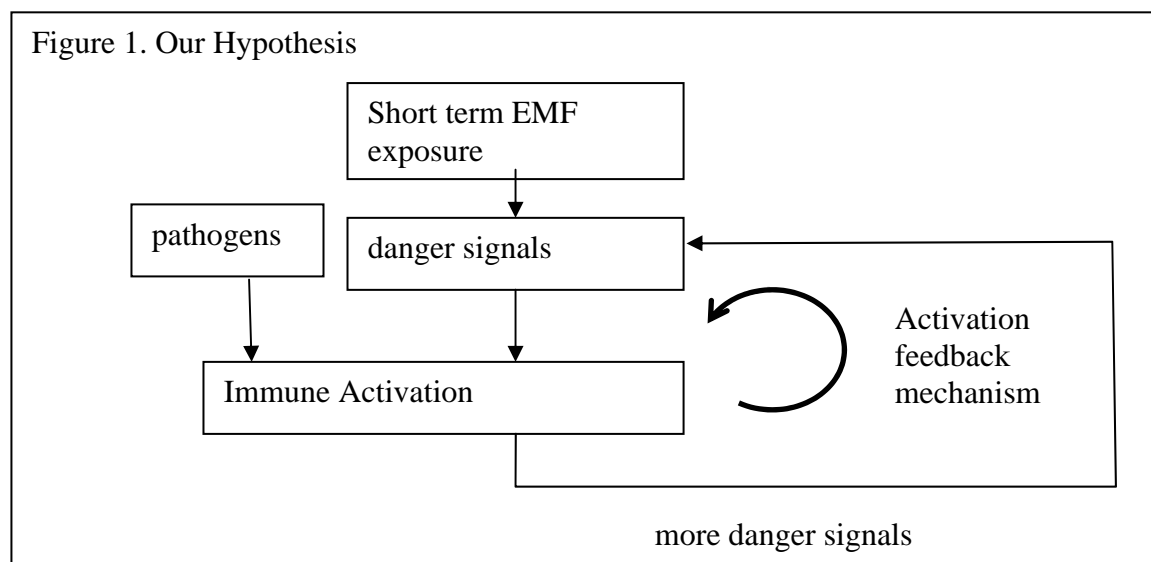

In the experiments without treatment mortality was about 50% after 18 days, while the treatment at 5 μ T reduced it to 20%.

In a third experiment the treatment field strength was varied between 0,05 μ T and 50 μ T in 6 steps. The decrease in mortality after EMF exposure was equally strong between 0,15 and 50 μ T and only slightly less strong at 0,05 μ T. In a fourth experiment the field strength was further reduced to 0,01 and 0,003 μ T. The effect is gone at 0,001 μ T and below, while the situation between 0,003 and 0,06 μ T an increasing dose response is visible.

Introduction

Immune has designed a proprietary low field strength (around 5 micro Tesla) LF EMF treatment, aimed at stimulating the immune system. In another paper in this proceedings (Cuppen et al. 2006a), it is proposed (see Fig. 1.) that the working mechanism of this treatment is that LF EMF induces stress at cell level, which causes an increased production of cytokines (called danger signals) that put the immune system in a higher state of alertness and activity. This reduces the time that it takes for a self sustained immune reaction to pathogens to be established. Therefore pathogens have less time to multiply and damage is reduced.

In aquaculture and farming, infectious disease is one of the biggest, if not the biggest problem and challenge, economically as well as in terms of animal welfare and environmental pressure. "Disease is the biggest single impediment to aquaculture development," said Rohana Subasinghe, Senior Fisheries Research Officer at the United Nations' Food and Agriculture Organization (FAO). Total damage in aquaculture of infectious disease is estimated at 9 billion \$ yearly. In Ecuador in 1999 70% of the crop of farmed shrimp was lost due to a single virus infection, that led to a national crisis and a loss of 150.000 jobs. Environmentally, infectious disease causes a lot of pressure: by the chemicals and pharmaceuticals used, by the pathogens that multiply in farms and increase disease pressure on the surrounding wildlife, and by the pressure on farmers to abandon farms with disease and start new farms in nature areas.

Fish and other aquatic animals such as shrimps are particularly vulnerable to infectious disease because they have no, or much less adaptive immune system and have no transferred immunity from the mother.

Simkó, Droste, Kriehuber and Weiss (2001) and Lupke, Rollwitz and Simkó (2004), have demonstrated that human and murine macrophages can be stimulated to higher activity through LF EMF. In this research we will likewise determine the effect of the Immune signal at cell level by measuring oxygen burst, and then proceed to in vivo experiments aimed at demonstrating, and then optimizing the effectiveness of Immune treatment on fish.

Materials and methods

In vitro experiments

Common carp head kidney-derived phagocytes were used to measure oxygen burst activity as a measure for immune activation.

Oxygen burst causes a marked increase in oxygen uptake, which is mainly channeled to a pathway initiated by the reduction of oxygen to super oxide anion (O_2^-), using NADPH or NADH as the electron donor. The O_2^- is subsequently converted to hydrogen peroxide (H_2O_2) with the aid of the enzyme super oxide dismutase (SOD).

The objective of this test is to measure the modulation of the oxygen burst activity in macrophages and neutrophilic granulocytes of the carp pronephros, or head-kidney.

The measurement is based on the reduction of a salt: Nitro Blue Tetrazolium NBT by O_2^- . This results in a blue color, which is measured spectrophotometrically.

Biochemical Materials

Phorbol 12-myristate 13-acetate (PMA), 0.01 $\mu\text{g}/\mu\text{l}$, a standard chemical stimulant of Oxygen burst in leukocytes known to give a high response as a positive control

RPMI without phenol red: washing and culture media (the red indicator dye disturbs the final reading on the spectrophotometer)

Nitro Blue Tetrazolium in RPMI without phenol red. (NBT; grade III) 1 mg/ml final concentration

2N KOH (Potassiumhydroxid)

100% and 70% methanol

Dimethylsulfoxide (DMSO)

flat bottomed 96-well microtiterplate (sterile) coated with adherent cells

spectrophotometer with filter at 690 nm

Biochemical Methods

Leukocytes are collected from the head kidney and placed at 4 degrees Celcius overnight. Next, they are plated

out in 96 well trays with 100 μ l in each well. The cells are allowed to adhere for 30 mins at 27 °C (5 % CO₂, humidity 100 %). After inspection, non-adherent cells are washed away by rinsing twice with 100 μ l of RPMI-phenol red culture medium (one row at a time).

The NBT assay is started by removing the supernatant and by adding 150 μ l of NBT and subsequently the stimulators (10 μ l of PMA and/or 30 mins EMF), followed by or, in case of EMF, in parallel to incubation of the cells for 90-120 minutes at 27 °C (5 % CO₂, humidity 100 %).

After the incubation, the NBT solutions are removed and the cells are washed once by rinsing with RPMI medium without phenol red. The remaining cells are fixated for 5 minutes with 100 μ l 100 % methanol, then washed twice with 100 μ l 70 % methanol to remove possible NBT-rests. The plate is left to dry.

The blue formazan inside the cells is solubilized in 100 μ l 2N KOH to which 100 μ l DMSO is added. The content of the well is mixed thoroughly.

The optical density is measured at 690 nm (ref. filter at 414 nm) in a spectrophotometer.

EMF materials

An exposure magnet was designed for exposing one or two rows of a 96 well plate simultaneously. Since earlier experience indicated cross talk to controls at enormously low field strengths we aimed for the lowest fringe fields possible. Based on experience from MRI magnets, eight Ferrite C arm units were built (six used), each for exposing one or two rows of a 96 well plate to a uniform AC magnetic field. The “C” of the magnet was built of 16 mm² Ferrite 3C90, the pole shoes were 99x30x8 mm. above and below the pole shoes, coils with 600 turns each were placed around the C arm. Saturation in the ferrite occurs above 170 mT, therefore this setup allowed a field strength of 5 mT to be achieved in the exposure gap without saturation effects in the C. A uniformity of 10% or better was achieved at the well positions.

Side ways, the fringe field was measured to decrease by at least a factor 2 every 2 cm. Thus at a distance of 5 meters (which was kept for the controls) one may safely assume the fringe field to be below 1 pT. It was no longer measurable with our equipment at 1 m distance.

Signals were generated by an Immune signal generator, capable of generating field strengths between 0,15 μ T and 1.5 mT in the exposure area, with a proprietary signal consisting of several LF components with frequencies between 100 and 10.000 Hz.

The signal generator monitored currents through the coils during the experiment, which were calibrated to correspond to the desired field strength using an F.W.Bell 7000 Tesla Meter with sensitive probe.

Experiment design

Each run measured 48 samples, in six groups of 8 samples. Half of the groups were not chemically pre-stimulated (negative) and half were pre-stimulated with PMA (positive). Two groups were taken as controls, while EMF stimulation was done on four groups, two at 5 μ T field strength and two at 1,5 mT field strength.

Exactly those runs were included in the results where the positive control average exceeded the negative control average by at least 50%, independent of the measurements for the EMF exposed cells. If that is not the case it must be assumed that the cell isolation was not properly done. This led to the exclusion of 6 runs out of a total of 20 runs executed.

In vivo experiments

Subsequently, a series of experiments were performed using fantail goldfish (*Carrassius auratus spp.*), heavily infected with ecto parasites (gill parasites) such as *dactylogyrus/gyrodactylus*, *trichodina*, *chilodinella* and *costia*. Infection with those parasites occurs consistently at the grower and increases during storage, packing and international transport due to crowding. This and subsequent secondary bacterial infections cause high mortality if not treated. The progress of the diseases can be measured by daily counting and removing dead fish over a period of a few weeks. Fish were randomly allotted over the tanks. Individual fish weight was 2.5 (\pm 0.5 g)

Daily, the fish were checked for health. Dead fish were counted, removed and discarded.

The number of fish per replicate tank varied between the experiments, 12 in the first and second experiment, 21 in the third, and 30 in the fourth.

Fish were housed in PVC tanks with a content of 30 liter. Aeration of water and daily change of 20 % of the water maintained water quality. Fish were fed commercial feed ad libitum.

Groups of fish were housed under equal conditions in at least 4 control tanks and 8 to 16 EMF-exposed tanks. Exposure was done at field strengths between 0,15 and 50 μ T by coils positioned around the outside of the fish tanks, creating a predominantly vertical field. Lower field strength exposures were achieved by placing additional tanks in the stray field of a tank with a coil, calibrating that stray field to the current in the coil, and then controlling the current.

The tanks were standard PVC tubs of 50 cm height, 30 cm diameter, around which standard isolated 1.5 mm² electricity wire was tightly wound in 160 turns. At the lower end a spiral end cap of 12 turns over the outer half of the diameter and at the top flange 20 additional turns were wound to optimize uniformity in the tub. Thus inside the tubs a practical, but close approximation was achieved of the field of a long solenoid coil. The deviation of the theoretically uniform field of the solenoid was calculated using Vector Fields software by dr. Johan Overweg of Philips Research, MRI section, and is better than 5% in the water volume further than 4 cm from the lower outside circumference of the tub, and better than 20% further than 2 cm from that outside circle. The signal generator was as described above for the in vitro experiments.

Results and discussion

In vitro experiments

Oxygen burst measurements were averaged over the 8 samples available in each group. Averages of the measurements without pre-stimulation and of the positive control group (with pre-stimulation) were divided by the negative control average in the corresponding run. The averages of pre stimulated measurements were divided by the corresponding positive control average. The resulting data, with standard deviation estimates derived from the data in each group, are given in Table 1.

Oxygen burst was increased in 12 out of 14 cases after 5 μ T treatment, in 11 out of 14 cases after 1,5 mT treatment. With pre stimulation, oxygen burst was further increased in 9 out of 14 cases at 5 μ T, and in 12 out of 14 cases at 1,5 mT.

On average, exposure to 5 μ T or 1,5 mT led to 42% or 33% increase in immune activity, respectively, compared to negative control values. EMF could also additionally stimulate PMA-stimulated samples up to 18% (5 μ T) or 22% (1,5 mT). Statistical analysis was carried out with SAS via a meta-analysis of the 14 datasets. A significant ($p < 0.0001$) increase on the response of the EMF exposed cells was found.

These data are in line with those reported for 50 Hz, sinusoidal, 1 mT fields in murine and human macrophages in Simkó et al. 2001 and Lupke et al. 2004.

In vivo experiments

The subsequent series of experiments with diseased goldfish returned the following results. In each graph mortality is indicated in % of the total number of fish in each test group, as it develops over the course of the experiment. As can be seen the horizontal mortality lines after day 20 in experiment 3 (no further mortality), after 18 to 20 days usually the surviving fish had recovered from the diseases both in the control and the test groups, as was confirmed by visual inspection. Most test groups consisted of at least 4 replicates, in which the number of fish initially was gradually increased after more experience was gained. For some experiments

however with gradually varying parameters 2 replicates were taken.

Please note that in each experiment a new batch of fish was procured from the importer of the fish. Fish from groups heavily infected with parasites were selected. However the initial disease/health level of the fish varies between experiments. The absolute levels of survival between experiments are therefore not comparable. Within one experiment the fish had comparable health so the comparisons within one experiments are valid.

The first experiment compared survival in 4 control groups with 8 groups treated at 5 μ T. Each group contained 12 fish.

Figure 2. Experiment 1.

As can be seen there is a large difference in the survival, which was consistently more than 80 % better in the treated group over the course of the experiment. The end values were 52% \pm 14% untreated and 19% \pm 10% treated. The experiment was repeated, this time with 12 treatment groups of 12 fish each.

Figure 3.

This time the improvement was again a factor 2. The end values were 52% \pm 8% untreated and 26% \pm 19% treated.

In order to find out more about the field strength dependency of the effect and to determine the required distance between tubs for parameter variation experiments, a next experiment was done with varying field strength. There

were 4 control groups and 2 test groups for 6 different field strengths varying from 0.15 to 50 μT . Each group contained 21 fish initially.

Figure 4.

In this figure for 6 different field strength, ranging from 0.15 μT (thin solid line) to 50 μT (thick, long dashed line) the mortality development is given as before. Again, the control groups suffered mortality increasing to 52% on day 28 (upper, thick short dashed line). The average of all treatment groups is also given (thick solid line), this increases to 15% at day 28. The end values were 52% \pm 29% untreated and 15% \pm 11% treated (all together). Again, the treatment resulted in a strong decrease in mortality at all field strength levels. The final percentages at day 28 are given for clarity also in Figure 5.

Figure 5.

The result indicated that the decrease in mortality after EMF exposure was equally strong between 0,15 and 50 μT , except at 15 μT . There seems to be a decrease in effectiveness from 0,05 μT downwards which becomes noticeable at 0,015 μT .

Since for our application especially the lowest field strength range is important a follow up experiment was performed that simulated lower field strength than $0,15 \mu\text{T}$ by placing test tubs in the stray field of a $5 \mu\text{T}$ tub. This was done because the voltages and currents needed to create such small fields are so low that electronic noise became too high. The $5 \mu\text{T}$ tub is built as a solenoid coil along the complete height of the tub. Such a solenoid coil has a small but rather uniform stray field that is suitable for the analysis that we wished to perform. The result is given in Figure 6.

Figure 6.

From the $0,06 \mu\text{T}$ group in Fig. 6 one replicate was lost due to a technical problem.

It can be observed that over the whole period mortality is highest in the control group and lowest in the group treated at $5 \mu\text{T}$. From day 7 onwards mortality is strictly increasing with decreasing field strength.

Even at $0,003 \mu\text{T}$ (3 nT) these results indicate that there still is an effect of the treatment.

These results indicate that in order to be reasonably confident that there is no influence of EMF on control groups one must go to field strength levels of 1 nT or lower.

Conclusions

This research shows that the ELF EMF treatment as used by Immunent is capable of stimulating the immune system. On a cell level phagocytosing cells have been shown to become more active after treatment. This result was obtained at $1,5 \text{ mT}$ as well as at $5 \mu\text{T}$.

On the level of the whole organism it was shown that at and around $5 \mu\text{T}$ the survival of diseased fish could be greatly improved by the treatment. In the light of the cell experiments also reported on, it is likely that this is based on an increased immune activity of the fish. The effect is present in a large window of field strengths around $5 \mu\text{T}$, and one must go to the level of 1 nT or lower to be confident that the effect is no longer present. Proper distances between controls and test tubs are therefore important.

Because of the low field strengths required, and the surprisingly large effects on animal health, the results indicate that practical application with important economic advantages for farmers is possible. Moreover, the new experimental model used in this study can be important for bioeffects studies for EMF in general.

ENVIRONMENTAL ANALYSIS OF THE ELECTRIC FIELD DUE TO MV OVERHEAD LINES SUPPORTED BY CONCRETE POLES

D. DESIDERI, A. MASCHIO, E. POLI

UNIVERSITY OF PADOVA, DEPARTMENT OF ELECTRICAL ENGINEERING
VIA GRADENIGO 6/A, I-35131 PADOVA (ITALY)

Abstract

This paper presents an environmental analysis of the electric field due to MV overhead lines supported by concrete poles with a pole-top-pin construction. A three-phase system of voltages has been applied to an electric model of the configuration and a three-dimensional numerical analysis has been done by using the charge simulation method. The time variation of the electric fields at the frequency of 50 Hz has been numerically computed and the obtained results have been experimentally validated by means of an extensive campaign of measurements. The preliminary set-up checks in order to minimize the perturbation error due to the measurement instrument are described. The rms values of the three components of the electric field have been measured and the data obtained around a MV line, at different heights (up to 2 m from the ground), far and near a supporting concrete pole are reported. A significant result is that the electric field at the pole surface at the height of 2 m is greater than the one at the same level under the line in the midpoint of the span.

Introduction

A three-phase MV overhead power line is relevant to an environmental analysis of the electromagnetic field in the ELF range. Poles made in reinforced concrete are extensively used as line supporting structure [1, 2], but their inclusion in the electric field evaluation is not easy. In fact, the electric field analysis far from the concrete poles, e.g. in the midpoint of the span, is a well-known case, and a bi-dimensional (2-D) model can be used obtaining good results [3, 4]. On the contrary, the inclusion of a supporting conductive structure is complicated, requiring the use of a three-dimensional (3-D) model [5].

In the following the results of an analysis on a pole-top-pin configuration used in MV overhead lines are referred. The paper is split in three sections; the first section reports the numerical analysis of the configuration, starting from an electric model, and then describing the numerical method and the obtained results. The second section reports the extensive campaign of measurements performed, whose data have been used for the validation of the numerical results. The third section presents a discussion of the results. The conclusive remarks have been reported in a final short summary.

Numerical analysis

a) *Electric model of the pole-top-pin construction*

The simplified structure of the analyzed MV overhead line supported by concrete poles with a pole-top-pin construction is shown in fig. 1. The three wires are represented by three straight cylindrical conductors; each one of them will be referred to in the remainder as "overhead conductor"; the axes of the conductors are parallel to each other and to the ground. The diameters of the overhead conductors (\varnothing) are the same. A three-phase system of voltages is applied to the overhead conductors.

The supporting concrete pole (referred to in the remainder as "pole") is assumed to be a cylindrical conductor, with vertical axis and radius R of the cross-section. The pole is assumed equipotential with the ground.

A Cartesian coordinate system has been adopted, where z is the vertical pole axis and x is the direction of the central overhead conductor (fig. 1).

The height of the pole is a . The axis of the central top overhead conductor (marked with 2 in fig. 1) is high b over the top of the pole, while the axes of the two lateral overhead conductors (marked with 1 and 3 in fig. 1) are high a over the ground and distant c from the pole axis.

In MV overhead lines with a pole-top-pin construction different values are used for the geometry, i.e. for the pole height, the pole diameter, the spacing of the overhead conductors, or the wire diameter. Among all the cases, for the numerical analysis an average value for a and typical values for the other parameters have been

chosen. The following values have been taken: $a = 10.5$ m, $b = 0.8$ m, $c = 0.76$ m, $R = 0.1$ m, and $\varnothing = 0.01$ m [1, 2].

Fig. 1 Three-phase MV power line: overhead conductors, pole and ground.

b) The charge simulation method

The electric field around the MV power line was computed by using the charge simulation method (CSM). In this method conductors and their surface charges are replaced by simulating charges placed inside the equipotential contours of the conductors [6-9]. The presence of the ground plane is taken into account by a corresponding set of image charges. The charge density is initially unknown but is readily calculated when potentials are set on a number of points of the contours. Then potentials and electric field can be computed everywhere. The accuracy of the method is tested, by determining potentials and fields on control points of the conductors different from those at fixed potential.

In this study, uniformly charged segments have been used. A section of the MV line, extending 30 m apart from the pole on both sides, was considered: the equipotential contour of each overhead conductor was simulated by means of 60 couples of segments, symmetrically placed close to the axis and parallel to it, one twentieth of the radius apart from the axis. Other 70 couples of segment charges were arranged in the same way to simulate the pole equipotential contour. These 70 couples were placed on two axes, parallel to the pole axis and at opposite sides to it along y .

The accuracy was tested following two different, widely used, criteria, on potentials and on fields [7]. With 1 kV applied on one phase and 0 V on the other two, an electric potential difference generally lower than 0.2 V was found on control points. Furthermore, the ratio between tangential and normal components of the electric field on control points on the surface of the conductors was calculated, and resulted to be generally lower than 0.01 (i.e. a deviation of less than one degree of the direction of the computed field from the normal to the surface of conductors).

It is worth noting that the charge simulation method was chosen in this study because it allows to compute the electric field with a very small number of simulating charges: for the calculation, a matrix of only 500x500 elements shall be solved. Consequently, each computation run requires about 5 seconds on a PC with 256 MB RAM, 1.8 GHz Pentium IV.

c) Electric field computations

It is well known [1, 2] that the electric field around a three-phase transmission line is generally a vector rotating in a plane, where it draws an ellipsis. In order to get the complete description of the ellipsis, in this research the field was computed by means of the CSM at different times along the whole cycle: the direction and magnitude of the electric field at its maximum and minimum were recorded, giving the major and minor axes of the ellipsis and the plane where it lies.

In order to achieve this result, the three contributions to the electric field due to each conductor at unit potential, while the two others are at zero potential (with the pole always at zero potential), were computed.

Indicated with $\mathbf{E}(x, y, z, V_1, V_2, V_3)$ the vector of the electric field in a point x, y, z due to the potentials V_1, V_2, V_3 applied to the three overhead conductors 1, 2 and 3, the contributions are:

$$\begin{aligned}
\mathbf{E}_1(x, y, z) &= \mathbf{E}(x, y, z, 1, 0, 0) \\
\mathbf{E}_2(x, y, z) &= \mathbf{E}(x, y, z, 0, 1, 0) \\
\mathbf{E}_3(x, y, z) &= \mathbf{E}(x, y, z, 0, 0, 1)
\end{aligned} \tag{1}$$

and the total electric field is:

$$\mathbf{E}(x, y, z, V_1, V_2, V_3) = \mathbf{E}_1(x, y, z) V_1 + \mathbf{E}_2(x, y, z) V_2 + \mathbf{E}_3(x, y, z) V_3 \tag{2}$$

The potentials V_1 , V_2 , V_3 have been set with reference to a three-phase line voltage of 20 kV rms: 3600 values have been computed with an iteration process, by increasing the phase of 0.1° each step, in order to cover the whole cycle of 360° .

Recording the maximum of E_x , E_y and E_z , their rms value can be computed simply dividing the maximum by $\sqrt{2}$. Moreover the rms value of the intensity of the total electric field results as the root sum square of the three rms values of E_x , E_y and E_z .

Finally, the major and minor axes of the ellipsis are found by recording the maximum and minimum of the magnitude of $\mathbf{E}(x, y, z, V_1, V_2, V_3)$, while the values of the three components E_x , E_y and E_z at the maximum and the minimum give the direction of the axes.

d) Numerical results

As a first analysis, the rms values of E_x , E_y and E_z on the plane $y = 0$ have been considered up to $z = 2$ m. The numerical results of E_x , E_y and E_z at $z = 1$ m and at $z = 2$ m are reported in fig. 2, respectively on the left, at the centre and on the right. The data are reported up to 10 m from the pole.

Fig. 2 Numerical results of E_x (left), E_y (centre), E_z (right) at $y = 0$, $z = 1$ m (continuous lines) and at $y = 0$, $z = 2$ m (dashed lines).

The effect of the pole is clear. At the pole, the electric field is normal to the pole surface. E_x is large, while E_y and E_z are null.

Moving from the pole in the x direction, from fig. 2 it can be seen that E_y quickly reaches the same value that is found far from the pole, i.e. at the midpoint of the span at $y = 0$. In particular the effect of the pole for E_y is extremely localized. E_x and E_z reach the same value found far from the pole approximately after a few meters. Increasing x , at $y = 0$, E_x tends to zero, while E_z increases its value at the one expected at the midpoint of the span.

It can be noticed that the reinforced concrete pole makes E_x at the pole even higher than the values of E_y and E_z evaluated at the midpoint of the span.

A second analysis has been performed at $x = 0$ and at $x = 5$ m and the rms values of E_x , E_y and E_z have been considered again up to $z = 2$ m. The values at $x = 5$ m are assumed not affected by the pole, as indicated by the data reported in fig. 2. On the other hand, the data at $x = 0$ are reported to analyze the effect of the pole in the y direction.

The numerical results of E_y and E_z at $z = 1$ m and at $z = 2$ m are reported in fig. 3 and fig. 4 respectively, showing on the left the value at $x = 0$ and on the right the value at $x = 5$ m. The data are reported up to $y = 10$ m. Again, at the pole, the electric field is normal to the pole surface. At $x = 0$, on the pole surface, E_y is large, while

E_x and E_z are null. It is worth noting that the value of E_y at the pole surface is equal to E_x , at the pole at $y = 0$, as shown in fig. 2.

At a few meters from the pole E_y has the same value at $x = 0$ and at $x = 5$ m, and E_z behaves in the same way. It is again confirmed that at this distance the pole effect is negligible.

From the numerical analysis it results that E_x is null at $x = 0$, as expected from the symmetry of the configuration, and quite small (only few volts per meter) at $x = 5$ m and z not greater than 2 m.

Fig. 3 Numerical results of E_y on the left at $x = 0$, $z = 1$ m (continuous line) and at $x = 0$, $z = 2$ m (dashed line); on the right at $x = 5$ m, $z = 1$ m (continuous line) and at $x = 5$ m, $z = 2$ m (dashed line).

Fig. 4 Numerical results of E_z on the left at $x = 0$, $z = 1$ m (continuous line) and at $x = 0$, $z = 2$ m (dashed line); on the right at $x = 5$ m, $z = 1$ m (continuous line) and at $x = 5$ m, $z = 2$ m (dashed line).

A third analysis was done on the magnitude and on the direction of \mathbf{E} at its maximum and minimum, thus identifying the axes of the ellipsis drawn by the field. The direction can be indicated by means of the angles of the vector of the field with the three coordinate axes. As an example, in the plane $z = 2$ m and on $x = 0, 0.5, 1$ and 5 m, the magnitude of the field vector and its minor angle ($0 \div 90^\circ$) with the vertical axis z , as a function of y up to 10 m, are reported in fig. 5, on the left and on the right respectively.

About the angle with the z direction, at $x = 0$, it is noticed that on the pole surface only a field at 90° with z is allowed, while, increasing the distance from the pole, the angle is reduced to 20° at $y = 2$ m, is almost null at $y = 5$ m, and is about only 10° for greater distances. Near $y = 0$, at $x = 0.5$ m the influence of the pole gives still a deviation of about 70° from the perpendicular, while at $x = 1$ m the angle is reduced to 40° . Finally, for $x = 5$ m the angle with the z direction is generally equal or less than 10° for any y up to 10 m.

It is interesting to note that also the data reported in fig. 5 show that the influence of the pole tends to vanish at a distance of a few meters, in agreement with the observations done on the electric field components.

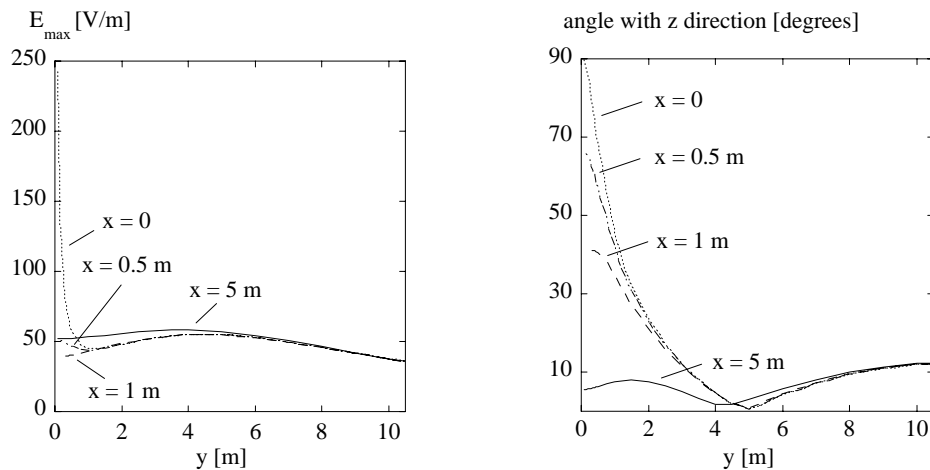

Fig. 5 Numerical results of E_{\max} and the angle with the z direction versus y at different values of x .

Experimental results

a) Instrumentation and perturbation error

The instrumentation used for the electric field measurement consisted in a PMM EHP-50C probe, connected via an optical fibre to a PMM 8053 portable field meter.

The probe is approximately a cube with 8 cm side. The experimental data are referred to the barycentre of the probe: therefore with the probe placed on the ground, the z quote is 0.04 m.

The probe was taken at a distance of at least five meters from the PMM 8053 and the operator. The PMM 8053 unit was set to measure electric fields in the frequency range $6 \div 500$ Hz; the display showed the rms value of the total electric field, together with the rms values of the three field components along the probe axes. The system allows the analysis resolved in frequency of the measured signal and the measure of the rms value of the electric field at a specific frequency (among those allowed).

For the measurements at different heights, the probe is installed on an insulating rod and then connected to a supporting structure, mainly a wooden tripod with a limited metallic parts, e.g. at the connection between the insulated rod and the wooden tripod.

The effect of these metallic parts on the measurements was investigated. It was considered that if a local variation was due to these metallic parts and the probe was near to them, the probe should have measured a distorted electric field, so affecting the data. In this respect a few measurements have been taken with different distances d between the EHP-50C probe and the metallic parts of the tripod. The data have been taken under a MV power line, with the two configurations planned for the experimental campaign. The most critical was the configuration for the measurements at $z = 1$ m, where d might be taken very small. At $z = 1$ m, a clear variation on the measurements have been obtained with d set at a few centimetres, while the effect became negligible when d was kept greater than about 0.3 m. For the experimental campaign it has been decided to keep d greater than 0.4 m, for the measurements taken at $z = 1$ m. For the measurements at $z = 2$ m, d was always about 0.7 m.

b) System description

Fig. 6 shows the place where the measurement campaign has been performed. No objects of any kind (trees, fences, etc.) are present at a distance less than 20 m from the pole.

Measurements of the geometry have been done by a laser meter (Bosch, mod. DLE 150). The height a of the pole was about 10.5 m; the spacing of the overhead wires at the pole were in good agreement with the b and c values used for the numerical analysis. The pole radius was about 0.15 m at the ground level, and was reducing its value of about 0.075 m per meter of increase along the pole height.

Small ground irregularities and few centimetres of grass and brushwood, evenly distributed, have given local perturbations to the electric field at ground level.

On the side where the measurements have been done, the increase of the ground level was of about 0.1 m at a distance of 10 m from the pole under the overhead wires. By using a rough estimate of the sag in the midpoint of the span, combined with the catenary curve, at 10 m from the pole the overhead wires lowering was estimated to be about 0.3 m.

A Cartesian system was used, the same indicated in fig. 1.

Fig. 6 The MV power line.

During the experimental campaign, the measurements were performed with the PMM EHP-50C probe at three different distances from the ground: 0.04 m, 1 m and 2 m respectively. Preliminary measurements have been done to check the contribution of harmonics to the electric field. As they have shown to be negligible, the data have been obtained with the range $6 \div 500$ Hz and assumed to be due only to the main component, at 50 Hz.

The measurements have been performed in three days of fine and dry weather, with a temperature between 18°C and 24°C . About the measurement uncertainties, from the certificate of calibration of the instrument, the expanded uncertainty [10] at 50 Hz is 3% on the magnitude of the electric field at $23 \pm 3^{\circ}\text{C}$. Moreover a temperature effect of $0.05 \text{ dB}/^{\circ}\text{C}$, obtained from the probe technical data sheets, has also been considered. With a temperature between 18°C and 24°C , a maximum value of 0.4 dB has been considered due to the temperature effect. Without considering further components of uncertainties, with a normal distribution for the uncertainty reported on the certificate of calibration, and a rectangular distribution for the temperature, a combined standard uncertainty has been calculated and a coverage factor of two has been used for obtaining the expanded uncertainty [10]. In this way the uncertainty results 6% of the total electric field value.

The rms value of the line voltage was 20 kV.

c) *Experimental results and validation of the numerical analysis*

A first set of experimental results is reported in fig. 7. The data are taken at $y = 0$.

Fig. 7 Comparison between numerical and experimental data. Numerical results of E_x (left), E_y (centre), E_z (right) at $y = 0, z = 1\text{ m}$ (continuous lines) and at $y = 0, z = 2\text{ m}$ (dashed lines). Experimental data of E_x (left), E_y (centre), E_z (right) at $y = 0, z = 1\text{ m}$ (full squares) and at $y = 0, z = 2\text{ m}$ (full diamonds).

The rms values of E_x , E_y and E_z at $z = 1$ m and at $z = 2$ m are reported respectively on the left, the centre and the right of fig. 7: full squares show the experimental data at $z = 1$ m, and full diamonds show the experimental data at $z = 2$ m. For comparison, also the numerical data at $y = 0$ are reported: continuous lines show the numerical results at $z = 1$ m, dashed lines show the numerical results at $z = 2$ m. The numerical data are those already reported in fig. 2, which are repeated here for a simpler comparison between numerical and experimental data. It can be noticed a good agreement between the results obtained from the CSM and the experimental data. Moreover the lowering of the overhead wires, combined with the variation of the ground level, agrees with the increase in the experimental data of E_y and E_z at distances greater than about 4 m from the pole.

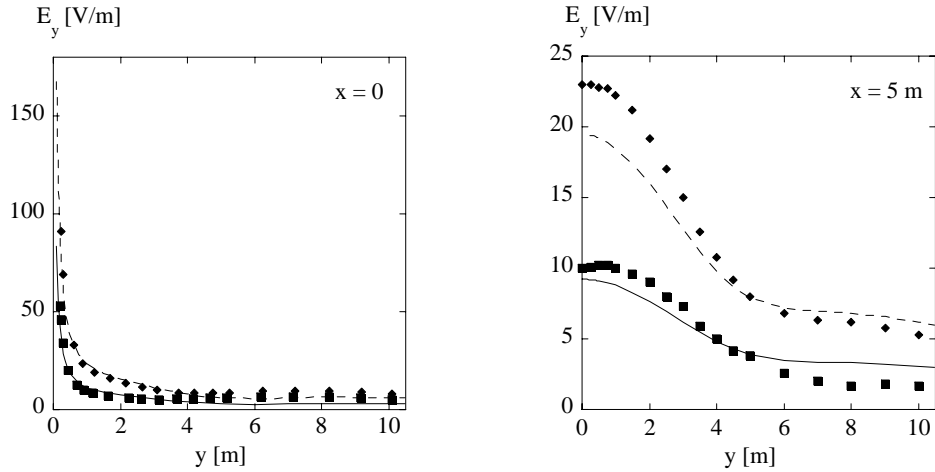

Fig. 8 Comparison between numerical and experimental data. Numerical results of E_y on the left at $x = 0$, $z = 1$ m (continuous line) and at $x = 0$, $z = 2$ m (dashed line), on the right at $x = 5$ m, $z = 1$ m (continuous line) and at $x = 5$ m, $z = 2$ m (dashed line). Experimental data of E_y on the left at $x = 0$, $z = 1$ m (full squares) and at $x = 0$, $z = 2$ m (full diamonds), on the right at $x = 5$ m, $z = 1$ m (full squares) and at $x = 5$ m, $z = 2$ m (full diamonds).

Fig. 9 Comparison between numerical and experimental data. Numerical results of E_z on the left at $x = 0$, $z = 1$ m (continuous line) and at $x = 0$, $z = 2$ m (dashed line), on the right at $x = 5$ m, $z = 1$ m (continuous line) and at $x = 5$ m, $z = 2$ m (dashed line). Experimental data of E_z on the left at $x = 0$, $z = 1$ m (full squares) and at $x = 0$, $z = 2$ m (full diamonds), on the right at $x = 5$ m, $z = 1$ m (full squares) and at $x = 5$ m, $z = 2$ m (full diamonds).

A second analysis has been performed at $x = 0$ and at $x = 5$ m. The rms values of E_y and E_z at $z = 1$ m and at $z = 2$ m are reported in fig. 8 and fig. 9 respectively, showing on the left the values at $x = 0$ and on the right the values at $x = 5$ m. In both figures numerical and experimental data are reported: continuous lines show numerical results at $z = 1$ m, dashed lines show numerical results at $z = 2$ m, full squares show experimental data at $z = 1$ m, and finally full diamonds show experimental data at $z = 2$ m. The numerical data are those already

reported in fig. 3 and fig. 4.

Numerical and experimental data are in good agreement, with in general a difference of about 20% for E_z and a lower difference for E_y . Therefore the validation of the numerical analysis previously reported has been obtained.

Discussion

The analysis performed up to $z = 2$ m, has shown that a reinforced concrete pole used in a MV power line, with a pole-top-pin construction, and with a height of 10.5 m, extends its effects in the electric field configuration around the pole up to a few meters.

At the pole, at the quote $z = 2$ m, the value of the electric field normal to the pole equipotential surface is higher than the value of its main component at the midpoint of the span. This result appears from the values of E_x , E_y and E_z under the line ($y = 0$) reported in fig. 7, and the values at $x = 0$ and at $x = 5$ m reported in fig. 8 and fig. 9. Therefore, the usual analysis performed at the midpoint of the span is not able to give an evaluation of the maximum exposure to the electric field with a MV power line supported by reinforced concrete poles, at least with reference to a maximum quote of $z = 2$ m.

Summary

The electric field due to a MV power line with a pole-top-pin construction has been analyzed in this paper.

A numerical analysis has been performed, based on an electric model equivalent to the configuration. The numerical results have been validated by an extensive experimental campaign of measurements, performed after checks on the measurement equipment, in order to minimize the perturbation errors.

At $z = 2$ m, at the pole surface, the maximum rms value of the electric field has been obtained: this value is greater than the one calculated far from the pole at the midpoint of the span.

DEVELOPMENT OF A SIMPLE AND LOW COST MAGNETIC FIELD MEASUREMENT EQUIPMENT UP TO 400 kHz

D. DESIDERI, A. MASCHIO

UNIVERSITY OF PADOVA, DEPARTMENT OF ELECTRICAL ENGINEERING
VIA GRADENIGO 6/A, I-35131 PADOVA (ITALY)

Abstract

In this paper the design, realization and operative ratings of a new simple and low cost magnetic field measurement equipment in the frequency range from 10 Hz to 400 kHz are reported. The design specifications of this device have been chosen following the indications given for the magnetic field reference sensor in Standard EN 50366, concerning emissions of household and similar electrical appliances with reference to human exposure to electromagnetic fields. The developed equipment consists of three mutually perpendicular concentric coils, each one of two turns, for magnetic field analysis up to 400 kHz. By using operational amplifiers, an electronic elaboration of the coil signals has been done and is described. The characterization of the equipment has been performed by using a laboratory set-up, where the test magnetic field configuration has been obtained with a single layer solenoid in house developed.

Introduction

Quantitative determinations of the magnetic field emissions from equipments in the Extremely Low Frequency (ELF) range have been performed and reported [1, 2]. The analysis of electric appliances, relevant to the evaluation of the human exposure to electromagnetic fields, is in particular required by Standard EN 50366, that in general considers for the magnetic fields a frequency range from 10 Hz to 400 kHz [3].

Purpose of this work is to develop a new simple and low cost instrument able to measure the magnetic field in the above mentioned frequency range.

The paper is divided in two main sections. In the first part, the design and realization of the measurement equipment are reported. In the second section, the laboratory set-up used for the characterization of the system is depicted, and the obtained operative ratings of the developed device are reported.

Finally, in the summary, the conclusive remarks are given.

Design and realization of the measurement equipment

a) Coils

For the measurement of the magnetic flux density, Standard EN 50366 indicates a reference sensor that consists of three mutually perpendicular concentric coils, with a total measuring area for each coil of $100 \pm 5 \text{ cm}^2$. The outside diameter of the reference sensor must be lower than 13 cm.

Following the specifications given in Standard EN 50366 for the magnetic field reference sensor, a simple and low cost probe has been developed.

It consists of three mutually perpendicular concentric coils. Three two turns coils have been built by using a transformer wire with a cross-section area of 0.3 mm^2 . Two of the three coils are almost rectangular in shape, with dimensions for each turn of 65 mm x 76 mm and 64 mm x 78 mm respectively; the third coil has a circular cross section, with diameter of each turn of 79 mm. In such a way a measuring area of about 100 cm^2 is obtained for each coil.

For supporting the three mutually perpendicular coils a PVC cylindrical structure has been built, 68 mm height and 80 mm diameter, on which three grooves have been drawn for placing the coils. Each coil ends with a twisted pair 0.6 m long.

The cylindrical PVC structure is mounted on a PVC base.

For the wires a fixing structure has been set, in order to make the system stable during operation.

In fig. 1 a picture of the three coils probe is shown.

Fig.1 Picture of the three-coils probe

b) *Equivalent electrical parameters for a coil*

The frequency range of interest for the system is the one indicated in the Standard EN 50366, i.e. from 10 Hz to 400 kHz. Related to it, an electrical analysis of each coil has been performed.

The length of the wires of the three coils is almost equal for all of them; so their electric resistance R can be considered the same, and it is about 0.12Ω in DC. When the frequency f increases, the resistance increases due to the skin effect. The parameter involved is the penetration depth δ that is:

$$\delta = \frac{1}{\sqrt{\pi f \mu_0 \sigma}} \quad (1)$$

with the permeability of free space $\mu_0 = 4 \pi \cdot 10^{-7}$ H/m and the conductivity of the copper $\sigma = 5.8 \cdot 10^7$ S/m. At 400 kHz, δ is about 0.1 mm, and assuming a current evenly distributed near the surface on a depth equal to δ , it results an estimated value for R of 0.22Ω , in agreement with the value obtained by an LCR meter (Agilent 4285A) that has been of about 0.25Ω at 400 kHz.

As far as the calculation of the inductance L is concerned, being the coils made up of only two turns, the concept of total inductance L_{tot} of a circuit split in two parts has been used:

$$L_{\text{tot}} = L_1 + L_2 + 2M \quad (2)$$

where $L_1 = L_2 = L$ is the self inductance of one turn and M is the mutual inductance between the two turns. For the evaluation of L and M , the two rectangular coils have been approximated with a square one (side length 71 mm); according to [4], the corresponding value of L_{tot} is $1 \mu\text{H}$ when the current is evenly distributed inside the coil conductor. Increasing the frequency, a correction due to the skin effect could be introduced as the current tends to concentrate on the outer part of the conductor, but is quite small and can be neglected: in fact, with the current concentrated on the conductor surface, the inductance decreases down to $0.97 \mu\text{H}$. In a similar way, for the circular coil, a value of $0.92 \mu\text{H}$ for the current evenly distributed and $0.90 \mu\text{H}$ for the current concentrated in the outer part of the conductor have been estimated. Finally, an additional term of about $0.15 \mu\text{H}$, due to the length of the twisted pair connection, must be added to the previous values. By using an LCR meter (Agilent 4285A) a value of about $1.2 \mu\text{H}$ for L was measured for the three coils (with their connections) up to a few MHz, in good agreement with the estimation above reported.

A coil, without load, has an output voltage $v_0(t)$ equal to:

$$v_0(t) = -\frac{d\Phi(t)}{dt} = -\frac{d}{dt} \int_{A_p} \mathbf{B}(t) \cdot \mathbf{n} dA = -A_p \frac{d}{dt} B_{\perp av}(t) \quad (3)$$

where A_p is the coil area and $B_{\perp av}$ is the average value on A_p of the component of \mathbf{B} perpendicular to the coil area.

In the frequency range from 10 Hz to 400 kHz, an equivalent electrical scheme of the probe, shown in fig. 2, is

therefore given by an ideal voltage source in series with a resistance R and an inductance L , with R and L above reported; with $v_1(t)$ it has been indicated the coil output voltage.

Fig.2 Equivalent electrical parameter for a coil.

Finally, in the frequency domain, by using phasors, (3) becomes:

$$\bar{V}_0 = -j\omega A_p \bar{B}_{\perp av} \quad (4)$$

where $\omega = 2\pi f$; j is the imaginary unit, and \bar{V}_0 and $\bar{B}_{\perp av}$ are the phasors of $v_0(t)$ and $B_{\perp av}(t)$ respectively.

c) Electronics

An integration of the coil output signal is required in order to obtain the value of $B_{\perp av}$, as derives from (3). Therefore the electronic circuit is basically an integrator, combined with a low pass filter, as schematically indicated in fig. 3.

Fig.3 Schematic of the electronic circuit.

Fig.4 The integrator.

For the integrator, the basic circuit is the one commonly used for magnetic field coil, depicted in [5]. The detailed circuit is reported in fig. 4. An OP-27G has been used as operational amplifier. In the input, zener diodes and 1N4148 diodes are placed for protection. The input of the integrator has two resistances (R_1) each one of

DEVELOPMENT OF A MAGNETIC FIELD MEASUREMENT EQUIPMENT

1.5 k Ω : when the coil is connected to the integrator, it results that the resistance R and the inductance L , equivalent of the coil, are in series with R_1 , and, on considering their values and the frequency range of interest, R and L can be neglected in the analysis. Therefore, in the frequency domain and using (4) it results that:

$$\bar{V}_1 = \bar{V}_0 = -j\omega A_p \bar{B}_{\perp av} \quad (5)$$

In the frequency domain, with \bar{V}_2 phasor of the integrator output voltage, the transfer function $A_1(j\omega)$ of the integrator is:

$$A_1(j\omega) = \frac{\bar{V}_2}{\bar{V}_1} = -\frac{R_2}{R_1} \frac{1}{1 + j\omega C R_2} \quad (6)$$

with R_1 , R_2 , and C indicated in fig. 4. The DC gain of the integrator is 80dB (i.e. 10000), and a pole is set at 10 Hz.

An active filter has been placed after the integrator: it is a second order Butterworth low-pass filter [6]. In the frequency domain, with \bar{V}_3 phasor of the low-pass filter output voltage, the transfer function $A_2(j\omega)$ of this filter is:

$$A_2(j\omega) = \frac{\bar{V}_3}{\bar{V}_2} = K_1 \frac{1}{1 + j\omega R_3 C_3 (3 - K_1) - (\omega R_3 C_3)^2} \quad (7)$$

C_3 has been set at 1 nF, R_3 at 390 Ω , and therefore the cutoff frequency has been set at 400 kHz, in order to filter the noise at frequencies higher than those of interest. The DC gain K_1 is equal to 4dB, i.e. 1.586.

Fig.5 Bode diagram of the amplitude of $A_V(j\omega)$.

Combining the two electronic stages, a voltage transfer function in the frequency domain $A_V(j\omega)$ results, that is given by the product of (6), and (7):

$$A_V(j\omega) = A_1(j\omega) A_2(j\omega) = \frac{\bar{V}_3}{\bar{V}_1} \quad (8)$$

The Bode diagram of the amplitude of $A_V(j\omega)$ is reported in fig. 5.

In the frequency range from 10 Hz to 400 kHz, the amplitude of the voltage transfer function of the electronics has a slope of -20dB/decade, from 84dB at 10 Hz down to -8dB at 400 kHz.

d) Coil function transfer

Considering the coil, from (5) and (8), the function transfer $H(j\omega)$ of the system results:

$$H(j\omega) = \frac{\bar{V}_3}{\bar{B}_{\perp av}} = \frac{\bar{V}_1}{\bar{B}_{\perp av}} \frac{\bar{V}_3}{\bar{V}_1} = -j\omega A_p A_V(j\omega) \quad (9)$$

The coil therefore adds a zero to the transfer function $A_V(j\omega)$, resulting a Bode diagram of the amplitude of

$H(j\omega)$ that has been reported in fig. 6.

Fig.6 Bode diagram of the amplitude of the function transfer of the system $H(j\omega)$.

Therefore, in the frequency range from 10 Hz to 400 kHz, the integrator stage and the coil (that makes the derivative of $B_{\perp av}$) give an output voltage proportional to $B_{\perp av}$; a constant gain of 80dB (i.e. 10000) results, i.e. at 100 μ T of average perpendicular magnetic flux density corresponds an output voltage of 1 V. Frequency components out of the considered frequency range are filtered.

As the output voltage can vary from ± 10 V, a maximum rating of 1 mT results. It must be noticed that, due to the slew rate (typically of 2.8 V/ μ s) of the OP-27G that has been used in all the electronic stages [7], a distortion of the signal occurs with the maximum output signal at the highest frequencies of the considered frequency range.

Characterization of the measurement equipment

An experimental laboratory set-up has been performed for the characterization of the measurement equipment. It consisted of a large solenoid, inside which the three coils have been placed during the tests.

a) Test solenoid

A single layer cylindrical solenoid, with the characteristics given in Table I, has been realized. The solenoid ends with a twisted pair 4.5 m long. The solenoid has been built on a polypropylene tube, 5 mm thick and with nominal minor diameter of 305 mm. The turns have been realized by using a conductor with a section of 2.5 mm².

Table I. Construction data of the test solenoid.

Number of turns	N	187
Internal diameter	Φ	0.305 m
Length	a	0.67 m
Section of the conductor	S_{cond}	2.5 mm ²
Diameter of the conductor (including insulation)	Φ_{cond}	3.6 mm

Two LCR meters (a Metrix IX 3131 at 120 Hz and 1 kHz, and an Agilent 4285A from 75 kHz up to 30 MHz) were used for evaluating the parameters of the solenoid. The equivalent circuit consisted of a capacitance C in parallel to the series of a resistance R and an inductance L .

Table II. Electrical parameters of the test solenoid.

Inductance	L	4.3 mH
Capacitance	C	220 pF
Resistance (DC)	R	1.6 Ω

The parameters found for the solenoid are reported in Table II; L and C values hold up to a few MHz. With reference to the measured inductance value, it is well in agreement with the one estimated from the geometry: in fact, the short solenoid approximation gives for L an estimated value of 4.1 mH. From the short solenoid

DEVELOPMENT OF A MAGNETIC FIELD MEASUREMENT EQUIPMENT

approximation also results that the calculated magnetic flux density in the centre of the solenoid is $316 \mu\text{T}$ (directed along the axis of the cylinder) for 1 A of current in the solenoid turns.

A check of this value has been performed by measuring the current in the solenoid turns with a LEM PR50 (DC-50 MHz bandwidth) current probe and the magnetic flux density with a PMM EHP-50C (DC-100kHz bandwidth) probe connected via an optical fibre to a PMM 8053 portable field meter. Tests have been performed at 50 Hz, 100 Hz, 1 kHz, and 10 kHz, and the magnetic flux density directed along the axis of the cylinder was between 330 and 340 μT for 1 A of current in the solenoid turns. This values are in good agreement with the estimated one.

b) *Test circuit*

Two power supplies have been used for the solenoid: a Kepco BOP-100-4D and an Agilent 33120A function generator. The output signal from the electronic circuit has been acquired by a Yokogawa DL1540L digital oscilloscope. The block scheme of the test circuit is shown in fig. 7.

Fig.7 Block scheme of the test circuit for the probe characterization

The probe has been placed in the centre of the solenoid, with the coil under test with the area perpendicular to the solenoid axis. The solenoid has been connected to the Kepco BOP-100-4D power supply, driven by the Agilent 33120A function generator.

c) *System ratings*

An offset was present at the output of the electronics, and was eliminated by selecting the AC signal input coupling of the oscilloscope: a less than 10 Hz cutoff frequency is introduced in this way.

An output voltage noise of about $\pm 2 \text{ mV}$ has been measured, that is 0.02% of the output maximum voltage.

Fig.8 Test at 1 kHz: (1) electronics output voltage $v_3(t)$ and (2) solenoid turns current (1 V corresponds to 1 A).

By using the test circuit previously described, tests have been performed at 10 Hz, 1 kHz, 10 kHz and 100 kHz. At 10 Hz and 1 kHz, the maximum of the magnetic flux density was 1 mT (i.e. $707 \mu\text{T}$ rms value), obtained with a maximum current in the solenoid turns of 3 A (i.e. 2.12 A rms value); the electronics output voltage $v_3(t)$ was

measured and the rms value is reported in Table III. As an example, at 1 kHz, in fig. 8, the electronics output voltage $v_3(t)$ and the solenoid turns current (1 V corresponds to 1 A) are reported, indicated with (1) and (2) respectively.

The test circuit could not test the system at the maximum ratings at 10 kHz and 100 kHz, and therefore at these frequencies the tests have been performed at the reduced ratings shown in Table III. The solenoid turns current has been measured directly at the output of the solenoid, in order to avoid the capacitance effect of the connections.

The results are in good agreement with the design ratings.

Table III. System ratings

Frequency [kHz]	B [μ T] rms	I [A] rms	V ₃ [V] rms
0.01	707	2.12	5.00
1	707	2.12	7.07
10	70.7	0.212	0.723
100	1.5	0.0045	0.015

c) Analysis at 400 kHz

At 400 kHz the analysis has been performed by using a simple equivalent model of the system.

The power supply has been modelled with an ideal voltage source, and the solenoid has been considered an ideal inductor (with $L = 4.3$ mH), magnetically coupled with the coil. The ratio between the ideal voltage source and the coil output voltage results of about 1300.

For the test, the Agilent 33120A function generator has been used as solenoid power supply. Its $50\ \Omega$ equivalent output resistance is in effect negligible compared with the equivalent impedance of the test solenoid at 400 kHz. With a 7 V rms value of power supply voltage and the test circuit of fig. 7, the electronics output voltage was about 2 mV rms value. This value is in agreement with the value expected from the system, even if it is close to the noise of the electronics output voltage.

Summary

A new simple and low cost magnetic field measurement equipment in the frequency range from 10 Hz to 400 kHz has been developed.

The design and realization of the equipment has been reported. The function transfer of the system has a constant 80dB gain in the above mentioned frequency range.

The characterization of the system has been performed at maximum ratings from 10 Hz up to a few kHz. At the higher frequencies, the characterization has been performed only at small signals.

The results are all well in agreement with the design ratings.

Abstract

The rapid expansion of mobile communication has generated intense interest, but has also fuelled ongoing concerns. Radiofrequency radiations are suspected to affect cognitive functions in both humans and animals. Previous studies have suggested that biological parameters of central nervous system can be impaired by “Global System for Mobile Communication” (GSM) exposure in animals.

In this study, the effect of GSM radiation on kindled seizures (as an index of neural excitability) was investigated. All the animals were implanted with a tripolar (stimulating and recording) electrode in the amygdala and were kindled by daily electrical stimulating of amygdala. Different groups of full kindled rats exposed by radiofrequency fields emitted from GSM (950 MHz, Band with: 200 kHz, pulsed at 217 Hz) mobile phone simulator (output power of antenna: 3 and 5 W, power density: 1.8 mW/cm^2) for 2 and/or 4 hours and at different times after the last kindling seizure (24, 48 and 72 h) and their seizure parameters (afterdischarge duration, latency to stage 4 seizure, stage 5 seizure duration and seizure stage) were measured immediately after radiation. The exposed rats were compared to those of sham-exposed and cage-control rats. There was no difference between exposed, sham, and cage-control rats. Therefore, the data indicates that GSM radiation with the mentioned parameters had no effect on seizure severity in kindling model of epilepsy.

Keywords: GSM, mobile phone, neural excitability, seizure, kindling

Introduction

The increasing use of mobile communication has raised serious concerns among people and governments about possible health hazard effects. Radiofrequency waves emitted by GSM mobile phones have a frequency band between 890 MHz and 960 MHz. Mobile phones in operation emit a pulsed radiofrequency electromagnetic field (EMF), a large part of which is absorbed into the user's head [1]. Some EEG and ECG studies have reported that GSM-EMF affects brain electrical activity [2, 3, 4, 5, 6, 7, 8], specially during cognitive performance [9, 10]. Also other investigators that have worked on this issue believe that mobile phones exposure modifies biological parameters of excitable tissues and disturbs performance of neural systems [11, 12, 13, 14, 15, 16, 17]. In a recent study it has been suggested that the EMF emitted by a commercial GSM mobile phone affects regional cerebral blood flow (rCBF) in human [18].

On the contrary, some of the studies have revealed that mobile phones EMF have no significant effects on human health [19, 20, 21, 22, 23]. These results have remained controversial yet. In this study we tried to investigate the effect of GSM EMF on neural excitability. Using kindling model of epilepsy, we created seizure conditions in rats. In this situation the excitability of the CNS was high enough to study if the GSM field had any effects on this excitability. Chronic exposure of kindled rats by magnetic field (50 Hz, 100 micro tesla) exerts weak inhibitory effects on some seizure parameters [24]. However there is no report concerning effect of mobile phone (GSM-900) field on neural excitability in kindling model of epilepsy.

Materials and Methods

Surgical and kindling procedure

Male Sprague–Dawley rats weighing 330–360 g, under ketamin and rampoune anaesthesia (50 mg/kg) were stereotaxically implanted with bipolar stimulating and monopolar recording electrodes (twisted into a tripolar configuration) terminating in the basolateral amygdala of the right hemisphere (coordinates: A, 2.5 mm; L, 4.8 mm and 7.5 mm below dura). Electrodes (stainless steel, Teflon coated, A-M Systems, Inc., USA) were insulated except at their tips. Two other electrodes were connected to skull screws, placed above the left cortical surface, as earth and differential electrodes. One week after surgery, afterdischarge (AD) threshold was determined in the amygdala by a 2 s., 60 Hz monophasic square wave stimulus of 1 ms per wave. The stimulations were initially delivered at $10^{\mu A}$ and then at 5 min intervals increasing stimulus intensity in increments of $10^{\mu A}$ until at least 5s of AD were recorded as previously described [25]. Then, animals were stimulated daily at the AD threshold intensity until five consecutive stage 5 seizures (according to Racine, 1972) were elicited [26]. The recorded parameters were: a) seizure stage (SS) which was measured by observing the behaviour of the animal; b) AD duration (ADD) which was measured from starting of stimulation to the end of AD recording; c) the latency to the onset of bilateral forelimb clonus (S4L) which was measured from starting of stimulation to starting of stage 4 seizure; d) the duration of stage 5 seizure (S5D) which was started with loss of balance and stopped after acquisition of balance; and e) seizure duration (SD) which was measured from starting of stimulation to the end of seizure behaviours.

Radiation procedure

The EMF was provided by a GSM simulator in two level 3 and 5 mean power. When the GSM system was on, the antenna emitted a 950 MHz EMF with mean field strength 1.8 mW/cm^2 pulsed at a frequency of 217 Hz with a pulse width of 0.577 ms. According to the measurements that achieved by Iranian atomic energy organization experts, field strength was 1.78 mW/cm^2 and 1.82 mW/cm^2 for 3 w and 5 w mean power of antenna, respectively. Thus mean field strength of this EMF is double of workers permissible limits [27].

Exposure chamber that we employed for radiation procedure was a cylindrical shape with 30 cm height and 30 cm diameter of base circle. It was made of special hard transparent PVC. The Simulator antenna with 15 cm height was placed in the centre of base circle (Fig. 1).

Exposure chamber was placed in a greater space (we call it radiation box) with dimensions of $1.1 \text{ m} \times 1.1 \text{ m} \times 1.1 \text{ m}$. For protection intentions the external sidewalls of the box covered with aluminium sheets. Long time EMF radiation generates hot and cavity spots throughout the radiation space. Hot spot have high density of field lines and energy and cavity spots have no field lines or energy. Avoiding to this phenomena and creation a uniform RF field around the chamber, we used conical shape absorbers that were made of graphite dyed spongy matters in internal sidewall of the radiation box. Fig. 2 shows these electromagnetic absorbers dimensions. Reflection Coefficient for these electromagnetic absorbers in 950 MHz is -40 dB approximately [28]. Obviously, in this condition we would have a uniform field throughout the exposure chamber. Fig. 3 shows a rat in near field of the antenna within the exposure chamber and radiation box, respectively. During radiation, for eliminating the external stress, animal was released in the chamber. So average distance from antenna was 10 cm that is equal with near field of GSM antenna [29]. Mean field strength was measured in this distance.

Fig. 1. The exposure chamber and the position of the antenna.

Fig. 2. Electromagnetic absorbers

Fig. 3. A rat is released in near field of the antenna within the exposure chamber. The black shapes are electromagnetic absorbers in internal sidewall of the radiation box.

We only considered non-permanently effects of GSM exposure on kindling parameters. In this way, we used four radiation paradigm and a different group of full-kindled animals ($n=6$) were employed in each experiment. The results were expressed as the mean \pm S.E.M. for each test groups. The comparison between last fully kindling (control) values and sham exposure or GSM radiation values was done by paired t-test. A P-value of less than 0.05 was considered to represent a significant difference.

Results

The assessment of probable effect of radiation chamber and its dark environment on seizure severity was an essential note for research accuracy. Therefore, 24 h after the last kindling seizure, rats were affected by muted GSM generator (sham exposure) for 2 hours. This work was repeated at 48 and 72 h after full kindling creation for each subject, similarly. Immediately after each radiation animals were stimulated and their seizure parameters were measured and were compared with the last kindling or control values. Obtained results showed no significant differences between data (Table 1).

The above method was performed similarly, except that GSM exposure had a mean power of 3 watt and field strength of 1.78 mW/cm^2 (experiment 2) or a mean power of 5 watt and field strength of 1.82 mW/cm^2 (experiment 3). Statistical analysis showed no significant affect of GSM on seizure parameters (Tables 2, 3). In experiment 4, at 24 h after the last kindling seizure animals affected by GSM generator with a mean power of 5 watt and field strength of 1.82 mW/cm^2 for 4 hours and seizure parameters were measured immediately after radiation. Again, no significant difference was observed in compared to pre-exposure data (Table 4).

Discussion and Conclusion

In this study we found that, a GSM simulator with field strength of 1.8 mW/cm^2 and mean power of 3 and 5 watt doesn't create any considerable effect on amygdala kindled seizure parameters and there is no evidence for predicting reduction or increasing in neural excitability. Radiation time for 2 and 4 hours had no sensible or measurable effects too. Therefore these results confirm that radiation time and mean power of GSM antenna have no essential effects on seizure parameters in kindling model of epilepsy. This conclusion is in adjusted with several studies that have indicated mobile phone and radiofrequency fields have no effect on neural excitability [21, 22, 30, 31]. It is specially in adjusted with a coincident study that has showed a 900 MHz exposure with SAR of 0.25, 1, 2, 4 W/kg, has no effect on hippocampus parameters of free rats in cage [32].

However, this study doesn't confirm EMF field effects on epileptiform activity induced by amino pyridine in hippocampal slices [33, 34]. Additionally, according to this study, GSM EMF field, hadn't any inhibitory effects on seizure parameters in kindling model of epilepsy such as low frequency magnetic field [24, 35].

Also these results are differing with another research that has investigated effects of GSM-900 field (SAR less than 2 W/kg) on neural lesion possibility in rats [36].

Compatibility, some studies have suggested that GSM field couldn't change EEG parameters (that shows normal function of neural activity) in volunteers. Therefore GSM mobile phones exposure (according to this study conditions) couldn't modify seizure parameters in an excited neural system and have no significant effects on seizure biological parameters in kindling model of epilepsy. Obviously, this conclusion is exceptionally fastened to above conditions, experimental setup and methodologies.

Abstract

In our previous works we found that different strains of bacteria are affected by the magnetic field exposure. The decrease of CFU number (colony forming units) was observed in cultures of different bacterial strains after 12 minutes exposure to 10 mT 50 Hz magnetic field. This effect was strain dependent and the relative decrease was from 30% (*Escherichia coli*) to 12% (*Staphylococcus aureus*). We observed that rod-like bacteria (*Escherichia*, *Leclercia*) are more affected than spherical ones (*Staphylococcus*, *Paracoccus*). We carried out AFM study to determinate surface changes of bacteria after 60 minutes of 50 Hz 10mT magnetic field exposure of *Escherichia coli* and *Paracoccus denitrificans*. We have not observed any change in bacterial morphology of both used bacterial strains. Magnetic field did not influence the surface and shape of bacteria.

Introduction

Investigation of effects of electromagnetic fields on living organisms is needed in our community. It is important to know, how biological objects react to exposure of external electromagnetic field. According to this knowledge, we will be able to estimate health and economical aspects of using of many electrical and magnetic devices. Recently, there have been a lot of studies concerning these problems. We can find many studies of magnetic and microwave effects on DNA (1-3), enzymatic activity (4,5), proliferation control (6,7) and many others (8,9).

In our previous studies we have found, that effect of 50 Hz magnetic fields on different types of bacteria is strain-dependent (10-13). This effect was even shape dependent. We used CFU – colony forming units – method to determinate proliferation of bacteria after magnetic field exposure. Rod-like bacteria (*Escherichia coli* and *Leclercia adecarboxylata* - decrease of CFU number after 12 minute exposure to 10 mT 50 Hz magnetic field was about 40%, respectively 30% - survived in lower number than spherical ones (*Paracoccus denitrificans* and *Staphylococcus aureus* - decrease of CFU number after 12 minute in 10 mT 50 Hz magnetic field was about 14%, respectively 21%). Thus, we decided to measure surface characteristics of *Escherichia coli* and *Paracoccus denitrificans* with AFM technique to estimate possible morphological change after magnetic field exposure.

Material and Methods

Bacteria *Escherichia coli* was obtained from Biological department of Masaryk university Brno (strain K12, Row, genotype 58–161 *metB1rpsL* 1+ F^{def}P.Fredericq), *Paracoccus denitrificans* CCM 982 (NCIB 8944) was obtained from the Czech Collection of Microorganisms. For AFM measurements was used Explorer AFM (Veeco). Cylindrical coil parameters are given in our previous papers (10-12).

For morphological changes determination we used this procedure: bacteria were placed on thin glass surface. After evaporating, we take control samples measurements. Then were the bacteria placed to center of the coil and kept here for 60 minutes in 10 mT 50 Hz magnetic field. After this exposition we took another AFM pictures. Thus, we were able to detect the same bacteria before and after exposure.

Results and Discussion

On Fig.1 and Fig. 2 we can see the AFM pictures of control and exposed samples of bacteria. We have done some correlation data processing (for x,y and z position of every pixel on AFM picture). We have found, that the bacteria had not changed their morphology. There were only small changes on edges of samples, but these could be satisfactory explained by AFM head drift. Every experiment was at last 3 times repeated in high-resolution scans (area around $5 \times 5 \mu\text{m}$) and 3 times in low resolution (area around $50 \times 50 \mu\text{m}$).

Fig. 1 *Escherichia coli*, sample before exposure (left), and exposed sample (1 hour 10 mT, 50 Hz) – (right)

Fig. 2 *Paracoccus denitrificans*, sample before exposure (left), and exposed sample (1 hour 10 mT, 50 Hz) – (right)

We have found, that both types of used bacteria - *Escherichia coli* and *Paracoccus denitrificans* did not change their shapes after 1 hour exposure to 50 Hz magnetic field, $B_m=10$ mT. We used AFM method for bacterial surface monitoring.

Abstract

The aim of the study was to investigate the effect of EMF from mobile phones and stress perception on general health condition. The subjects were 208 GSM communication workers who responded to a 53-item questionnaire. Most of them (57%) assessed their health condition as good, 14.% as very good and 18% as fair. The level of stress was assessed in 89 workers (mean age 30.3 ± 7.7 , employment duration 4.1 ± 1.7 years) using the Perceived Stress Scale (PSS) by Cohen and the Subjective Assessment of Work Characteristics Questionnaire (SAWCQ). EMF exposure was calculated as daily call duration (CT). The study population was divided into two groups (similar in age and employment duration): I with CT below 60 min., mean 23 min., II with CT above 60 min., mean 158 min. Group II more frequently reported headache (58% vs. 78.4%, $p=0.045$), dizziness (10% vs. 32.4%; $p=0.009$), impaired concentration (2% vs. 13.5% $p=0.05$), and heat sensation in the auricular area (30% vs. 51.4%, $p=0.044$). The score on SAWCQ was higher in group II ($p=0.05$). The risk of a headache was significantly dependent both on CT (OR=3, $p=0.0044$) and PSS (OR=1.12, $p=0.043$). EMF exposure and stress significantly contributed to an increased rate of subjective symptoms reported by GSM workers.

Introduction

The professional group of mobile communication workers who can experience simultaneous exposure to EMF and work-related stress has developed as a result of the dynamically growing mobile communication systems and the increasing demand for mobile phone services. Mobile communication workers are exposed at work to stress related to a high pace of work performance (time pressure), high responsibility and continuous contact with customers; the level of stress depending on a given workpost. When evaluating the impact of work environment on the workers' health, one should take into account the factors related to job characteristics. Relevant literature reports on the significance of psychosocial factors such as work-related stress, effort-reward imbalance, shift work, sedentary work and other work-related stressors [1]. It seems then, that apart from the 'hard' parameters of work environment, such as EMF, one should also consider the potential influence of the psychosocial factors. Therefore, our study focused on the assessment of the level of stress related to work and everyday activities. Stress at work is associated not only with some objective factors but depends on the subjective assessment of working conditions and job requirements. This assessment evokes emotions that in turn trigger different physiological processes and mechanisms that can lead to adverse health effects if such activity is long-term or too intensive [2,3,4]. The health impact of prolonged experience of stress combined with EMF exposure may concern large communities because most of the executive staff and administration, whose duties can be perceived as highly stressful, can also be subjected to EMF exposure, as a result of a common use of mobile communication both at work and at home.

The aim of the study was to investigate the combined effect of EMF from mobile phones and stress perception on the health condition of GSM workers.

Material and Methods

Study population

The study was performed on a population of Polish workers of GSM network who are occupationally exposed to EMF from mobile phones. For this population it was possible to precisely determine the level of EMF exposure through analysis of billing and work history documentation to elicit call duration and time of EMF exposure. Some of the workers performed their duties using a stationary telephone (Call Centre operators), while others (sale dept. workers and individual and company service workers) used mobile phones. We could thus ensure study groups with

SUBJECTIVE SYMPTOMS IN GSM NETWORK WORKERS

varying type and level of exposure for our investigation. In total, 208 workers were qualified for the survey. Of this number, 89 persons responded to the psychological questionnaire.

Exposure to EMF evaluation

Since most of the workers used the same type of mobile phone in their job, exposure assessment could be limited to analyzing the parameters regarding the intensity of phone use. The level of occupational exposure to EMF was calculated based on the time and frequency of mobile phone calls, SAR, and an output for a given phone used.

Each worker had the following parameters calculated:

- total period of mobile phone use
- mean daily number of calls
- mean duration of a single call
- mean daily exposure (call) duration (mean call time x daily number of calls)

Questionnaire on subjective symptoms related to mobile phone use

The questionnaire was designed specifically for this study and focused on general health condition and health complaints as well as the frequency of mobile phone use. It was tested on a group of 600 individuals using mobile communication. When developing the questionnaire, the authors consulted Scandinavian and Australian researchers about similar surveys conducted in their countries. Finally, some items from a Swedish and an Australian questionnaire were included to facilitate comparison with their findings [5,6].

The questionnaire comprises 53 items regarding (a) personal data: age, gender, education, history of work under EMF exposure; (b) self-assessment of health condition, and specific symptoms: headache, dizziness, tinnitus, visual impairments, skin symptoms of the head and neck area, sleep disturbances, and present or past diseases; (c) mobile phone use: type of phone (handsets, hands-free kits), and (d) habits related to phone use: frequency and duration of calls; (d) subjective symptoms related to mobile phone use.

Stress evaluation:

- Subjective Assessment of Work Characteristics Questionnaire (SAWCQ). The questionnaire has been developed and validated at the Nofer Institute of Occupational Medicine, Lodz, Poland. It consists of 50 items inquiring about different psychosocial stressors (factors) related to work [7]. Each subject is asked to assess whether a given factor occurs at his/her workpost and if so, to what extent it accounts for his/her irritation, fatigue, anger, stress, etc. A five-point scale is used to assess the impact of every potential stressor. The individual index of job stressfulness is calculated as a total score on all questionnaire items indicated by the subject. SAWCQ proved to be a reliable measuring instrument: $r_t = 0.87$ and Cronbach $\alpha = 0.84$. Raw scores can be transformed into normalized scores on a 10-point scale. The questionnaire was positively validated on a large sample ($N = 2570$) of Polish working population
 - low level of stress - score 65-80 points
 - medium level of stress - score 81-101 points
 - high level of stress - score about 102 points
- Perceived Stress Scale (PSS) developed by Cohen [1983]. The Scale is used for measuring the perceived stress, both related to everyday life situations and work performance [8]. The Scale consists of 14 questions on the frequency of recent stressful conditions that the person could or could not cope with. The recipients answer the questions using a five-point scale, with '0' denoting the absence of such a situation and '4' a high frequency of stressful events. The higher the total score, the more a given individual perceives his life course as unpredictable and beyond his/her control.

Statistical analysis

The following methods were used for the statistical analysis: Student's t-Test or F-Snedecor test to compare mean values of parameters in the study groups; χ^2 test or Fisher exact test for comparing frequency of the analysed parameters in the study groups; uni- and multivariate logistic regression for quantitative risk assessment of symptoms in relation to exposure level, after adjusting for confounders.

Results

The study population was homogenous with regard to the occupation, educational level, lifestyle, health status etc., while it differed with respect to the level of EMF exposure and work-related stress.

Mean age of the examined workers was 30.3 ± 7.7 years (21-62 years). The study group included 41 female workers aged 23-45 years (mean 27.8 ± 4.5) and 48 male workers aged 21-62 years (mean 32.4 ± 9.2). The mean age of female workers was significantly lower ($p=0.0089$).

Mean employment duration was 4.1 ± 1.7 years (2 month-8 years) and did not differ significantly in relation to gender: 3.5 ± 1.7 years (from 2 months to 6.5 years) for female workers and 4.6 ± 1.7 years (from 2 months to 8 years) for male workers.

The mean daily duration of phone calls was 80.4 ± 105.1 min. (2 min.- 600 min.) and was similar in both groups: 75.8 ± 97.5 min. (2 min.-400 min) for females and 84.1 ± 111.8 min (2 min.- 600 min) for males (table 1).

Most of the subjects (75.4%) had university education and 24.6% of workers presented secondary/college level education.

Table 1. Exposure characteristics for the total study population

Exposure parameters	Mean value \pm SD
period of mobile phone use (years)	4.1 ± 1.8
mean daily call duration [min]	80.4 ± 105.1

Self-assessment of general health condition and subjective symptoms

Most of the examined people (57%) assessed their health condition as good, 14% as very good and 18% as fair. Nobody reported bad or very bad condition of health and no significant differences in the health status could be found between male and female workers.

67,5% subjects complained of headache; this symptom was significantly ($p=0.05$) more frequent in female workers (78% vs. 58%) but only 10% of female workers related this symptom to using a mobile phone. 19% of the total subjects reported dizziness; it was more prevalent among females (27% vs. 12.5%) but the difference was statistically insignificant. Other symptoms, like tinnitus, visual impairments etc., were reported by 12.5% of the subjects, with roughly similar prevalence in the groups of female and male workers (17.1 % vs. 10.4%). Impaired concentration occurred in 37.1% of respondents, prevailing among females (41.5% vs. 33.3%). Sleep disturbances occurred in 30.3% of the subjects; they were more frequent among males (33.3% vs. 26.8%) but the difference was statistically non-significant. Facial dermatitis was reported by 12.6% of the subjects. The most prevalent symptom related to mobile phone use was the thermal sensation within the auricle and behind/around the ear. This was reported by more women than men (43.9% vs. 33.3%). 15.7% of the subjects reported fatigue after the call, even if the conversation was a pleasant one, and 6.7% impaired concentration. 11.2% reported difficulties in recalling what they had been doing before they answered the phone call (short-term memory impairments). This symptom was significantly more prevalent among male workers (18.8% vs. 2.4%).

Stress assessment

In the study population, the level of general stress was estimated at 22.1 ± 6.9 and was significantly ($p=0.0089$) higher among female workers (24.2 ± 6.6 vs. 20.3 ± 6.7). The work-related stress was assessed at 95.3 ± 19.1 and a higher level was found among male workers (96.8 ± 20.2 vs. 93.5 ± 17.8) but the difference was not statistically significant. Although in the study group, the level of stress, according to the classification adopted in earlier studies, assumed medium values (81-101), some individual workers presented very high values (134-145).

Analysis of relationship between reported symptoms and occupational factors (EMF from mobile phone, and stress)

The study population was divided into two groups according to EMF exposure calculated as daily call duration (CT):

- Group I (50 subjects): CT below 60 min., mean 23 min (2-50 min).
- Group II (39 subjects): CT above 60 min., mean 158 min (60-600 min).

These groups were similar with respect to age and employment duration.

The prevalence of the symptoms depended on the total daily duration of calls: the subjects with CT of more than 60 min. more frequently reported symptoms than the subjects with shorter CT (Table 2).

SUBJECTIVE SYMPTOMS IN GSM NETWORK WORKERS

Table 2. Prevalence of symptoms in relation to call duration

Symptoms	Group 1	Group 2	p
Headache	58%	78.4%	0.045
Dizziness	10%	32.4%	0.009
Headache related to mobile phone use	4%	16%	0.05
Impaired concentration	2%	13.5%	0.05
Impaired short-term memory	4%	21.6%	0.01
Thermal sensation in the auricular area	30%	51.4%	0.044
Thermal sensation in the auricle	26%	51.4%	0.015

The level of stress was assessed in the study group with different exposure levels (table 3)

Table 3. General and work-related stress in relation to exposure level

Study groups	General stress (Cohen)	Work-related stress
(I)	21.2±7.3	92.0±18.2
(II)	23.1±6.5	100.2±19.9
(p)	ns	0.05

Analysis by exposure and stress parameters

The analysis was made using logistic regression model including EMF exposure parameters and level of stress.

After adjusting for stress, in group I (with CT of more than 60 min), the risk for headache related to mobile phone use was four times as high as in group II with CT of up to 60 min (Table 4).

Table 4. The risk for headache related to mobile phone use

Parameters	Regression coefficient (B)	Standard error (SE)	p	Odds ratio (OR)
Stress after Cohen	0.11	0.062	0.059	1.1
CT	1.44	0.87	0.075	4.2

The risk for headache as a symptom that was not associated with mobile phone use was also significantly higher in group II than in group I (OR=3).

Apart from the duration of the call, also stress perception significantly contributed to an increased risk for headache (Table 5).

Table 5. The risk for headache not related to mobile phone use

Parameters	Regression coefficient (B)	Standard error (SE)	p	Odds ratio (OR)
Stress (Cohen)	0.11	0.04	0.0044	1.12
CT	1.10	0.54	0.043	2.97

The risk for dizziness unrelated to mobile phone use was significantly higher (OR =6.8) in group II in comparison with group I (Table 6).

Table 6. The risk for dizziness unrelated to mobile phone use

Parameters	Regression coefficient (B)	Standard error (SE)	p	Odds ratio (OR)
Stress (Cohen)	0.17	0.07	0.0084	1.19
CT	1.91	0.70	0.0058	6.81

As regards concentration impairments, both related and unrelated to mobile phone use, the risk for this symptom was higher among the workers with a high level of work-related stress but was not dependent on the intensity of the calls (tables 7, 8).

Table 7. Risk for concentration impairments related to mobile phone use

Parameters	Regression coefficient (B)	Standard error (SE)	p	Odds ratio (OR)
Work-related stress	0.15	0.05	0.0044	1.17

Table 8. The risk for concentration impairments unrelated to mobile phone use

Parameters	Regression coefficient (B)	Standard error (SE)	p	Odds ratio (OR)
Work-related stress	0.04	0.014	0.0026	1.049

At the next stage of the analysis, we investigated whether including the duration of daily calls in the model describing stress and exposure parameters had influence on the risk for a given symptom. The daily call duration did significantly increase the risk for headache related and unrelated to mobile phone use ($p=0.0063$ and $p=0.02$, respectively), after adjusting for other parameters. Likewise, the risk for dizziness significantly increased with an increasing duration of daily calls ($p=0.0041$). No relationship was found between sleep disturbances and the level of stress.

Summary

The findings of the present study revealed that EMF exposure from mobile phone combined with parallel stress perception significantly increased the prevalence of symptoms reported by GSM workers. This referred to headache, dizziness and sleep disturbances that were much more frequent among workers who reported intensive use of mobile communication (frequent and long calls) and had a high level of stress perception. Concentration impairments were significantly related to the level of occupational stress. It seems that the best parameter to assess EMF exposure was the daily call duration, for it significantly correlated with the prevalence of the reported symptoms.

The study demonstrated that parallel activity of these factors: EMF from mobile phone and a high level of stress, both of the general and work-related stress, produce negative health consequences and increase the prevalence of subjective symptoms among workers. No research has been performed that could explain whether this effect is additive, duplicate or potentiating.

The results of our previous studies indicated that exposure to EMF from mobile phone might increase arterial blood pressure, have influence on melatonin level resulting in sleep disturbances, produce concentration and short-term memory impairments [9,10]. Similar physiological reactions (increased blood pressure, heart rate, headache, sleep disturbances) have been associated with stress.

Surveys on subjective symptoms from mobile phone use conducted in Sweden, Norway, UK, US, New Zealand and Australia revealed headache as the most frequently reported symptom [6,11,12,13]. The Australian study demonstrated that headache (including cluster headache and migraine) appeared during or shortly after the phone call and often turned more intense during the day. About 50% of the subjects reported that they had receded within one hour after the call was over and the rest of the subjects complained they could persist throughout the whole day and recede no earlier than in the evening or even on the day after [6]. The first reports on headache following exposure to microwave and radiofrequency EMF were published about 30 years ago but at that time EMF exposure at these frequencies was not common and the findings had little if any response [14]. Apart from headache, the persons using mobile phone reported malaise and fatigue, muscle pain, nausea, and thermoregulation impairments [15].

Seeking explanation to the concomitant activity of electromagnetic fields emitted by mobile phones and stress needs further studies.

Abstract

This work aimed to determine the effect of ELF-EMF (50Hz,1mT) on 1-apoptosis of cells induced with the hydrogen peroxide and 2- quercetin on K562 cells. Quercetin is a flavonoid, a group of polyphenolic phytochemicals known for their beneficial effects. Quercetin has been shown to induce apoptosis. Oxidative stress is well known for its apoptosis or necrosis inducing effect. Recent work has shown that ELF-EMF affects the free radical levels probably by increasing their life-time. K562 cells were induced with quercetin or H₂O₂ and ELF-EMF (1mT,50 Hz) was applied for three hours. ELF-EMF decreased the number of viable cells in H₂O₂ induced cells. ROS levels were increased with ELF-EMF application implying the free radical stabilizing effect of ELF-EMF on free radicals and were well correlated with the viability of cells. When quercetin was used to induce cells to apoptosis it was observed that ELF-EMF abolished the apoptotic effect, increasing viability to control levels suggesting that ELF-EMF interfered with apoptotic pathway. In conclusion we showed that ELF-EMF affected the viability of cells induced with quercetin or oxidative stress and that a free radical stabilizing effect of ELF-EMF may be involved.

INTRODUCTION

The extremely low electromagnetic fields have been found to produce a variety of biological effects. It has been shown that ELF-EMF can cause changes in cell proliferation, cell differentiation, cell cycle, apoptosis, DNA replication and expression [1,2].

Flavonoids are a large group (5000 flavonoids described) of low molecular weight naturally occurring polyphenolic compounds distributed in vascular plants and are important constituents of human diet. They have a broad range of biological functions in plants and also in animal cells since they have co-existed for over a billion years [3]. They regulate the activity of many enzymes and cell cycle progression they can alter gene expression and have anti-oxidative properties. Quercetin (3,3',4',5,7-pentahydroxyflavone) is a plant flavonoid that occurs naturally in a wide range of fruits and vegetables. It is the most studied flavonoid. It has been observed that Quercetin interferes with regulatory pathway of apoptosis [4] and causes cell cycle arrest [5].

ROS including H₂O₂, O₂ .- and OH⁻, are endogenously generated inside cells by a variety of enzymes and through the mitochondrial respiratory chain. ROS levels are balanced by the intracellular

antioxidative defense which consists of enzymatic (superoxide dismutase which reduces $O_2 \cdot^-$ to H_2O_2 , catalase, and glutathione peroxidase which reduce H_2O_2 to H_2O) and nonenzymatic components (the vitamins C, A, E, lipoate, thiols, urate, ubiquinone, glutathione (GSH), thioredoxin, and glutaredoxin) [6]. However exogenous H_2O_2 can cause cellular injury by both apoptosis and necrosis.[7]

Extremely low frequency electromagnetic fields are considered to be weak stressors and it is thought that they may act as costressors in the presence of a stress factor [8]. And since membrane poses a barrier to these weak fields the interaction must involve a physicochemical change in the membrane leading to changes in the signal transduction system of the cell [2] and/or as Myrtil proposed cause deleterious effects by stabilizing the metabolically formed free radical [9]

Taking these facts into consideration we aimed to determine the effect of ELF-EMF on viability of K562 induced with the two above mentioned stressors. The results were correlated with ROS levels.

1. Materials and Methods

a. Cell Culture

K562 cells were cultured at 37°C in suspension in RPMI 1640 (Sigma-Aldrich Chemie GmbH, Taufkirchen, Germany) containing 10% FCS (Gibco-Invitrogen Ltd. , Paisley, Scotland) in a humidified 5% CO_2 atmosphere. Cell count was made with trypan blue. Viability was 85-90%. Quercetin (Sigma-Aldrich QO125) was added by the indicated concentrations. K562 cells were induced to apoptosis with 150, 300 μM H_2O_2 (Riedel Dehaen D3016)

b. Exposure System

Electromagnetic field was generated with two solenoids (25 cm diameter and 10 cm height) serially connected each having 400 turns of copper wire. During exposure the cells (control and ELF-EMF applied) were kept in a water bath ($37^\circ \pm 0.5^\circ C$) . The magnetic field, obtained with 20V 1 mA was measured to be 1mT. Field intensity varied for $\pm 0.1mT$ during exposure. For the measurement a Hall Effect Teslameter of Leybold Heraeus 54 050 model was used. 1mT, 50Hz ELF EMF was applied for three hours.

c. Apoptosis detection and Annexin V Staining Protocol

After induction with quercetin or H_2O_2 and/or application of ELF-EMF cells were washed twice with PBS and suspended in 1x binding buffer at a concentration of approx. 1×10^6 cells/ml. 5 μl of Annexin V-FITC and 10 μl of propidium iodide was added to each cell suspension (control and induced). After incubation at room temperature for 10 minutes the fluorescence of the cells was determined immediately with a flow cytometer (Becton-Dickinson FACSCalibur).

d. ROS determination

After washing with PBS, cells were plated in 96-well plates (10^4 cells/well). Cells were incubated for 45 min with PBS supplemented with 1 mM p-nitro blue tetrazolium (NBT, Molecular Probes), 1 mM $CaCl_2$. Measurements were made in the absence or presence of EMF exposure. O_2^- generation reduces NBT to blue formazan within the cells, which was measured using a microplate reader (Thermo Multiscan EX) at 550 nm. Intracellular formazan crystals were solubilized in 100 μl DMSO prior to reading.

SUMMARY

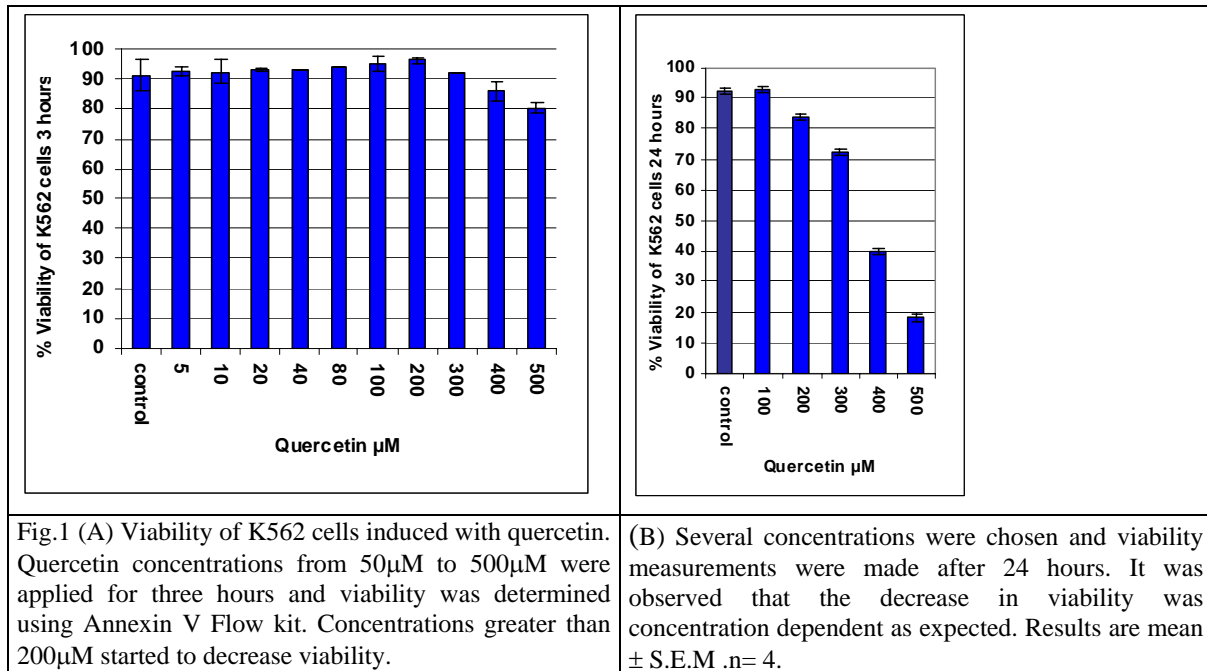

1. Results

a. Viability of cells induced with different concentrations of quercetin.

The viability of K562 cells were determined starting from 5 μM quercetin to 500 μM quercetin to be able to obtain a concentration response. Indicated concentrations of quercetin were added for three hours and viability measured with flow-cytometer using Annexin V Flow kit taking into consideration apoptotic

EFFECT OF ELF-EMF ON APOPTOSIS OF K562 CELL LINE INDUCED WITH QUERCETIN AND OXIDATIVE STRESS

and necrotic cells. As can be seen from Figure 1(A,B) viability decreased starting from 200 μ M quercetin. After having determined the breaking point, several concentrations were chosen and viability measured after 24 hours of quercetin induction (Figure 1.).

b. Effect of ELF-EMF on quercetin induced apoptosis of K562 cell line.

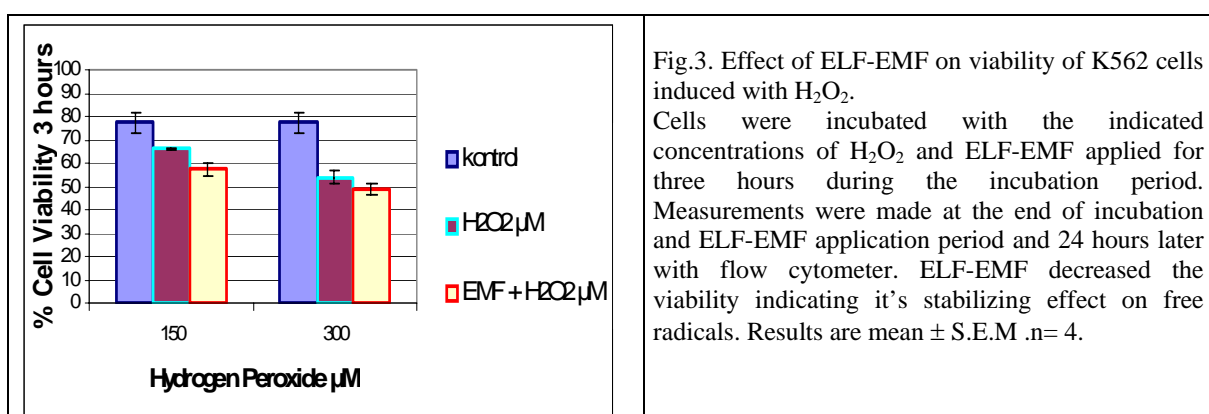

300 μ M quercetin was chosen to determine the effect of ELF-EMF on quercetin induced apoptosis of K562 cells. Cells were induced with quercetin for three hours and ELF-EMF (1mT, 50Hz) applied at the onset of induction for the same duration. Measurements of viability were made at the end of ELF-EMF application and 24 hours later with Annexin as indicated in Methods. (Fig.2)

Quercetin decreased the number of viable cells (about 12% decreases in 24 hours) as expected. ELF-EMF alone did not change the viability of K562 cells although a slight increase which did not seem to be significant, in the number of cells was observed. When ELF-EMF was applied together with quercetin it was seen that ELF-EMF increased % of viable cells indicating that it blocked the apoptotic pathway induced by quercetin.

c. Effect of ELF-EMF on viability of K562 cells induced with H₂O₂

Two H₂O₂ concentrations (150 μ M and 300 μ M) were used to determine the effect of ELF-EMF on the viability of K562 cells. Cells were induced with H₂O₂ for three hours and ELF-EMF applied during induction. Viability was determined at the end of three hours using Annexin. As expected H₂O₂ decreased viability. Application of ELF-EMF decreased viability which was seen to be more pronounced for 150 μ M H₂O₂ . (Fig.3).

d. Effect of ELF-EMF on ROS levels in K562 cells with or without H₂O₂ induction.

Cells were kept for three hours under ELF-EMF (1mT, 50Hz). In case of H₂O₂ induction, ELF-EMF was applied immediately after induction. As can be seen from Fig.4 ELF-EMF increased ROS levels either with or without H₂O₂ induction. When cells were induced with H₂O₂ the increase was more pronounced with 150 μ M H₂O₂. The results indicate the stabilizing effect of ELF-EMF on free radicals.

EFFECT OF ELF-EMF ON APOPTOSIS OF K562 CELL LINE INDUCED WITH QUERCETIN AND OXIDATIVE STRESS

2. Discussion

We observed that the concentration of quercetin that caused a decrease in viability, through apoptotic pathways, was 200µM to 300µM (Fig1). This is in contrast with the observation of Kothan et al [10]. They found that much lower concentrations of quercetin caused early apoptosis. On the contrary we found that low concentrations of quercetin protected the cell from oxidative stress (data not shown). As expected viability decreased with increasing concentrations of quercetin.

300µM quercetin, which was the concentration that initiated a decrease in viability, was chosen to determine the effect of ELF-EMF. The reason for this choice was that since ELF-EMF is weak stressor [8] higher concentrations of quercetin would suppress the effect of ELF-EMF. ELF-EMF caused a small increase in the viability of cells in 24 hours indicating that it interfered in the apoptotic pathway of quercetin (Fig2). There may be two reasons for this. It has been shown that quercetin modifies the membrane via reaction with lipids and proteins and thus may cause alterations in lipid transduction pathway [11]. ELF-EMF might have interfered with this modification by altering the electrical properties of the membrane. Or the reason may be a change in the expression of heat-shock proteins. It has also been observed that Quercetin and other flavonoids inhibited the induction of heat shock proteins [12]. However Goodman et al has shown that ELF-EMF increases heat shock protein levels that were exposed to short term 60 Hz. magnetic field [13] ELF-EMF may have increased hsp levels thus protecting the cell from quercetin induced apoptosis.

Reactive oxygen species are known to cause apoptosis and necrosis in many cell types [14]. This cytotoxicity is mediated by an oxidative event that produces the hydroxy radical. We first measured the concentration dependence of the viability of K562 cells induced with 150µM, 300µM and 600µM H₂O₂ which as expected decreased with increasing concentration (data not shown).

To be able to detect the effect of ELF-EMF two H₂O₂ concentrations (150µM, 300µM) were chosen. As can be seen from Fig.3. ELF-EMF caused a small but significant decrease in viability. These results were correlated with ROS measurements. It was observed that when ELF-EMF was applied to H₂O₂ induced K562 cells ROS levels increased for both of the concentrations used. This correlated very well with the decreased viability of these cells under the same conditions (Fig.4). Application of ELF-EMF alone without any H₂O₂ induction was also seen to increase ROS level which is another indication of the free radical stabilizing effect of ELF-EMF.

Abstract

Magnetic fields (MF) are widely distributed in the environment and their effects are increasing by the development of electrical machines. Moreover, many investigators are studying the effect of MF on the various functions or living organisms. In the present study, we tested the influence of exposure to 30 mT static magnetic field (SMF) on seed germination, growth and some physiological and biochemical aspects in roots and shoots of intact pea plants (*Cicer arietinum*). The results showed that under SMF with 30 mT intensity, seed germination was increased. The root growth was inhibited but shoot length partially increased. Furthermore, a significant increase was observed in the activity of amylase and peroxidase enzymes probably due to the oxidative stress in both roots and shoots. In addition, lignin content was increased in both roots and shoots but the level of increase of lignin in shoots was not significant.

Introduction

With the increased extent of urbanization application of electrical appliances are increasing and living organisms are inevitably subjected to the frequent exposure to low electric and magnetic fields (Patterson, 1992; Breysse et al., 1994; Frey, 1994; Merchant et al., 1994). The magnetic fields (MF) generated by electrical equipment are many times higher than those occurring naturally, and their prevalence is a consequence of technological developments in the second half of the 20th century (Jackson, 1992). However, the role of MF and its influence on organisms' functioning are still insufficiently investigated (Belyavskaya 2001). There have been several studies on the effects of MF on plants (Kato et al., 1989; Phirke et al., 1996; Ruzic & Jerman, 2002). Smith et al. (1993) found that using different field combinations, one could separately alter the root mass, leaf size and stems thickness. Roots seem much more susceptible to the magnetic than shoots (Kato, 1988; Kato et al., 1989). The 15-min treatment of wheat seeds by MF (30 mT) followed by 17-h imbibitions, when they initiated root growth, increased the root formation (Aksyonov et al., 2001). Singh et al. (1994) found that MF with a magnetic flux density of 3000 gauss applied from a permanent magnet for 1-6 h inhibited the growth of *Anabaena doliolum*. Takahashi et al. (1985) investigated the effect of MF on the growth of *Chlorella* using MF with magnetic flux densities of 60-580 gauss, and have identified facilitation of growth below 400 gauss and inhibition of growth at 580 gauss. The mechanisms of facilitation or inhibition of the growth of microorganisms by MF still remain to be elucidated. It has also been found that such fields cause an increase in the free radicals activity in living organisms (Savitz, 1995; Kula et al., 2002) which results in the formation of excessive amounts of reactive oxygen species (ROS). In the present study, in order to obtain more insights into the effects of a MF on plants, we investigated the influence of 30 mT SMF on the growth and certain physiological and biochemical aspects of the growth of pea plant (*Cicer arietinum*).

Seeds of uniform size were selected and surface sterilized with 0.1% sodium hypochlorite solution for 10 min and then germinated between wet filter paper at 25°C in the dark for 4 days, with or without exposure to magnetic field. The seedlings of uniform size were then transferred to sand culture in plastic pots in growth chamber providing white fluorescent light with an irradiance of 150 $\mu\text{mol m}^{-2} \text{s}^{-1}$, 25 \pm 3 °C and 60 (\pm 5) % relative humidity, for 20 days.

Exposure to SMF was performed by a locally designed SMF generator. The electrical power was provided using a 220 V AC power supply equipped with variable transformer as well as a single-phase full-wave rectifier. The maximum power and passing current were 1 KW and 50 A DC, respectively. This system designed to generate SMF in range of 0.5 μT – 30 mT with stable conditions. It consisted of two coil (each 3000 turns of 3 mm copper wire) equipped with a U-shaped laminated iron core (to prevent eddy current losses). Using two vertical connectors, the arms of the U-shaped iron core were terminated to four circular iron plates covered with thin layer of Nickel (each 23 mm thickness, 260 cm in diameter). An electronic board was used to stabilize the system so that we always got a uniform SMF. A water circulation system around the coils was employed to avoid the increase of the temperature.

EFFECT OF SMF ON PHYSIOLOGY AND BIOCHEMISTRY OF PEA

The temperature between the circular iron plates (where the samples were located), was measured by a thermometer and was almost the same as other parts of the room (e.g., the location site of the control cells) $\pm 1^\circ\text{C}$. Since no other electric appliance was working, the control samples were only exposed to the extremely low MF of the earth, as the treatment group was too. Moreover, the control cells were kept far enough from the EMF producing apparatus, to avoid any potential exposure to the magnetic field. Calibration of the system as well as tests for the accuracy and uniformity of the magnetic fields were performed by a Teslameter (PHYWE, Germany) with a probe type of Hall Sound. The accuracy of the system was $\pm 0.1\%$ for static field and the range of measurements was 3 μT – 30 mT. 20-day old pea plants were treated with 30 mT, discontinuously for 5 days, each 5 h. After treatments, the roots and shoots of pea were harvested and frozen in liquid N_2 and kept at -80°C until used for biochemical measurements. Iodometric method was used to determine the endo-amylase activities (Lecker & Khan, 1996). The starch solution (1.5 g/L) was made by dissolving starch in 2 M NaOH solution at room temperature, followed by the addition of an equal volume of 2 M HCl. The resulting solution was then heated to a clear solution before its pH was adjusted to desired value by addition of 2 M NaOH. Final solutions were made by dilution with buffer at the desired pH. A solution (126.9 mg/L), containing the same volume of 0.1 M iodine and 5 g/100 mL potassium iodide, was diluted with cold distilled water to obtain a cold iodine solution (around 2°C). Activity values were determined at 25°C by allowing the enzyme solution in buffer (0.5 mL) to react with the starch solution (5 mL) for 2 min. The reaction was then stopped by adding 2.5 mL of cold iodine solution, which converts the nonhydrolyzed starch to starch-iodine blue complex. The resulting solution was afterwards placed in a thermostatic bath at 25°C for 10 min and its absorbance was measured at 615 nm.

Peroxidase (PO) was extracted and determined in three fractions; the soluble-(SPO), ionically-(IPO) and covalently-(CPO) bound fractions, using guaiacol as an electron donor, as described previously (Ghanati et al. 2004). The activity of SPO and IPO was expressed as the increase in absorbance per min per mg protein and of CPO was expressed as the increase in absorbance against cell wall dry weight. The protein content was determined by the method of Bradford (1976) using bovine serum albumin (BSA) as a standard.

Total sugar content was measured by the anthrone-sulfuric acid method (Dubois et al., 1956).

Lignin content was measured via a modified acetyl bromide procedure (Iiyama & Wallis, 1990). In brief, 6 mg of fine-powdered wall preparation was treated with a mixture (total of 2.5 ml) of 25% (w/w) AcBr in HOAc and 0.1 ml of 70% HClO_4 at 70°C for 30 min with shaking at 10 min intervals. After cooling with ice, the digestion mixture was transferred to a 25 ml volumetric flask containing 5 ml of 2 M NaOH and 6 ml HOAc and made up to 25 ml. The lignin content was determined by measuring the absorbance at 280 nm using a specific absorption of $20.0\text{ g}^{-1}\text{ L cm}^{-1}$. All of the experiments were carried out with at least three independent repetitions in triplicate. All values are shown as the mean \pm SD. Statistical analysis was performed using Student t-Test and the differences at level of $p < 0.05$ were considered significant.

Exposure to 30 mT SMF had a positive effect on germination of pea seeds but it inhibited elongation of those seedlings that had not been treated with MF during their germination (data not shown).

The sugar content of roots and shoots of pea was affected greatly by SMF and a significant increase was observed at 30 mT (Fig. 1).

The starch content of roots and shoots was considered as the activity of amylase enzyme. Compared to the controls, we found that the starch content of roots and shoots of pea plant reduced significantly after exposure to 30 mT SMF (Fig. 2).

Our experiments showed that the activity of SPO in roots of pea plant was significantly increased by exposing to 30 mT SMF (Fig.3 A,D). Moreover, the activity of IPO and CPO increased substantially compared to those in control plants (Fig.3 B,C,E,F).

The lignin content of roots of pea plant treated with 30 mT SMF was significantly higher than non-treated roots (Fig. 4). Compared to the control, an increasing in the lignin content was also observed in shoots of pea plant treated with 30 mT SMF, although it was not statistically significant (Fig.4).

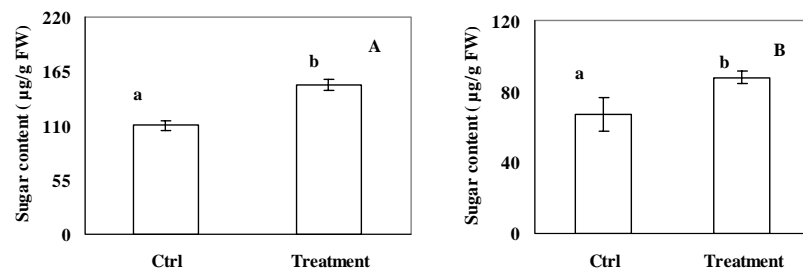

Fig.1 Effect of SMF on sugar content of shoot (A) and roots (B) of pea. Data are means of at least three different experiments in triplicate \pm SD. Signs with different letters indicate significant differences at $P < 0.05$ according to Student's t-Test.

Summary

Investigations of many authors showed that treatment of plants seed by MF increases their germination. In our study, germination of pea seeds increased by 30 mT SMF. Similar results were obtained by the effect of MF on rice, wheat, barley and soybean seeds (Cho et al., 1992). The studies show that this increasing in germination is probably due to the alteration of water relations in seeds by MF (Reina et al., 2001). Root growth reduction may be related to a reduced extensibility of the cell wall. Such effect could result from the stiffening of the wall, partly regulated by PO responsible for the polymerization of monolignins (Fry, 1986). In shoots, we have seen a slight increasing on the length of two latest internodes. This increasing was probably due to the lower synthesis of lignin in shoots than roots under 30 mT SMF, resulted in enhancement of cellular turgor and cell enlargement. Negishi et al. (1999) were observed the epicotyle elongation in pea seedlings exposed to MF. They suggested that the promotion of cell elongation under MF may relate to an increase of osmotic pressure in the cells. The effects of MF on photosynthesis in plants have not been studied in detail. In our study, the sugar content in roots and shoots of pea plant increased at 30 mT SMF. These results suggest that MF probably promote the photosynthetic processes. The similar results were obtained at the study of the effect of MF (100 gauss) on photosynthesis of the *Spirulina platensis* (Hirano et al., 1998). The authors suggested that MF accelerate the light excitation of chlorophyll, reactions of electron transfer and the conversion of light energy to chemical energy.

It has been proposed that α -amylase may be a regulatory enzyme of starch breakdown since this enzyme, unlike β - amylase, can attack and degrade intact starch granules (Dunn, 1974; Manners, 1985), while β -amylase is thought to hydrolyse oligosaccharide products of α -amylase activity and play a secondary role in the regulation of starch hydrolysis (Gallagher et al., 1997). In this research, increased soluble sugar content and also decreased starch in MF-exposed roots and shoots suggest that the hydrolysis of starch under 30 mT SMF is mainly attributed to the enhanced amylase activity. This enhancement was probably due to the increasing of ROS production under MF stress. Similar to our observations, enhanced amylase activity have been reported under water stress in barley leaves (Jacobsen et al., 1986) and cucumber cotyledons (Todaka et al., 2000). Furthermore, Mishra et al. (2005) reported significant increase in activity of amylase by increase in the level of ROS in *Bacillus subtilis*. These authors showed that the increase in enzyme activity was result of adaptive responses induced under oxidative stress.

POs are heme containing proteins that utilize H_2O_2 in the oxidation of various organic and inorganic substrates (Asada, 1994). These enzymes participate in developmental processes, ethylene biosynthesis, defense, wound healing, etc. (Asada, 1992). POs are widely accepted as stress enzymes (Asada, 1992). Induction in PO activity has been documented under a variety of stressful conditions such as water stress (Zhang & Kirkham, 1994), salinity (Mittal & Dubey, 1991), chilling (Prasad et al., 1995) and γ -radiation (Wada et al., 1998). In plants, POs have been mainly detected in cell walls, endoplasmic reticulum, Golgi apparatus and vacuoles, and this distribution is presumably related to different physiological functions (Pandolfini et al., 1992). It has also an important role in the lignification (Asada, 1992; Castillo et al., 1984) and the formation of cross-links between extension and feruloylated polysaccharides, resulting in the

EFFECT OF SMF ON PHYSIOLOGY AND BIOCHEMISTRY OF PEA

increase of wall stiffening and reduction of cell expansion (Castillo et al., 1984). Our results indicated an enhancement in the activity of SPO in both roots and shoots of pea plants when compared to controls. It is demonstrated that the activity of SPO is related to the stress conditions (Pandolfini et al., 1992). Furthermore, in the present study an increased activity was seen in IPO and CPO in both roots and shoots. In some cases, the increased activity is mainly due to the extracellular POs (cell-wall-bound) which are known to play an important role in the lignification and the formation of cross-links between extension and feruloylated polysaccharides (Castillo & Greppin, 1986; Fry, 1986). The enhanced PO activity in the intercellular spaces, involved in cell wall lignification might represent a mechanical defense under biotic and abiotic stress conditions (Gaspar et al., 1985; Castillo, 1986).

DISCUSSION ON THE INFLUENCE OF THE ELECTRIC CHARGE OF AEROSOL PARTICLES ON THEIR DEPOSITION IN HUMAN RESPIRATORY SYSTEM

ZYGMUNT J. GRABARCZYK

CENTRAL INSTITUTE FOR LABOUR PROTECTION – NATIONAL RESEARCH INSTITUTE, ul. Czerniakowska 16, 00-701 Warszawa, POLAND

Abstract

Aerosol particle deposition in human respiratory system is a complex function of the size and geometry of the particles. There are distinguished three main mechanisms of the deposition of the particles during the breathing – inertial force, Brownian motion and gravitational force. Depending on the size, the significance of that mechanisms and the region of respiratory system the efficiency of them is different. The fourth mechanism – electrostatic forces – because of the theoretical predictions (mainly the works of Yu) is neglected usually. The theoretical analysis of the electric forces is limited to passive mechanisms of electrostatic dispersion and the image force in tubes and bulbs of smooth, grounded surfaces and the viscous gas medium. The experimental work of Cohen made with the cast of human air ducts shows that deposition can be significantly higher than that theoretically predicted. The analysis of the influence of the image forces acting at the distance lower than free length and hypothetical non-zero potential of the parts of inner duct surfaces on the particle settlement shows that it can be more efficient for nano-particles than the previous theoretical and experimental works showed.

Key words: aerosol, electric charge, respiratory system, particle deposition, image force

Introduction

The influence of the electric charge on the aerosol particles on the efficiency of their deposition in human airways is usually neglected. A lot of theoretical and experimental work has proved that the deposition of uncharged aerosol particles in airways is governed by following mechanisms:

- diffusion towards the inner surfaces of the respiratory ducts,
- gravitational sedimentation,
- inertial impaction,
- interception.

The deposition efficiency of individual mechanisms depends on particle size and shape and on the considered part of the airways. Diffusion dominates for small particles, especially for nano-particles, and sedimentation dominates in case of coarse particles (larger than 1 μm). The efficiency of deposition in different parts of human respiratory system was shown in Fig. 1. This picture was obtained by NRBP on the basis of calculations using HRTM model (2004). The other authors report the similar deposition curves, so this one can be treated as a representative view. The experimental and analytical research work during the years has shown that the electrical charge of the particle increases its deposition. Those research works could be divided into few groups:

- measurements of the dust retention in exposed animals,
- measurements of the dust retention in exposed humans (very rare),
- measurements and calculations of the deposition in the surrogates of parts of the air ducts,
- measurements of the particle deposition in the hollow airway cast of the human lungs.

The data from the human studies made *in vivo* are rare and difficult to obtain, especially concerning the values of regional depositions. For that very important are studies with hollow casts of human airways, which seem to be the closest to the real conditions and can be useful for verify calculations.

Cohen et al. (1995) gave the detailed review of research results up to 1995. Generally, she contrasted theoretical and experimental results. They showed that the real increase of the deposition of charged particles in airways surrogates or casts (especially in her own experiments) is higher than that predicted theoretically (e.g. Yu, Yu and Chandra). There is general agreement, that the dominating electrical mechanism for the typical particle concentrations is the image force attracting the charge toward the conducting surface.

The new impact to the scientific interest of the share of the image forces in the particle deposition, brought the hypothesis of *Fews, Henshaw et al.* (1999 a, b) for the explanation for the increase number of some cancer cases (especially childhood leukaemia) among the populations living in the vicinity of very high voltage AC powerlines, shown in epidemiological studies. There is a common believe that the very weak AC magnetic fields (about 0.5 to few hundred of nT) could promote the development of some rare kind of cancers, but still the mechanisms of that are not understood. According to *Henshaw, Fews, et al.*, the corona discharge in HV powerlines could charge the particles of aerosol pollutants passing with the wind through the corona region. This could cause the increased deposition of charged pollutants, including cancerigenic substances existing in the air, in human respiratory system, and increase the risk of developing of some pulmonary and cancer diseases. They experimentally confirmed the existence of the cloud of ions on the leeward side of the HV AC powerlines on the basis of measurements of the vertical component of the electrostatic field at the ground level, up and down the wind. In 2005, *Grabarczyk et al.* (2005) confirmed the existence of increase in the concentration of the space charge carried by the particles sized 2 - 22 nm, down the wind of the 110 and 400 kV AC powerlines. This hypothesis was analysed carefully by the *ad hock* group of experts, and the results were published by National Radiological Protection Board (2004). They concluded that the probability of the adverse health effects of pollutants charged by HV AC powerlines is not high, but many questions need the answer before the conclusions.

The main problem, which still is not clear, is the difference between the calculated and measured deposition of charged particles in the respiratory system. It seems that this is important only near processes, which can generate the high fractions of charged nano-particles or charge fine and coarse particles close to their charge saturation.

Figure 1. Total and regional deposition efficiency of spherical, uncharged particles in human respiratory system, after NRPB calculations using HRTM model (2004)

Discussion

There are the crucial points of the discussion on the significance for human health of the inhalation of the charged aerosol particles:

- 1) the potential margin for the possible increase of the deposition by any active factor, other than diffusion, gravitation impaction or interception,
- 2) the real values of deposition enhancement by the image forces,
- 3) the influence of image forces on the regional increase of deposition,
- 4) the health effects of the deposition increased by image forces,
- 5) the way in which image forces can enhance the efficiency of the other, mentioned above, mechanisms:

Ad 1. The potential, theoretically possible increase of the deposition is shown in Fig 1 (the grey area over the total deposition curve). It can be seen well, that for the particles sized below 10 nm and above 5 μm, the margin is very low, about a few percent. However, in the size range 0.1 – 1 μm the margin is very wide, and at about 0.3 – 0.4 μm ten-fold increase of deposition is theoretically possible. In this range, all the local depositions are low, so they could be potentially increased.

Ad 2. The real values of deposition efficiency can be calculated for all airways generations and then be summed, or total deposition can be measured with hollow cast model. Those data are not complete now and need further studies. Especially the reason for which the experimental exposition is higher than theoretically predicted, should

DISCUSSION ON ELECTRIC CHARGE OF AEROSOL PARTICLES

be explained. *Yu* et al have done most of the theoretical calculations. He derived formulas for calculating the deposition efficiency at different generation of air ducts, for parabolic and for slug airflow, and some calculations for bend pipes and some calculations for simultaneous electric effect and diffusion or gravitation.

Ad 3. As the image forces are “short distant” they can be effective rather in the narrow air tubes (e.g. bronchial region or alveoli). They should be active in similar region as the diffusion deposition dominates.

Ad. 4. The health effects of deposition depend on the kind and amount inhaled material rather than on the mechanism of deposition. So the electrostatic deposition potentially could be biologically active it could significantly increase the amount of deposited pollutants or move the deposition to the more sensitive region. The last one not seems very likely. On the other hand if image forces enhanced the deposition, they should in obvious way to cause earlier deposition, that means in lower (in sense of the number) generations.

Ad. 5. This not clear if the electrical and mechanical forces responsible for deposition can enhance or weak each other. The simplest way is to treat them as the additive factors, but likely they are not. *Chen* and *Yu* (1993) proposed the formula for the combined efficiency $\eta = \sqrt{\eta_1^2 + \eta_2^2 - 2\eta_1\eta_2}$ where η_x - individual efficiencies by factor 1 and factor 2.

This should be noticed that in the atmospheric conditions the aerosol particles are in thermodynamic equilibrium, and the charge carried by particles is rather low (see Fig. 2.), especially in the case of free molecular regime particles (very small particles), so probably the health effect could be small or negligible. However, if compare the atmospheric aerosol to the industrial one, especially to the particles being atomized mechanically or charged electrically (e.g. electrostatic painting), their charge could be closer to the possible maximum (limited by the electric breakdown of the air – about $3 \cdot 10^6$ V/m) and the image effect could be significant.

Figure 2. Number of elementary charge carried by aerosol particles seized 1 nm – 10 μ m. Grey line – maximum values limited by electric breakdown of the air, black line – the average values typical for the thermodynamic equilibrium in the atmospheric conditions.

The calculations made by *Yu*, were based on the simplifying assumptions of smooth inner surfaces of analysed pipe like surrogates of the airway, the ideal conductivity, and bioelectrical passivity (no biomechanical or bioelectrical activity of epithelial cells was concerned).

Figure 3. Critical distance from the conducting surface for which the thermal and electric energy (image force energy) are equal, versus number of elementary charge carried by particle.

Diffusion and image force are “short distance” mechanisms of deposition. Potential energy of image force of

charged particle is proportional to the second power of the particle charge. If neglect the other forces acting on the particle, every particle with energy of image force greater than thermal energy, should achieve the conducting surface. The relation between the particle charge and the border distance at which both kinds of energy are equal, is shown in Fig. 3. Particles below the curve in Fig. 3 theoretically, should settle on the conducting surface. However, for the longest distances and coarse particles, this could take a long time, probably longer than sedimentation for large particles. For that, the more effective is to compare the time of flight T of the air along the considered airway (e.g. pipe model) with the time τ of the drift of the particle from the point placed at the input cross section to the inner surface of the pipe. Practically the task is to find the minimum radius of the cylinder coaxial with the pipe, above which all the particles carrying charge q are deposited, it means for which $T \geq \tau$. The profile of the airflow in the pipe is complex. Usually there have been analysed two modes of the laminar airflow – the mode without the boundary layer at the inner surface of the pipe (air speed is constant at the all cross section area – slug flow), and with boundary layer (parabolic flow). The choice of the model depends on the length of the pipe, sharpness of the surface, and air speed, usually for short airways there is no enough time for developing full parabolic flow. According to the calculations by Yu and Chandra (1978), the deposition by the image forces is more effective for slug than for parabolic flow.

Figure 3. The simplified model of image effect of charge q over the conducting plane ($U = 0V$)
 R - the distance between the charge and the conducting, grounded plane, $(-q)$ – image of the charge (q).

For the analysis of the image, force effect there can be used the model shown in Fig. 3. This is the exact model for plane, conducting and grounded material. In case of the respiratory system the cylindrical pipes or spherical conducting cavities are used, where $(-q) = K \cdot q$, where K is a function of the shape of the conducting material and distance of the charge q to the conducting surface. In the atmospheric air, there is the most important, and usually correct the common assumption that the charged particle moves along the electric field line, with the average speed:

$$\overline{\mathbf{v}(\mathbf{r})} = \mu \mathbf{E}(\mathbf{r}), \quad (1)$$

where, μ is the mobility of the charged particle.

In geometry case shown in Fig. 3, in the atmospheric air, which is viscous, the particle movement forced by the image force can be described by the following differential equation:

$$\frac{dr}{dt} = -\mu E = -\frac{\mu q}{16\pi\epsilon_0 r^2}, \quad (2)$$

with the initial condition for the particle drift $r(t=0) = R$.

That relation is only statistically true. If the distance R is enough small, comparable with the particle free path, the particle movement can be described by the following equation:

$$m \frac{d^2 r}{dt^2} = qE = \frac{q^2}{16\pi\epsilon_0 r^2}, \quad (3)$$

and the initial conditions are: $r(t=0) = R$ and $v(t=0) = 0$, where m is the particle mass.

Solution of the Eq. 2 is:

$$\tau = (R^3 - r^3) \frac{16\pi\epsilon_0}{3\mu q}, \quad \text{or} \quad r = \sqrt[3]{R^3 - \frac{3\mu q}{16\pi\epsilon_0} \tau}, \quad (4)$$

and, solution of Eq. 3 is:

$$\tau = \sqrt{\frac{32\pi\epsilon_0 m}{3q^2} (R^3 - r^3)}, \quad \text{or} \quad r = \sqrt[3]{R^3 - \frac{3q^2}{32\pi\epsilon_0 m} \tau^2}, \quad (5)$$

where $d/2 \leq r \leq R$, and d is the particle diameter.

The ratio of the time of flight τ_2 of the distance R in case without collisions (Eq. 5) to the time τ_2 with collisions

DISCUSSION ON ELECTRIC CHARGE OF AEROSOL PARTICLES

(Eq. 4) is:

$$\frac{\tau_2}{\tau_1} = \sqrt{\frac{\gamma\mu^2}{2\varepsilon_0}}, \quad (6)$$

where γ is the particle material density. This ratio is always less than one, and for the fine particles τ_2 is a few orders of magnitude smaller than τ_1 .

The free path l of aerosol particle of diameter d and density γ can be calculated from the Eqs 6, 7, after *Friedlander* (2000):

$$l = \frac{\sqrt{(mkT)}}{3\pi\eta d} \left(1 + \frac{2\lambda}{d} \left(A_1 + A_2 \exp\left(-\frac{A_3 d}{\lambda}\right) \right) \right), \quad (7)$$

where, $A_1=1.257$, $A_2=0.400$, $A_3=0.55$, η - dynamic viscosity of air, λ - mean free path of the air particles (about $0.065 \mu\text{m}$), and

$$m = \frac{4}{3}\pi \left(\frac{d}{2}\right)^3 \gamma. \quad (8)$$

The relation (Eq. 7) is shown in Fig. 4.

Figure 4. The mean value of the free path l of the aerosol particle of density for $\gamma = 10^3 \text{ kg/m}^3$ and diameter d

The fraction of the particles for which the ratio (a) of a free path to the mean free path is inside the range $\langle a_1; a_2 \rangle$, can be calculated as difference of probabilities $p(a_1) - p(a_2)$. The probability function $p(a) = \exp(-a)$ is shown in Fig.5.

Figure 5. Probability $p(a)$ that the free path of the particle is a – folds of the mean free path.

It can be seen that the free path is larger than mean free path for about 37% of the particle population and larger than twice mean free path for 13,5%. So the image force effect without particle collisions is effective only at a distance from few tenth to few hundred of nanometres, but at such distance it is very strong and all charged particles (even with one elementary charge) would be deposited onto the airway surface. In this case the charged particles which are attracted toward the conducting surface by image force, achieve the surface much sooner than 1 ms if not collide with air particles. This effect can increase the deposition efficiency in smaller airways and if turbulent flow takes place. The effect should be studied more precisely and it seems that it was not concerned before.

Generally, because of *Yu* calculations, there exists general opinion that the image forces do not influence the

deposition in significant level. To verify that opinion the following simple case study, based on the *Yu* and *Chandra* (1978) example of 1 μm charged particles, was carried.

This is put the assumption, that the efficiency of the deposition by image force, in generation number n is equal $\eta_{i\ n}$. If the image force would be the only active mechanism in the airway, the deposition in generations from $m=0$ to $m = n \neq 0$ could be expressed as follows:

$$\eta_{i\ 0-n} = \eta_{i\ 0} + \sum_{m=1}^n \eta_{i\ m} (1 - \eta_{i\ m-1}) \quad (9)$$

That should be noticed that Eq. 9 concerns only the population of the particles of defined diameter and charge, for which the values $\eta_{i\ m}$ were calculated before. As the number of generation is 24, even at the According to *Yu* and *Chandra*, the deposition efficiency at the chosen generation pipe of the inner radius R of inner hole, can be presented for laminar flow, as:

$$P = 1 - \left(\frac{r_c}{R} \right)^2, \quad (10)$$

for slug airflow, or:

$$P = \left[1 - \left(\frac{r_c}{R} \right)^2 \right]^2, \quad (11)$$

for parabolic airflow (with boundary layer), where r_c is the critical radius coaxial with the tested pipe, outside of which all particles are deposited.

The relation between r_c and the characteristics of the particle, pipe and airflow is:

$$\tau = 4 \left(\frac{R}{r_c} + 2 \ln \frac{r_c}{R} - \frac{r_c}{R} \right) \text{ for slug airflow, and} \quad (12)$$

$$\tau = 4 \left(\frac{R}{r_c} + 2 \ln \frac{r_c}{R} - \left(\frac{r_c}{R} \right)^2 + \frac{1}{3} \left(\frac{r_c}{R} \right)^3 - \frac{1}{3} \right) \text{ for the parabolic airflow,} \quad (13)$$

where, dimensionless time of residence was defined by *Yu* and *Chandra* (1978) as follows:

$$\tau = \frac{\mu q^2 L}{4\pi\epsilon_0 R^3 u_0}, \quad (14)$$

where, L is the length of the pipe and u_0 the velocity of slug airflow.

On the basis of Eqs. 11-14, *Yu* and *Chandra* (1978) calculated the deposition for each of twenty four generations of the human respiratory system, for the particles of diameter 1 μm and density 1g/cm³, carrying 100e charge, for breathing at 1000 cm³ tidal volume, 12 respirations/minute. Those calculations are presented in Figs. 5 and 6 for the parabolic and slug airflows. Additionally, at those Figures, the total efficiencies calculated according to the Eq. 9, are shown also. For chosen particles, the deposition efficiency is between 30% and 70%. To get the more exact results, the airflow profile in specified generation should be known. Theoretically, there is possible to deposit 100% of highly charged particles, including four mentioned before active mechanisms also.

Figure 5. The efficiency of deposition by image forces at the individual generations of human respiratory system, calculated by *Yu* and *Chandra*, and ascending cumulative efficiency of the first n generations, calculated in this paper, and real cumulative deposition in individual generations. Calculations are made at the parabolic airflow.

DISCUSSION ON ELECTRIC CHARGE OF AEROSOL PARTICLES

Figure 6. The efficiency of deposition by image forces at the individual generations of human respiratory system, calculated by *Yu and Chandra*, and ascending cumulative efficiency of the first n generations, calculated in this paper, and real cumulative deposition in individual generations. Calculations are made at the slug airflow.

The experiments of *Cohen et al.* (1995), mentioned before, with the deposition of charged particles in the hollow, conducting cast of human respiratory system showed, that the possible deposition of charged particles can be much higher than theoretically expected. There was measured the deposition of neutral particles, charged with $1e$ and neutralized particles. The studies with 20 and 125 nm particles were done; their results are shown in the Tab. 1.

Table 1. Deposition efficiency of the charged, neutralized and uncharged fluorescein particles in conducting hollow cast of human airways, at average airflow 5000 ccm/min, measured by *Cohen et al.* (1995)

Electrification of particles	Particle diameter $d = 20$ nm	Particle diameter $d = 125$ nm
	Mean value of deposition, %, $\pm 2\sigma$	Mean value of deposition, %, $\pm 2\sigma$
Single elementary charge ($q=1e$)	6.62 ± 0.70	1.61 ± 0.08
Charge neutralized	1.96 ± 0.29	0.70 ± 0.16
Neutral ($q=0$)	1.24 ± 0.09	0.26 ± 0.06

Those data show that the image force is an important factor enhancing the deposition of charged particles (5.3 folds for 20 nm and 6.2 for 125 nm). The model had to be different from the human respiratory system (e.g. lack of extrathoracic region), so the obtained deposition of neutral particles is significantly lower than that obtained by calculations (see Fig. 1). In case of particles sized above $0.1 \mu\text{m}$, which can carry much higher number of elementary charges than only one, there can be expected significantly higher efficiency, which was shown above (see Figs. 5 and 6).

In the cited studies, there were not considered electrical activity of the cells in air ducts. At this moment, there is no data for assessment the significance of bioelectric potentials in deposition of charged particles and the influence of the particles charge on the cilia activity.

Figure 7. Example of the ciliated cells from the trachea.

Cilia's dimensions are about $10 \mu\text{m}$ length and $0.3 \mu\text{m}$ diameter.

After: *Kenneth S. Saladin, Anatomy and Physiology, the Unit of Form and Function*, WBC/McGraw Hill, 1998, p. 116.

The cilia on epithelial cells (see Fig. 7) move the mucus along a surface layer of saline. This is very likely that the cilia, beating with the frequency about few tenth of Hertz, generate some evoke potentials which should be different during power and recovery strokes. Mucus and saline layers separate the inner space of the airway duct from them, but those layers are not ideal conductors and are not continuous, so there is possible the penetration of electrostatic field of them into the airway duct space. If consider the sizes of cilia and surrounding cells and typical bioelectrical potential, it can be expected the electric field strength of order several to few tenths of kV/m. Such potentials can be compared with electrostatic potentials induced by charged particles between them and the mucus layer or cilia. The potential distribution between the charged particle and conducting surface (as in the Fig. 3) can be expressed as:

$$U(r) = \frac{q}{2\pi\epsilon_0 R} \frac{r}{(R^2 - r^2)}, \quad (15)$$

and is illustrated for $q = 1e$ at the Fig. 8. The change of the potential conducting surface from zero up to U , in rough modelling, can be concern as a virtual change of the distance R . The result of approximate calculations of this change dr related to the distance R , are shown in Fig. 8. This is the case of the particle charge $q = 1e$, for which the sensitivity of the particle to the changes of the conducting surface potential is the highest. The sign of virtual dr is positive if the signs of the surface and particle are opposite, and negative if both signs are the same, respectively. For typical membrane potential about 20 mV, the influence of bioelectric potential is very effective compare to the image forces if $R > 1 \mu\text{m}$ ($dr/R > 0.9$).

Figure 8. The virtual change $|dr/R|$ of the distance R between the conducting plane and charge particle ($q=1e$), when change the conducting plane potential from zero to U .

Summary

The efficiency of charged particles deposition in human airways can significant, especially for highly charged aerosol particles. The above analysis made on the example of individual deposition efficiency of 24 generations of airway ducts, using calculation by Yu and Chandra, has shown that image forces acting alone are able to deposit up to 30-70% of highly charged particles. If include mechanical deposition factors, that efficiency could arise even more. Especially important can be increase of the deposition particles sized 0.1 - 1 μm , where the deposition spare margin is very large, up to ten folds. As the experiments of Cohen *et al.* showed, the deposition of charge 125 nm particles, can be about six folds higher than those of zero charged, potentially this margin can be filled. The analysis of the example of 1 μm and 100e charged particles showed that not only the total deposition increase, but the individual deposition in all generation also. So it seems unlikely, that charging of aerosol particles could cause stopping them in upper parts of airways and significantly prevent the deposition in bronchioli and alveoli, which could positive health effect.

The significant increase of charged particle deposition, on the theoretical basis seems to be very probable if the particles charge is close to their saturation charge, and the most of the particle population is highly charged. Such cases are very rare in practice, excluding some very special conditions like particles charge in electrostatic precipitators or portable electrostatic air cleaners, paint powder particles at the electrostatic painting, and some other technologies. In the processes of particle atomization, young particles which did not achieve the state of thermodynamic equilibrium, could be electrified highly also, and the almost whole population of them can be charged.

The attention should paid to bacteria, especially water born, which charge can be very high, in some cases even up to 10^4e (Mainelis, 2001), but always much higher than that of the non-biological particles in the same environment. For such biological objects, the deposition in human airways can be very effective.

Real efficiency of the image forces can be enhanced also, as it was shown above, by very fast non-collision drift of the particles to the duct surface from the distance close to the free path of the particles. In this case the most effective could be attracting of nano-particles (see Fig. 4) and the least effective of 0.3-0.4 μm particles. This hypothetical effect could enhance the deposition during turbulent airflow much more than during laminar flow.

Other proposed hypothesis is that the deposition of charged particles can be enhanced if some bioelectric potential differences occur on the inner surface of the air-ducts. This effect could modulate the virtual distance of the particles to the inner surface of air duct and could be significantly stronger, especially for small charge on the particles, than the image force effect. These hypotheses should be tested experimentally, but it seems very difficult in the latest case.

Abstract

Studies for the identification of suitable stem cells culture and differentiating conditions that are devoid of xenogenic growth supplements is actually considered an important issue for the clinical applicability of cell therapy for heart failure. We have recently demonstrated the possibility to obtain Cardiac Stem Cells (CSCs), from human endomyocardial biopsy specimens. CSCs self-assemble into multi-cellular clusters known as cardiospheres (CSps) that engraft and partially regenerate infarcted myocardium.

CSps were exposed for five days in an incubator inside a solenoid system with temperature and humidity and CO₂ regulated. This exposure system were placed in an a-magnetic shielded room in the simultaneous presence of a static MF and a low-alternating-frequency-MF, close to the cyclotron frequency corresponding to the charge/mass ratio of Ca⁺⁺ ion. In this exposure conditions CSps modulate their differentiation turning on cardiogenesis and turning off vasculogenesis. Cardiac markers such as Troponin I (TnI) or Myosin Heavy Chain (MHC) were up-regulated, conversely angiogenic markers such as Vascular Endothelial Growth Factor (VEGF) or Kinase Domain Receptor (KDR) were down-regulated as evidenced by immunocytochemistry. The improvement in the cardiogenic differentiation was confirmed by Real-Time PCR and Western Blotting analysis. Interestingly, an increase in the proliferation was observed and evidenced by Brd-U incorporation (ELISA) and cell counting kit-8 (WST-8) analysis.

Exposure to Extremely Low Frequency Magnetic Field (ELF-MF) can modulates the cardiogenic *versus* angiogenic differentiation process of *ex vivo* expanded CSCs. This may pave the way for novel approaches in tissue engineering and cell therapy.

Introduction

In order to increase the reliability and the clinical feasibility of the CSCs employment for cardiac cell therapy we need new methods that allow a modulation of the differentiation process with a minimal cell manipulation.

CSCs can be clonally expanded from myocardial biopsies; these cells are spontaneously shed from human surgical specimens and murine heart samples in primary culture. This heterogeneous population of cells expresses c-kit. These cells are self-renewing, clonogenic and multipotent giving rise spontaneously to cardiomyocytes, smooth muscle cells and endothelial cells. In suspension culture they form multicellular clusters dubbed Cardiospheres (CSps).¹

Recently spontaneous differentiation of ES cells into cardiac myocytes by exposure to ELF-MF has been reported². We assessed the hypothesis that the exposure of CSps to defined Magnetic Field could modulate the cardiac differentiation process with a minimal cell manipulation.

Methods and results

Human biopsy specimens were obtained from patients undergoing clinically-indicated percutaneous endomyocardial biopsy and processed. Samples were stored on ice in high potassium cardioplegic solution and processed within two hours. Briefly, samples were cut into fragments, washed, partially enzymatically digested, and the single cells discarded. The remaining tissue fragments were cultured as explants on dishes.

A lawn of flat cells spreads from the biopsy and covers the bottom of the dish in 14-20 days. Cells can be seen budding off from the main explant and then seeding the dish, a process which is robust by 12-18 days. The cells surrounding the explant are harvested, initially after 5-7 days, and then every 4-5 days (for a total of 4 harvests). When grown in suspension, the cells form CSps within 12-20 days. On the basis of our previous results obtained with other cellular model (cheratinocytes, neuronal cells)³⁻⁵, CSps were exposed for five days in the a-magnetic room with simultaneous presence of a static Magnetic Field and a ELF-MF, close to the cyclotron frequency corresponding to the charge/mass ratio of Ca^{++} ion.

The equipment for electro-magnetic field (solenoid) production is installed in a-magnetic room. This equipment include cellular incubator made to a-magnetic material were temperature regulation ($37 \pm 0.1^\circ\text{C}$) and atmosphere (5% CO_2) and humidity were provided and continuously controlled and recorded by a lab view program embedded computer.

The main body of the solenoid is a cylinder in PVC 5 mm thick and has a diameter of 33 cm and a height of 3 m. It is made of 3,300 turns of 1 mm diameter copper wire. It is driven from three amplifiers and a signal generator that generated static and alternate current for electromagnetic field production. This equipment is able to produce 0.01Hz to 1 KHz frequency and 10 nT to 1mT of electromagnetic field and induction respectively at 33 mV RMS drove.

Under these conditions an increase in cell metabolism was observed and evidenced by cell counting kit-8 (WST-8) analysis (Fig. 1). Moreover, cardiac markers such as Troponin I (TnI) or Myosin Heavy Chain (MHC) were up-regulated. Conversely angiogenic markers such as Vascular Endothelial Growth Factor (VEGF) or Kinase Domain Receptor (KDR) were down-regulated as evidenced by immunocytochemistry (Fig. 2) and by RT-PCR (Fig. 3).

Figure 1: Metabolic activity

Evaluation of cell metabolism by utilizing sensitive colorimetric assays. WST-8 is reduced by dehydrogenases in cells to give a yellow colored product (formazan), which is soluble in the tissue culture medium. The amount of the formazan dye generated by the activity of dehydrogenases in cells is directly proportional to the number of living cells. Figure shows that cells exposed to ELF-MF (●) have higher metabolic activity then the unexposed cells (○).

Effect of field exposure on expression of cardiac markers such as cTnI, Nkx 2.5 and angiogenic markers such as VEGF after five days. The column diagram shows the differences in mRNA production of exposed (■) and unexposed (□) CSps.

Discussion

One hundred years ago the humans were exposed only to natural electromagnetic field (EMF). With technical and industrial growth, the EMF generated by human activities became several times higher than the field found in nature.

Because most of the physiological processes of the eukaryotic cell are voltage regulated, in the last 20 years underwent a strong increase of the interest to investigate the effect of extremely low frequency electric and magnetic fields⁶⁻⁸.

Some of this studies reported changes induced in calcium efflux from chicken brain hemispheres⁹, nerve regeneration¹⁰, alteration gene transcription¹¹, and they may also play a synergic role in cellular processes that are already activated, such as cell proliferation and cell differentiation.

The possible mechanisms of the induced effects are not known, although a number of theoretical models have been proposed¹²⁻¹⁴. Studies focusing on the role of Calcium signalling in the mechanisms of the ELF-MF-induced differentiation are ongoing in our laboratory.

We have obtained data showing that exposure of the *ex vivo* expanded CSps to ELF-MF modulates their differentiation turning on cardiogenesis and turning off vasculogenesis. Interestingly this effect was accompanied by increase of cellular metabolism and proliferation.

If confirmed, these results should increase the reliability and the clinical feasibility of the CSCs employment for cardiac cell therapy.

OCCUPATIONAL ELECTROMAGNETIC FIELD EXPOSURE AND INDUCED CURRENT'S HAZARDS FROM ELECTROSURGERY DEVICES

KRZYSZTOF GRYZ, JOLANTA KARPOWICZ

CENTRAL INSTITUTE FOR LABOUR PROTECTION

– NATIONAL RESEARCH INSTITUTE, WARSZAWA, POLAND, e-mail: krgry@ciop.pl

Abstract

The investigations concerning medical staff exposure to electromagnetic fields and induced currents hazards from electrosurgery devices have been completed. The exposure has been evaluated following the European Directive 2004/40/EC and national occupational safety and health regulations. The main sources of workers exposure are powered electrode and cables. Electromagnetic fields from electrosurgery devices are pulsed modulated and have heterogeneous spatial distribution. It has been found that in the vicinity of electrosurgical devices, the area of electromagnetic fields to which only workers operating the source of field should be exposed can exist up to the distance of tens of centimetres from the active electrode and supplying cables. In the case when the cables are placed directly on the surgeon's body the overexposure of workers can appear. The current flowing through the arm of surgeon keeping the electrode emitting electric field of the maximum strength (app. 1000 V/m or higher) can exceed the permissible value of 40 mA established by the Directive 2004/40/EC for contact current. The obtained results of measurements and suggestions for reduction of the surgeon's exposure are presented.

Keywords: electromagnetic fields, occupational exposure, induced currents, electrosurgery.

Introduction

Electrosurgery is used for various surgical treatments - to cut or to coagulate a patient's tissues. Electromagnetic hazards produced by these apparatus are essential for a big group of medical staff given a common use of electrosurgery devices. Electrosurgery devices consist of a generator (with output power of up to 500 W, but usually the output power used during surgical treatment is of 50-150 W), an active (powered) electrode connected with the generator by long cable and a passive electrode, fixed at a patient's body and connected by long cable with "0" electric potential of the generator.

Controllable surgical effect is a result of the flow of radiofrequency (RF) currents through the tissues of the body and local heating them. This current is the result of capacitive coupling of powered electrode with a patient's body. Current can flow with or without a direct contact between the active electrode and the body of patient if the potential of the electrode is higher than 200 V in the relation to potential of the tissues. Electric arc can be burned under the active electrode in the case of a higher potential of the electrode.

Currents of frequency above 300 kHz (up to approx. MHz) are used to avoid electrical stimulation of tissues. The waveforms of electric potential and current (and in consequences, electromagnetic field (EMF) produced in the vicinity of cables) depend on a type of a device and it's selected mode of a device operation. As a result, the EMF waveform changes from sinusoidal (usually exists during cut mode) to pulsed modulated (during different coagulation modes) – fig. 1, and additionally it is always pulsed modulated by the switch-on and switch-off actions of surgeon which are taking following surgical treatment needs.

The sources of the occupational exposure are mainly [2]:

- the active electrode at a high electric potential from which the RF current penetrates the tissue
- the cables connecting the generator with the active electrode, kept in the hand by a surgeon, and with the passive electrode (grounded plate), mounted to the patient's body.

The additional sources of EMF can be:

- the generator in the case of not leakproof housing (without electromagnetic shield),
- metallic objects located in the vicinity of the electrodes cables (for example, surgical or instrumentation's tables) and which can become secondary sources of EMF.

The EMF is produced from the moment of activation of an electrosurgery device. It may be operated by foot-control or through a button-control on the handle of the active electrode.

Fig. 1. Examples of EMF waveform registered in the vicinity of electrosurgery devices: a) pure cut mode; b) coagulation “spray” mode.

Electrodes and supplying cables are sources of strong electric field because of radiofrequency (RF) high voltage between electrodes. The exposure to EMF of a surgeon and medical staff depends on the selected mode of device operation, the kind of active electrode used and the location of cables connecting electrodes with generator.

During patient's treatment, generator and cables can be located in various places against to the surgical table and medical staff bodies. It is crucial for the level of exposure to electric field and capacitive coupling between elements of electrosurgery device and the worker's body and it determines the level of current flowing through the worker's body, similarly to currents through the patient's tissues. If the cables create loops, an increased magnetic field exists also in their vicinity.

The surgeon, who keeps the active electrode in hand, is usually the most exposed person from the team. The hand's exposure always exists, but other parts of the body can be also exposed as a result of the contact with cables, e.g. head's or torso's EMF exposure.

Methods

The EMF measurements have been performed to assess the medical staff exposure to EMF during the use electrosurgery devices [2]. The measurements of RMS electric and magnetic field strength have been conducted according to the Polish Standard PN-T-06580:2002 [6]. Broadband electric and magnetic field strength meter EMR 300 from Wandel & Goltermann with H-field probe type 13 (0.02-250 A/m; 300 kHz – 30 MHz) and E-field probe type 8 (1-800 V/m; 100 kHz – 3 GHz) has been used. The obtained results have been evaluated according to the Polish national regulations concerning the limitation of occupational exposure to EMF of 0 Hz - 300 GHz frequency range [5, 7]. This regulation stated that the worker's exposure assessment should be performed on the results of the spot measurements of RMS value of unperturbed (it means existing in the workplace during the absence of workers) electric and magnetic field strength (the maximum result of measurements over the worker's body position in the workplace).

Additionally, the investigated EMF exposure of medical staff has been analysed following the internationally published limitations [5], European Directive 2004/40/EC [1], ICNIRP's guidelines [3] and IEEE standard [4]. According to the European Directive, workers' exposure assessment should be performed on the results of measurements of RMS value of unperturbed (existing in the workplace during the absence of workers) electric and magnetic field strength averaged over the workers body position and averaged for particular time, which depends on the frequency of assessed fields. For example, for the EMF of the frequency 100 kHz - 10 GHz, E and H should be averaged within any 6 minutes of worker's exposure and E^2 and H^2 should be averaged over the worker's body position. Electric field strength (E) and magnetic field strength (H) were included into the set of the Directive's “action values”, which were defined as the set of external measures, which can be used to describe the EMF exposure for testing and roughly assessing environmental conditions in the workplace. The exposure results inside exposed body, which were taken as “exposure limit values” (internal measures) refer to

the physical quantities as current density (J) and specific energy absorption rate (SAR) should be considered in the case of environmental exposure conditions exceeding above-mentioned "action values". Additionally, Directive's provisions refer to contact current (I_C) and limb induced current (I_L), which can be also used for testing the compliance with "exposure limit values".

Exposure limitation in the frequency range of EMF produced by electrosurgery devices established by Polish national regulations and European Directive is shown in table 1.

Table 1.

Electric and magnetic field strength – exposure limitation established in Poland [6] and by European Directive's "action values" [1].

Frequency range	Exposure limitation in Poland				Directive 2004/40/EC	
	Electric field strength, E [V/m]		Magnetic field strength, H [A/m]		Electric field strength, E [V/m]	Magnetic field strength, H [A/m]
	prohibited exposure	8-hours exposure	prohibited exposure	8-hours exposure		
300 kHz $< f \leq 800$ kHz	1000	100	100	10	610	$1.6/f$
0.8 MHz $< f \leq 1$ MHz	1000	100	$80/f$	$8/f$	610	$1.6/f$
1 MHz $< f \leq 3$ MHz	1000	100	$80/f$	$8/f$	$610/f$	$1.6/f$

f - frequency in MHz

Measurements of RMS current flowing through surgeon's hand (fig. 2) keeping the active electrode (Holaday HI-3702 clamp-on meter) and through feet (Narda 8850 stand-on meter) have been also conducted. These currents are the results of coupling between element with high electric potential (active electrode or cable) and workers body. This current should be considered rather as induced current than contact current.

Fig. 2. The clamp-on meter measurements of the current in surgeon's hand.

The assessment of these quantities may be carried out following the permissible values as specified in Directive 2004/40/EC [1] and in ICNIRP guidelines [3] for contact current or permissible values for induced current in the feet specified in IEEE standard [4]. The Directive's criteria for induced current in limbs are not given for frequency below 10 MHz. Polish regulations don't refer directly to current inside workers body. Exposure limitation of contact and induced current in the frequency range of EMF produced by electrosurgery devices established by European Directive and IEEE standard is shown in table 2.

Table 2.

Contact and induced current – exposure limitation established by European Directive [1] and by IEEE [4].

Frequency range	Directive 2004/40/EC		IEEE			
	Contact current, I_C [mA]	Limb induced current, I_L [mA]	Contact current, I_C [mA]		Induced current in feet, I_L [mA]	
			for touch	for grasp	each foot	both feet
100 kHz $< f \leq 10$ MHz	40	not specified	50	100	100	200
10 MHz $< f \leq 110$ MHz	40	100	50	100	100	200

Measurements were performed for more than 30 types of common-used electrosurgery devices: various types of ERBE, Aesculap, Bovie, Valleylab and Olympus operated in the various modes. The output power during investigations (approx. 100-150 W) was a little higher than during normal work to obtain results representing the worst case of workers exposure conditions.

For the technical reasons, measurements have been performed during a simulated operation - absorbent cotton with saline has been used as phantom equivalent to the patient's body.

Results

The results obtained have shown that the surgeon is usually exposed to non-homogenous electric field. Metallic objects, which are in the operating theatre influence on spatial distribution of electric field. The level of exposure of medical staff can be changed by 2-3- fold depending on the location of these objects.

In the worst case implying the use of a monopolar electrode and non-shielded cables surgeon's hand keeping this electrode can be exposed to electric field exceeding 1000 V/m, head and torso up to a few tens V/m (fig. 3). When the cables touch the surgeon's body then the torso exposure is stronger, up to the level of the exposure of hand keeping electrode.

Near electrosurgical devices, the area of electric field strength exceeding 10 V/m can exist up to the distance of 70-100 cm from the active electrode and supplying cables.

Magnetic field in the nearest distance of electrodes and cables (5-10 cm) is usually below 1 A/m.

For the operation with output power less than 50 W or with the use of bipolar electrode, electric field exposing the hand is less than 80 V/m and less than 30 V/m in the case of head and torso exposure.

Electric field around the housing of the generator with effective EMF shielding is below 30 V/m during the use of both kinds of electrodes.

Fig 3. The examples of surgeon's exposure to electric field during the use of various electrosurgery devices (output power 100-150 W, a monopolar active electrode, cables far from the torso and head).

The execution of electrosurgical treatment with an electric arc burned under the active electrode lead to significant increase of electric field affecting on medical staff. The level of exposure during electric arc-surgery can be 4-fold higher in comparison to the operation without arc (fig. 4).

Waveform of EMF as well as the level of exposure in the vicinity of active electrode and supplying cables depend on the mode of electrosurgery devices operation. Figure 5 illustrates how electric field strength from the same electrosurgical device depends on it's selected mode.

Fig. 4. The examples of registration of electric field strength in the vicinity of active electrode:
a) cut mode without burned electric arc; b) cut mode with burned electric arc.

Fig 5. Examples of registration of electric field strength in the vicinity of electrosurgery device - various modes of operation: a) cut "pure"; b) cut "blend"; c) coagulation „desiccate”; d) coagulation „fulgurate”; e) coagulation „spray”; f) cut „pure” with argon; g) cut „blend” with argon; h) coagulation „spray” with argon.

The results presented indicate the possibility of a high exposure of the surgeon's hand in the case of keeping the active electrode or touching the cable to forearm. Measurements of current in surgeon's body may be used for additional assessment of exposure conditions and internal results in exposed body. The investigations carried out show, for example, that current in the hand keeping the active electrode can be of order 5 - 18 mA in the case of electric field strength of approx. 70 V/m in the distance of 5-10 cm from a monopolar active electrode (fig. 6), and significantly depends on the location of cable towards the hand.

Current in the feet of surgeon, insulated by shoes from ground and without direct contact with cables, is below 20 mA when electric field strength in the vicinity of monopolar active electrode is approx. 250 V/m. Taking into account the possibility of exposure to a stronger field (app. 1000 V/m or even higher) or a contact of the body with the cables, the current flowing through the arm of surgeon keeping the electrode can exceed the permissible values established in the Directive 2004/40/EC for contact current (40 mA).

The results obtained also indicate that current measured by clamp-on meter in the hand keeping the active electrode is approx. 2-fold higher than current measured by stand-on meter in the feet.

Fig 6. The examples of registration of current in surgeon's hand exposed to EMF from the electrode's cable.

The conclusive assessment of surgeons exposure to EMF, presenting compliance with European Directive provisions concerning internal measures ("exposure limit values"), will be possible after publishing harmonised European standards. These standards should fix in details the protocol for measurements or calculations, necessary for such exposure assessment. The numerical simulations for the verification of the compliance of particular EMF exposure scenarios with the Directive provisions need the use of a high resolution of the worker's body models and an adequate representation of the workplace environment. For the electro-surgeon's EMF exposure, the conditions such as calculations for particular exposure situations need high professional skills, specialised software and they are very often time-consuming. The basic problems identified during pilot calculations are: the representation of the realistic posture of worker's body, the adequate representation of the electrical grounding conditions at the workplace and the adequate representation of realistic impedance of near-field produced by electrosurgery devices, as well as its dynamic changes in the course of surgery treatment.

The additional problem with assessment of measurements results can appear for highly modulated EMF, when the properties of the used EMF meters calibrated in harmonic field cannot be relevant to such field's measurements and then the use of correction's factors taking into consideration the waveform of incident fields should be recommended. It was analysed for various kinds of modulations of EMF produced by various devices examined that the value of the measurement's uncertainty component coming in consequences of measurements of modulated fields in the case of common electrosurgery devices can be on the level of 50%. It is possible to find both effects, overestimation and underestimation in the EMF strength measurement's results.

Conclusion

In consideration of a necessity to keep the active electrode in the hand, complete elimination of surgeon's exposure to strong electric field is impossible. The reduction of the surgeon's exposure can be reached by the proper positioning of the cables supplying a monopolar electrode. The exposure of others persons from medical staff is relatively weak if they don't have a direct contact with cables. In the worst case of cable's location and electrosurgery device's output power, the EMF overexposure can occur. The surgeon's EMF exposure assessment for the case of the use of a monopolar electrode should be completed with measurements or calculation of currents flowing through the body.

The results of the investigations presented show that the effective reduction of the surgeon exposure can be obtained by keeping cables between the generator and the surgeon's hand without a contact with the bodies of workers. Cables located at the surgical table decrease the surgeon's exposure but increase the influence of electric field on other medical workers (e.g. nurses). A compromise is indispensable in that situation. A radical reduction of the EMF exposure level is possible by the use of the bipolar electrode if a kind of surgical treatment allows for that. Avoiding work with burned electric arc under the electrode reduces the exposure of personnel, too.

If weak electric field near the electrode is found (usually in the case when output power is approx. 50 W or less, the use of bipolar electrodes or shielded cables) measurements of electric field strength can be considered as

sufficient to confirm a low level of exposure there. The measurements uncertainty and the consequences of a high modulation of EMF from electrosurgery devices for the measurement's results should be analysed very carefully in every case when a relatively high level of exposure is found at the workplace.

-Measurement of Complex Permittivities of Biomedical tissue at Millimeter Wave Band

Abstract

For this paper, we directed our attention to the free-space method using a dielectric lens antenna, using this method to measure the permittivity of a cow's blood in the millimeter-wave band. We confirmed that measurement results under this method were in agreement with measurement results obtained by the coaxial probe method; here we report on the measurement results up to 65 GHz.

Introduction

Recently, utilized frequency band has been extended to higher frequency region including millimeter-wave band. The electromagnetic dosimetry is therefore required in the millimeter-wave band. This area of study deals with a simulation of exposure and a calculation of internal field within an exposed human body. A permittivity of a tissue is required for electromagnetic dosimetry and it well known that the permittivities of the biological tissues have frequency dispersion. Under these backgrounds, a great number of measurement methods of dielectric constants have been studied in various frequency bands [1]-[3]. However, few studies on permittivities of biological tissues have been reported in millimeter-wave band. Therefore strong demands for measurement of the dielectric constants of biological tissues in the millimeter-wave band exist.

In this study, we gave attention to a free space method using a lens antenna [4] and measured dielectric constants of cow's whole-blood samples from 33 GHz to 65 GHz. As a result, these were in good agreement with those measured by an alternative method (coaxial probe method). The result suggests that the proposed method can be used for permittivity measurement of a biological tissue in millimeter-wave band even higher than 65 GHz.

Measurement theory

We used the multi-line model for determining a complex coefficient of a surface of a liquid. We defined a measured cascade matrix of the glass of measured scattering parameter.

$$[T_g] = \frac{1}{S_{21}} \begin{bmatrix} (S_{21}S_{21} - S_{11}S_{22}) & S_{11} \\ -S_{22} & 1 \end{bmatrix} \quad (1)$$

The measured cascade matrix can be also be written as

$$[R_T] = [T_g][R_s] \quad (2)$$

Where cascade matrix $[R_T]$ and $[R_s]$ represent reflection coefficient of the glass and of the sample. If we neglect the reflection wave from the bottom of the holder, we can relate the complex permittivity of a liquid to the complex reflection coefficient. So from scattering parameter measurements, we determine the complex permittivity of the sample within the holder.

Measurement method

Fig.1. Composition and picture of sample holder.

Fig.2. Picture of measurement set-up.

Figures 1 and 2 show a measurement set up and a sample holder, respectively. As shown in Fig.2, a liquid agent is hold with an optical glass and a tank made from a stainless steel. This measurement, as shown in Fig. 1, an electromagnetic wave generated by a VNA (Vector Network Analyser) is transmitted from the lens antenna to a test sample held by the sample holder. The lens antenna then receives a reflected wave (S_{11}) from the sample. These waves and T-parameter of the optical glass are then used to calculate the complex permittivity of the sample. Since in this measurement the metal plate of the holder and deformation of the liquid surface on the top surface of the holder may result in measurement errors, a high-directivity lens antenna [4] was used, as well as a 65-cm² holder (sufficiently large for the test irradiation area). Calibration was carried out via TRL (Through-Reflection-Line), which does not require any open and load standards [5]. The room temperature and the temperature of the blood during measurement were approximately 24°C and 22°C, respectively.

MEASUREMENT OF COMPLEX PERMITTIVITIES OF BIOMEDICAL TISSUE AT MILLIMETER WAVE BAND

Measurement results

The permittivity of the blood of a cow was measured using the sample holder and the measurement set-up mentioned above. Fig. 3 shows the measurement results using the above set-up as well as measurement results using the coaxial probe method. Note that although the lens antenna used in measurement is functional in the frequency range from 18 GHz to 110 GHz, it features a cut-off frequency because it is connected to the VNA through a coaxial waveguide converter. Measurement was therefore performed using two types of waveguide, the WR22 and the WR15.

The measurement results using the WR22 and those using the probe method showed agreement, confirming that the measuring method proposed in this paper enables millimetre-wave band measurement of the permittivity of a biological tissue. Moreover, permittivity in a range from 50 GHz to 65 GHz (difficult to measure with existing coaxial probes) was measured by changing to the WR15 waveguide. As a result, the measurement results agree with those of the above-mentioned WR22 (with a difference of approximately 5%); we thus concluded that the experiment successfully demonstrated the possibility of measuring the permittivity of a biological tissue using a wide range of frequencies. We inferred that the difference noted above was most likely brought about due to factors such as variation in liquid temperature and absorption of water in the liquid agent.

Fig.3. Measurement result (blood).

Conclusion

For this paper, we directed our attention to the free-space method using a dielectric lens antenna, using this method to measure the permittivity of the blood in millimeter-wave band. Based on our results, we confirmed that the measurement values obtained under this method were in agreement with the measured values obtained by the coaxial probe method, demonstrating that this method is appropriate for the measurement of permittivity of a biological tissue in the millimeter-wave band. Investigation of changes in liquid temperature remains as issues to be resolved in the future.

Abstract

The increasing number of mobile phone base stations in Germany is associated with concerns in the population that the electromagnetic fields (EMF) could have adverse effects on health and well-being. The aim of the study was to investigate the association between EMFs of a UMTS-mobile phone base station and health of office workers.

A newly installed UMTS (Universal Mobile Telecommunications System) - base station was in a double blind fashion randomly turned on and off for 24-hours over a period of three months. Using an online questionnaire participants (n = 95) indicated their health at the beginning and the end of each working day. In addition, participants assessed whether the base station was turned on or off.

No evidence for an association between the exposure of the mobile phone base station and health of the participants was found. However, when the participants thought that the base station was turned on they indicated statistically significant more health complaints.

On the basis of the results of the study no association between the exposure to an UMTS base station and health could be shown. A follow-up study with a larger sample of the general population and personal dosimetry would be desirable.

Introduction

Proliferation of mobile phone base stations enables more and more people worldwide to use new telecommunication systems. However, many people are concerned about possible adverse health effects of the electromagnetic fields emitted by cellular phones and mobile phone base stations, even if exposure levels are far below those recommended. (Bavarian State Ministry of the Environment, Public Health and Consumer Protection, 2003). In Germany, introduction of UMTS (Universal Mobile Telecommunications System) requires installation of 15.000 new base stations. One reason for the concern about health effects of mobile phone base stations is the inability of neighbouring residents to regulate the duration and timing of these electromagnetic fields (Revermann 2003).

Despite the concerns, few studies of the effects of exposure to mobile phone base stations have been published. Published studies – e.g. by Santini et al. (2002) and Navarro et al. (2003) - have numerous methodological problems, so that their results are likely to be biased. The main issue is the valid exposure assessment, and it was not fully resolved in the pilot study of Hutter et al. (2002), who measured exposure to the base stations in the participants' bedrooms. Level of electromagnetic emissions of a mobile phone base station varies over time, making it difficult to capture accurately. To date, specific variation of the exposure over time has only been possible in laboratory studies.

Thus, the effects of UMTS exposure on human health and well-being have only been investigated in laboratory settings. Zwamborn et al. (2003) exposed people who reported sensitivity to radio-frequency waves (electrosensitive group) and a control group to a 1 V/m field at 900 MHz and 1800 MHz by replicating GSM fields, and also 2100 MHz UMTS fields. The study found a statistically significant association between the UMTS fields and well-being for both groups. By contrast, no effect was seen for the GSM frequencies at 900 and 1800 MHz. However, a Swiss follow-up study did not confirm these results (Regel et al. 2006). In a double blind provocation study (900 MHz GSM mobile phone signal), Rubin et al. (2006) tested persons reporting electrosensitivity and controls but found no evidence either for the ability of electrosensitive people to detect such signals or of any increased symptom severity among them.

Within the feasibility study presented here, a newly installed UMTS mobile phone base station could be used for study purposes over a period of three months. The aim of this double-blind experiment was to investigate whether the electromagnetic fields of a UMTS base station influence the well-being of office employees working in its proximity. In addition, it should be taken into consideration in what way psychological factors like causal attribution are involved.

Material and Methods

The study took place from September to December 2003.

Participants

Overall 104 employees of the Bavarian Environmental Agency participated in the study. Of them, 95 participants (67 male and 28 female), age between 26 and 62 years (median = 40), answered the questionnaire in the morning and in the evening on at least 25 percent of the 70 days of the study and could thus be included in the analyses. Of these 95 participants, 71 (75 %) completed the daily questionnaires on at least 42 out of the 70 working days (60 %). Reasons for questionnaire non-completion were holidays, work outside the agency or sickness leaves. Most of the participants had a high level of education (university degree or doctoral level). All subjects gave their written informed consent to the participation.

Study design

The UMTS-mobile phone base station was installed in summer 2003 on the roof of the Bavarian Environmental Protection Agency. The mobile phone base station was switched on or off (control days) for one, two or three consecutive business days. The number of exposure and control days was equal ($n = 35$ each). We thus created six different exposure conditions, which differed by operating status (on, off) and duration (one to three days). Differing duration of the UMTS-exposure would enable to assess its potential cumulative effects on health.

Double-blinding

Several measures were taken to ensure the double-blind design. The operating status of the base station was chosen randomly from three possible versions. The power of the base station was recorded over the study period, with notebook and record located in a closed room. A modification on the software of the base station guaranteed that the operating status of the base station could not be received by a mobile phone. In addition, the base station had its own electricity.

Exposures

The mobile phone base station manufactured by Kathrein (type K742 212) transmitted the UMTS signal with a mean frequency of 2167,1 MHz, 5 MHz frequency range und a transmitting power of 20 W. With the downward tilt of the antenna of 8° it was possible to achieve maximum exposure level in the office building.

The UMTS exposure of the participants differed by the location of their offices in the building. Exposure measurements were carried out in the empty offices of all participants on weekends with base station turned on. Measurements were done by a physicist of the Bavarian Environmental Agency. The UMTS exposure in the offices ranged from 0.05 V/m (detection limit) to 0.53 V/m. The mean level was 0.10 V/m (standard deviation 0.09 V/m).

MOBILE PHONE BASE STATION AND HEALTH

Questionnaire

Using an online questionnaire, participants indicated their health condition at the beginning and the end of each working day. The questionnaire contained items on health complaints that were used in connection with electromagnetic fields in several publications (Berg et al. 2004, David et al. 2002, Frick et al. 2002, Hietanen et al. 2002, Hillert et al. 1999, Rösli et al. 2004). A summary of the items is shown in table 1. In addition, participants were asked to guess whether the base station was on or off.

Table 1: Online-questionnaire used to evaluate health symptoms and the mean scores (M) and standard deviations (SD) of the score differences between morning and afternoon score, listed by operating status of the mobile phone base station (on or off)

Question: „How intensively did you experience the following health complaints today since you started working this morning? “

Answer categories: rarely–slightly–somewhat –strong–very strong

	M (SD)		p
	MBS switched off	MBS switched on	
concentration problems	0.090 (0.217)	0.138 (0.211)	0.680
lack of energy	0.037 (0.566)	0.065 (0.230)	0.161
headache	0.128 (0.274)	0.152 (0.214)	0.187
neck and shoulder pain	0.044 (0.194)	0.067 (0.182)	0.219
strong perspiration	0.008 (0.143)	0.029 (0.138)	0.181
dejection	0.002 (0.179)	0.018 (0.129)	0.172
feeling of pressure at the ear	0.010 (0.135)	0.022 (0.134)	0.616
tinnitus	0.020 (0.126)	0.032 (0.151)	0.075
breathing difficulties	-0.004 (0.077)	0.007 (0.039)	0.165
lack of appetite	0.000 (0.084)	0.003 (0.075)	0.563
paraesthesia	0.015 (0.120)	0.017 (0.106)	0.978
dry skin	0.006 (0.143)	0.008 (0.128)	0.685
allergic disorders	-0.005 (0.055)	-0.003 (0.055)	0.782
restlessness	0.020 (0.327)	0.021 (0.143)	0.371
cardiac symptoms	-0.001 (0.056)	0.000 (0.064)	0.699
nervousness	0.020 (0.206)	0.020 (0.129)	0.674
irritability	0.022 (0.245)	0.021 (0.123)	0.448

feeling of anxiety	-0.005 (0.220)	-0.009 (0.075)	0.237
limb pain	0.012 (0.101)	0.003 (0.098)	0.202
back pain	0.051 (0.171)	0.042 (0.186)	0.494

Statistical analyses

Complaints were assessed on a five-point Likert scale: “rarely” = 1, “slightly” = 2, “somewhat” = 3, “strong” = 4, “very strong” = 5. In order to assess the change in well-being during the day, the score difference between morning and afternoon was calculated. The overall level of well-being was calculated as the sum of answers to the 21 questionnaire items. Higher score indicated worse well-being. The absolute change in the overall score over the working day was calculated as the difference between morning and afternoon score.

We used two sided t-tests for paired samples and ANOVA to examine the research questions of this study. Statistical analyses were carried out using SPSS 11.5.

Results

On average, the well-being decreased slightly, but not significantly, over the course of the working day. As shown in table 1, the mean symptom score did not differ statistically significantly over the working day between exposure and control days. In order to study a potential accumulation of effects, the mean change in symptom scores over a series of 1, 2 or 3 days with exposure was compared with sham-exposure (table 2). The ANOVA did not indicate statistically significant differences between the exposure conditions. (operating status: $F = 1,36$, $p = 0,35$; duration: $F = 0,66$, $p = 0,52$; interaction: $F = 0,37$, $p = 0,69$).

In contrast, the mean symptom score was significantly higher if the participants considered the base station to be switched on ($M = 1,93$; $SD = 2,49$) than on days they considered unexposed ($M = 0,16$; $SD = 0,95$; $T(77) = -6,66$, $p < 0,01$).

Table 1: Mean scores (M) und standard deviations (SD) of the overall score differences from all participants dependant on the exposure of the mobile phone base station (MBS)

(n = 90 due to missing values)

	MBS switched off			MBS switched on		
	1 day	2 days	3 days	1 day	2 days	3 days
M	0,54	0,47	0,64	0,77	0,56	0,65
SD	(1,48)	(1,19)	(2,14)	(1,26)	(1,37)	(1,63)

Discussion

We aimed to investigate the association between electromagnetic fields of a UMTS mobile phone base station and health complaints reported by office workers. A newly installed base station was in a double blind design randomly turned on and off for 24-hours over a period of three months. 95 office workers participated in this field experiment and reported health status daily using an online questionnaire.

No evidence for an association between UMTS mobile phone base station exposure and self-reported health complaints was found. In general, the reported complaints increased over of the working day. This increase was associated neither with exposure presence nor with its duration. These findings are in agreement with previous provocation studies, which used different frequencies (Andersson et al. 1996, David et al. 2002, Hietanen et al. 2002, Koivisto et al. 2001, Lyskov et al. 2001, Radon and Maschke 1998, Regel et al. 2006, Rubin et al. 2006). As this was a pilot study including a relatively small sample the results can not be generalized.

Only the association of perceived exposure condition with health was statistically significant. This might be interpreted as an incorrect attribution, which strongly emphasises the importance of using (double-) blind designs in corresponding research. This effect has also been shown in studies on EMF and health complaints (Andersson et al. 1996, Bergqvist et al. 1998, Harlacher und Schahn 1998, Hillert und Kolmodin-Hedman 1997).

One advantage of our study was the objective exposure assessment. However, as only exposure in the workplace was taken into account exposure assessment was incomplete. This problem might only be overcome with personal dosimetry (Radon et al. 2006). Overall exposure levels in our study were comparable to those found in other studies (Schüz and Mann 2000, Bernkopf 2004).

The results of this pilot study show feasibility of using online questionnaire. However, an investigation with online questionnaire is only possible in a specific Internet-using population, like office workers. In a follow-up study it could be useful to employ a CAPI (computer assisted personal interview). Also the use of a PDA (Personal Digital Assistant) and Handheld-computer might be feasible as recently shown by Schreckenber and Guski (2005).

Overall, the results of this study show that the online questionnaire developed is practicable. The questionnaire instrument is capable to register health complaints. No evidence for an association between exposure to mobile phone base station and self-reported health complaints was found. However, well-being depended on the self-reported exposure condition. This might indicate an incorrect attribution, which strongly emphasises the importance of using (double-) blind designs in corresponding research. A follow-up study with a larger sample of the general population and personal dosimetry would be desirable.

Abstract

The purpose of this study is to investigate the effects of microwave exposure on biological free radical production, focusing especially on mobile radio frequencies. In vitro experiments for the hydroxyl radical production on human white blood cells after exposure to modulated or non-modulated 900 MHz and 2.45 GHz microwave were performed. Several signals were used: continuous-wave (CW), several typical modulations of the GSM, PDC, cdma2000, and non-modulated pulse-wave. Developed 900 MHz ridged-waveguide exposure equipment and 2.45 GHz open-type equipment were used for high intensity irradiation, and the specific absorption rates (SARs) were estimated by numerical simulations. The fluorescence probe method was adopted to estimate the radical production. Furthermore heat (20°C-39°C) was used for the purpose of controlling the hydroxyl radical excitation.

The exposure experiments were carried out by using about six hundred tissues, and the free radical production was estimated with the fluorescence images. Some irradiations produced a difference in free radical production. However, this difference disappeared when data was compared to the heat controls.

As a result, any free radical production due to non-thermal effect of microwave exposure was not detected.

Introduction

It has been already suggested that the microwave EMF interactions with biomolecules, or with portions of biological structure, are unlikely at the frequencies below the high gigahertz spectral regions [1]. However, to the best of the authors' knowledge, there have not been any investigations conducted so far concerning the possibility of biological interactions due to the microwave EMF, which may result in the production of free radicals.

A free radical is an atom or a molecule with an unpaired electron and has a high chemical reactivity. There are various kinds of free radicals. If the radical production occurs in living tissues, it can trigger a chain reaction resulting in various influences on important cellular components such as DNA, or the cell membrane in the worst case [2,3,4]. Thus, in the discussion on the adverse health effect issues due to microwave irradiation, it is very important to obtain reliable experimental evidences revealing the fact that microwave EMF irradiation might not affect free radical production directly.

It is known that white blood cells (WBCs) generate free radicals to destroy bacteria and viruses. In order to investigate the biological free radical production in human WBC, experiments of 900 MHz and 2.45 GHz microwave exposure are conducted in this study.

Materials and Methods

The procedure for preparing the WBC sample is shown Figure 1. Firstly, dextran is added to whole blood taken from a healthy person. After letting it stand for 30 minutes, the supernatant fluid is obtained. Secondly, in order to separate into an upper plasma layer and a lower WBC layer, the blood samples are centrifuged at 400 g for 6 minutes. The plasma layer is removed and then 2 ml calcium, magnesium free phosphate buffered saline (CMF-PBS) is added to the settlement cell. Finally, 1950 µl CMF-PBS and 100 µl 2',7'-dichlorodihydrofluorescein diacetate (DCFH) are added to this 50 µl settlement cell. This WBC sample is used for this experiment.

INVESTIGATION ON FREE RADICAL PRODUCTION IN HUMAN BLOOD CELLS

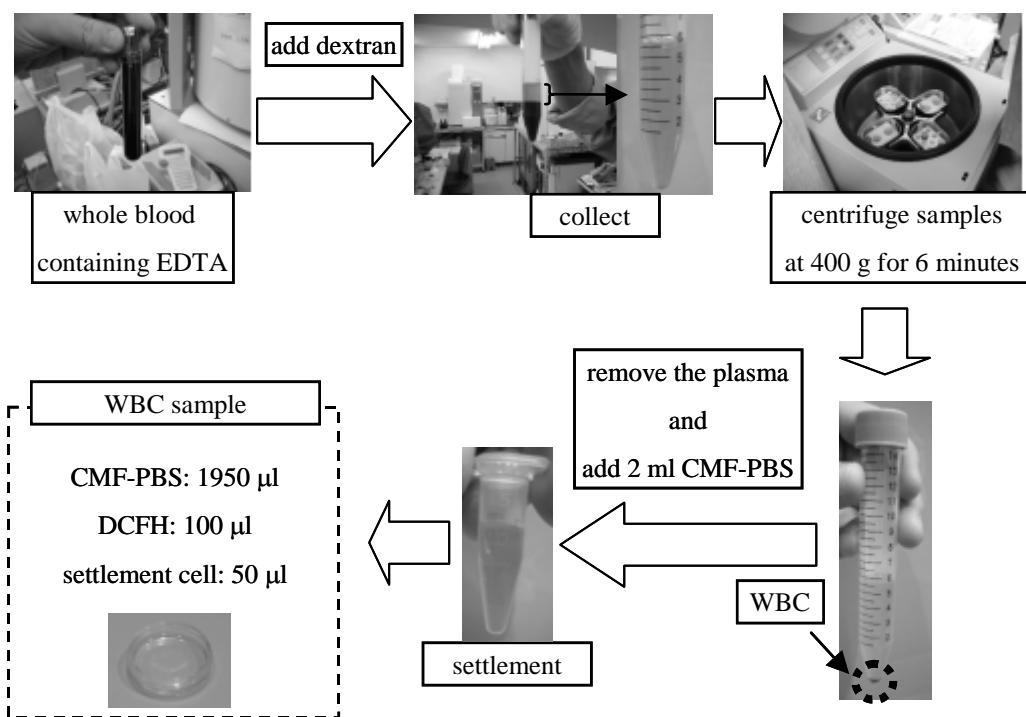

Figure 1. The procedure for preparing WBC sample

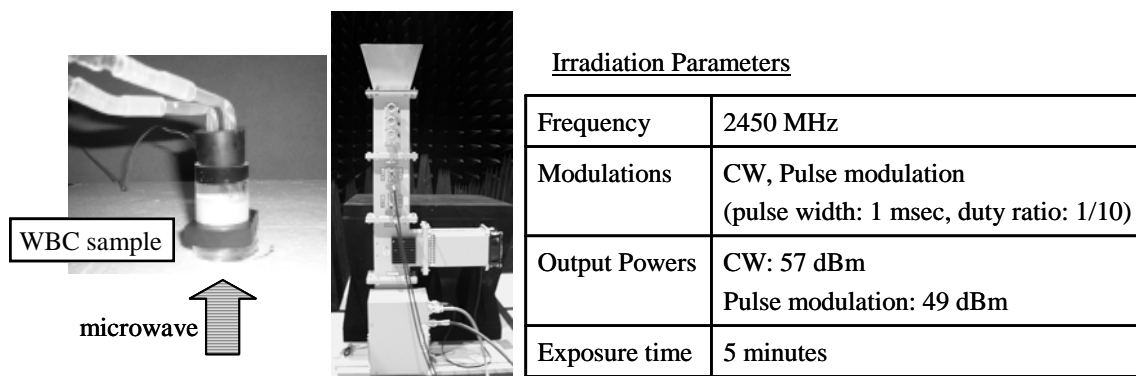

Figure 2. Open-type exposure equipment of 2.45 GHz

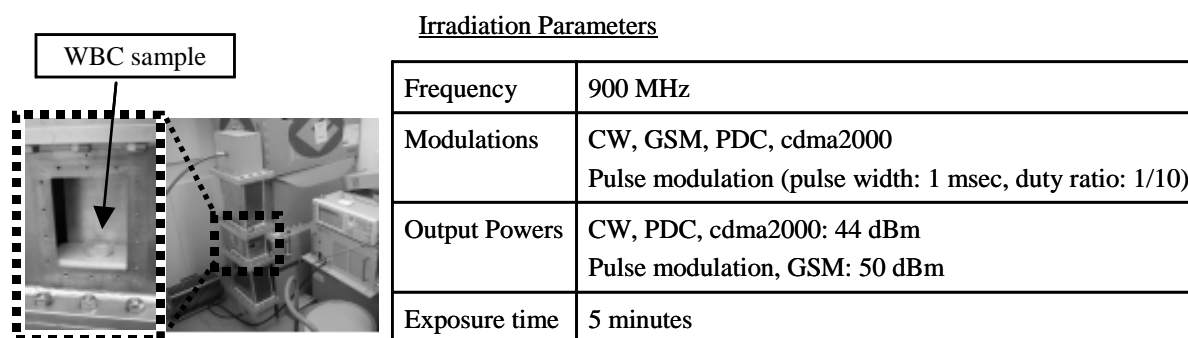

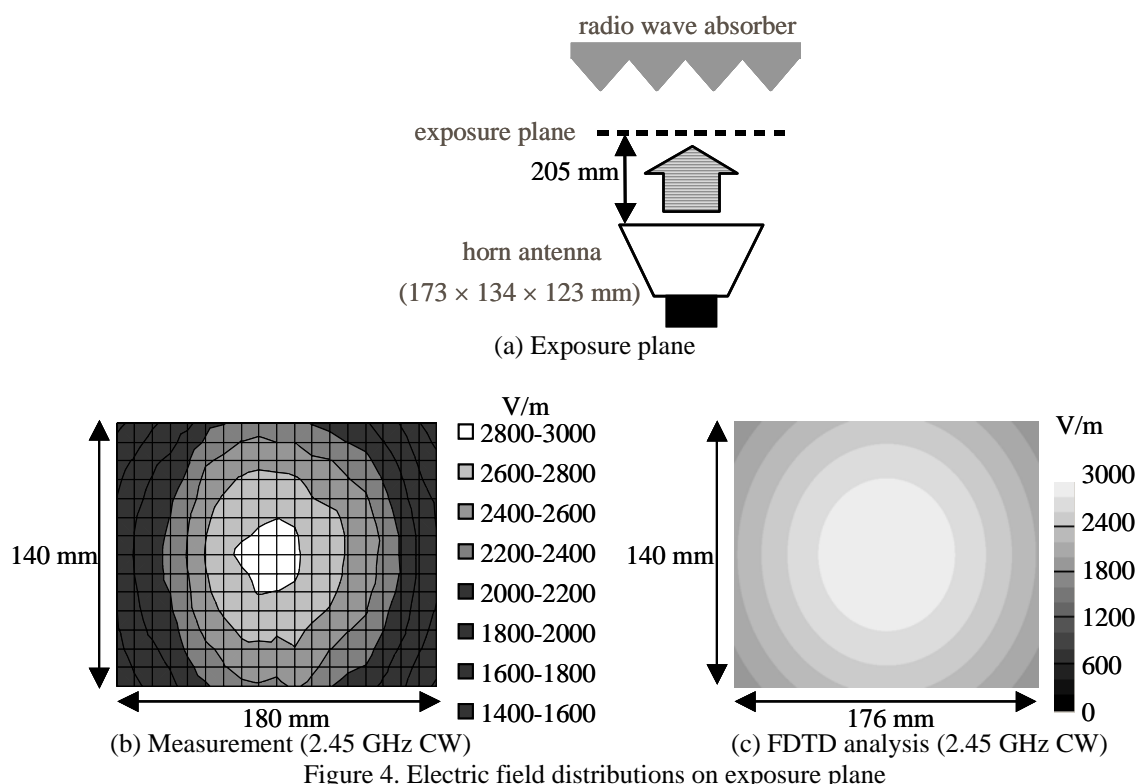

Figure 3. Ridged-waveguide exposure equipment of 900 MHz

Figure 2 and Figure 3 show the developed 2.45 GHz open-type exposure equipment and 900 MHz ridged-waveguide exposure equipment [5,6,7]. These exposure equipments can achieve high intensity and a uniform exposure on the WBC sample and they are available at the same time without special degradation of the impedance matching caused by the scattering waves from the WBC sample.

In the case of exposure to 2.45 GHz microwave, we carry out the irradiations for five minutes with continuous-wave (CW) or high power pulse modulated wave that provided the pulse width and duty ratio of 1 msec and 1/10, respectively. Figure 4 (a) shows the exposure plane on which the WBC sample is located. This plane is positioned at a distance of 205 mm from the centre of the horn antenna. Figure 4 (b) shows the electric field distribution of CW measured in this area. In addition, Figure 4 (c) shows the electric field distribution of CW obtained in this area by using numerical analysis. The FDTD based commercial software, SEMCAD [8] is used for the estimation. From these Figures, the computed result agrees well with measured ones. Furthermore, the thermostatic device shown in Figure 5 is adopted to maintain the temperature of the WBC sample at less than 39 degrees Celsius. The SAR of the WBC sample exposed on the petri dish is obtained by measurement and calculation. The increase in temperature during the exposure is used for estimation of SAR. FDTD analysis is used for SAR calculation as well. When we measure the SAR, the PBS does not touch the thermostatic device. Figure 6 shows the FDTD model. Figure 7 and Table 1 show these results as well.

Figure 6. FDTD model (2.45 GHz)

Figure 7. SAR distribution (2.45 GHz)

	measurement	FDTD analysis
Ave. SAR [W/kg]	725	632

Table 1. Measurement and analysis results of SAR (2.45 GHz)

In the case of exposure to 900 MHz microwave, the duration of exposure is 5 minutes. Moreover, several signals are used: CW, GSM, PDC (half rate), cdma2000 and pulse waves. During exposure, the temperature of the cells never exceeded 39 degrees Celsius. Table 2 shows both measured and calculated electric field strengths at the point that the WBC sample is located. In addition, the SAR of the WBC sample exposed on the petri dish is obtained by both measurement and calculation. In order to estimate the SAR of the WBC sample, the waveguide's output powers are measured. Then, the output power with or without the WBC sample in the waveguide are compared to estimate the SAR. Figure 8 shows the FDTD model. Figure 9 and Table 3 show these results.

	measurements					FDTD analysis
Modulations	CW	Pulse	GSM	PDC	cdma2000	CW
E-field strengths [V/m]	1140	615	960	1140	1160	1730

Table 2. E-field strengths central axis of the exposure plane (900 MHz)

Figure 8. FDTD model (900 MHz)

Figure 9. SAR distribution (900 MHz)

	measurement	FDTD analysis
Ave. SAR [W/kg]	150	276

Table 3. Measurements and analysis results of SAR (900 MHz)

The fluorescence probe method is adopted to estimate free radical production. First, DCFH which is used for fluorescence probe of hydroxyl radical production is added to the WBC sample. Secondly, the WBC sample is exposed to RF microwave for 5 minutes. Finally, fluorescence intensity is measured.

Results

Figure 10 and Figure 11 show the fluorescence intensities of WBCs after exposure to 2.45 GHz and 900 MHz microwaves respectively. The control (sham exposure) is defined as the WBC sample that was not exposed to microwaves and increased in temperature by thermostatic device. In the case of 2.45 GHz exposures, there are no obvious differences between the control and the WBC exposed by CW or pulse modulated microwave. In addition, in the case of 900MHz exposures, no significant differences in radical production are detected after any modulated microwave exposures. At both frequencies, no radical excitation is observed in the WBC after irradiation by microwaves, provided that the temperatures of target samples did not exceed 39 degrees Celsius.

INVESTIGATION ON FREE RADICAL PRODUCTION IN HUMAN BLOOD CELLS

Summary

Experiments for the biological free radical that treats human WBCs were performed. In the experiments, both modulated and non-modulated 900 MHz and 2.45 GHz microwaves were irradiated. Furthermore, the electric field strengths on the exposure plane and SARs of the WBCs were estimated by using measurement and FDTD simulation. The differences due to biological uncertainty in experimental results obtained under the same conditions (cell temperature, exposure condition) could not be negligible, and therefore, our experiments were carried out by using many WBC samples.

From our experiments, there was no difference in fluorescence intensities estimated by the fluorescence images of between the control (sham exposure) and the exposed samples. In addition, the intensities of the samples after exposure to modulated microwaves agreed with those after exposure to non-modulated microwaves. The fluorescence intensities which are proportional to radical production in WBCs depended on the temperatures of the samples. As a result, any free radical production due to non-thermal effects of 2.45 GHz or 900 MHz microwave exposure was not detected.

More precise SARs calculations and a statistical analysis of the fluorescence intensities data obtained by many of our experiments will be conducted.

ABSTRACT

The objective was to assess any signs of stress or apoptosis induced by radiofrequency (RF) fields, which corresponds to the limit of the average whole body SAR for general public exposure defined as a basic restriction in the ICNIRP guidelines. We investigated if continuous wave (CW) and Wide band Code Division Multiple Access (W-CDMA) RF fields at 2.1425 GHz, which corresponded to the middle frequency allocated to the downlink band of the IMT-2000 from mobile radio base stations, induce activation of hsp27 and p53. All levels and types of the investigated RF fields did not result in a statistically significant increase or decrease in hsp27[pS82] protein or p53[pS15] protein of each sample. No noticeable differences were observed between any of the RF field exposure groups and the sham exposed controls in the gene expression profile, including hsp or p53 related genes, in either the RF field experiments. These results confirm that RF exposure to W-CDMA and CW at 2.1425 GHz cannot be associated with apoptosis or cancer via induction of the p53 pathway or hsp response at the limit of the average whole-body SAR level (80 mW/kg) as defined by the ICNIRP guidelines.

INTRODUCTION

The rapid introduction of mobile telecommunication services over the last decade has drastically increased the amount of radiofrequency (RF) field irradiation frequencies and energies in our living environment. In order to continue stable growth and expansion of RF utilizations, it is necessary to investigate the possibility of any biological health effects of RF fields and to obtain reliable confirmation data with respect to safety. It is important to examine the possible biological effects and to obtain reliable data for 2-GHz band RF irradiation to facilitate the smooth deployment of the International Mobile Telecommunication 2000 (IMT-2000) cellular system. We conducted a study focusing on the effects of a practical modulated signal for Wideband Code Division Multiple Access (W-CDMA) as well as a continuous wave (CW) at 2.1425 GHz, which corresponds to the middle frequency allocated to the downlink band of IMT-2000 from mobile radio base stations.

French et al [2001] proposed that repeated exposure to mobile phone radiation acts as a repetitive stress leading to continuous expression of hsps in exposed cells and tissues, which in turn affects their normal regulation, and cancer results. Hsp27 phosphorylation in the human endothelial cell line EA.hy926 showed a transient increase by 1 h of non-thermal exposure to 900 MHz GSM mobile phone radiations [Leszczynski et al., 2002]. They proposed a hypothetical mechanism whereby RF exposure could be associated with cancer. We examined the induction of hsp27 phosphorylation and other cellular stress response that activate the p53 or the p53 signaling pathway using cultures of the human tumor A172 cells and untransformed IMR-90 cells. The results suggest that RF radiation at a SAR of the mobile radio base station level does not affect the stress response pathways following hsp27 phosphorylation.

METHODS

Exposure System

A detailed description of the exposure system has been published by Iyama et al. [2004]. Briefly, two identical RF field exposure incubators, one for RF field exposure and the other for sham exposure, were established in separate anechoic chambers, and a mechanical switch in a dummy box allows the selection of RF field exposure or sham exposure (Fig.1). This system allowed simultaneous exposure of 49 (7 x 7 array), 35 mm culture dishes to a 2.1425 GHz RF electromagnetic field, which corresponds to the center frequency of the IMT-2000 down link band, with a uniform SAR distribution in the medium of all 49 culture dishes. The main unit for the cell exposure provides identical air to the two culture units through sealed ducts at the appropriate temperature (37.0°C), CO₂ (5.0 %), and humidity (>90 %). The mean SAR of the culture fluid at the bottom of the inner 25 culture dishes (5 x 5 array) used in the *in vitro* experiments was 139 mW/kg for an antenna input power of 1 W, and the standard deviation of the SAR distribution was 47%. The W-CDMA cellular system is one of the component systems of the IMT-2000 cellular system, and its frequency spectrum is shown in Figure 2. W-CDMA adopts Direct Sequence CDMA (DS-SS) and Frequency Division Duplex (FDD) as a multiple access and duplex scheme, respectively. The chip rate of the spread code of this system is 3.84 Mcps. A beam-formed RF exposure incubator employing a horn antenna, a dielectric lens, and a culture case in an anechoic chamber was developed for large-scale *in vitro* studies.

Cells

Human glioblastoma A172 cells and human IMR-90 fibroblasts from fetal lungs were obtained from the American Type Culture Collection (ATCC, Rockville, MD). A172 cells were cultured in Dulbecco's Modified Eagle Medium (Invitrogen, Tokyo, Japan) supplemented with 10% heat-inactivated fetal calf serum (FCS; Invitrogen), 100 U/ml penicillin and 100 µg/ml streptomycin, and IMR-90 fibroblasts were grown in Eagle's minimal essential medium with Earle's balanced salts (Invitrogen) supplemented with 0.1 mM non-essential amino acids, 1.0 mM sodium pyruvate, 10% heat-inactivated FCS, 100 U/ml penicillin, and 100 µg/ml streptomycin. The both cells have been previously used in RF field research [Sakuma et al., 2006].

Experimental Design

The experimental design has been described by Hirose et al. [2006a,b]. A172 cells were exposed to W-CDMA radiation at SARs of 80, 250, and 800 mW/kg, and to CW radiation at 80 mW/kg for 24 or 48 h, which equates to one or two doubling times of the cell. IMR-90 cells were exposed to W-CDMA at 80 and 800 mW/kg, and CW at 80 mW/kg for 28 h, which is one doubling time of the cell. The cells were also exposed to W-CDMA radiation at SARs of 80 and 800 mW/kg for 2 h. The RF field exposure was processed in a blind manner. Exposure to W-CDMA signals in the study was 80 mW/kg, which corresponds to the limit of the average whole-body SAR for general public exposure defined as a basic restriction by the ICNIRP guidelines [1998]. The air temperature was monitored for all cultures during the course of the sham and RF field exposure, resulting in 37.0±0.3°C, 37.0±0.1°C, and 37.0±0.1°C at SARs of 800, 250 and 80 mW/kg for W-CDMA radiation, respectively.

Detection of Hsp27 and p53 Phosphorylation

To determine changes in hsp27[pS82] or p53[pS15], HSP27[pS82] and Total HSP27 or p53[pS15] and Total p53 Antibody Bead Kits (BioSource, Camarillo, CA) were used according to the manufacturer's instruction. The specific proteins were detected using the bead-based multiplex assay [Carson and Vignali, 1999], which is similar to a capture sandwich immunoassay.

Microarray hybridization

Human genome HG-U133 Plus2.0 (Affymetrix, Santa Clara, CA) was used for the analysis of heat shock and p53 related gene expressions in cells exposed to RF fields. Data were analyzed using Affymetrix®

Microarray Suite 5.0 software.

RT-PCR analysis

The pairs of primers and the TaqMan probes [tumor protein 53 (TP53), TP53 binding protein 2 (TP53BP2), apoptotic protease activating factor (APAF1), and caspase 9 (CASP9)] for the target mRNAs were purchased from Applied Biosystems (Foster City, CA). The TaqMan OneStep RT-PCR Master Mix Reagents Kit (Applied Biosystems) was used for the RT-PCR reaction. Amplification and detection were performed using the ABI PRISM 7700 Sequence Detector System (Applied Biosystems).

Indirect Immunofluorescence Analysis

For visualization, cells were incubated with anti-hsp27 (diluted at 10 µg/ml) or anti-hsp70 (diluted at 5 µg/ml) antibodies (Stressgen, BC, Canada) for 1 h, and then incubated with Alexa Fluor 488-labeled goat anti-mouse IgG antibody (Molecular Probes, Eugene, OR) diluted at 10 µg/ml for 30 min.

Detection of Apoptosis

Apoptosis was evaluated using the annexin V affinity assay [Koopman et al., 1994]. The procedure using the fluorescein-conjugated annexin V (annexin V-FITC; BD Biosciences, Franklin Lakes, NJ) was carried out according to the manufacturer's technical protocol. The cell samples were analyzed by flow cytometry (EPICS ALTRA, Beckman Coulter, Tokyo, Japan).

Statistical Analysis

The gene expression levels obtained with GeneChip expression analysis were analyzed by Welch's t-test using the data for the sham-exposed samples and the RF field-exposed samples in either the 2.1425 GHz W-CDMA at a SAR of 80, 250 or 800 mW/kg or CW at 80 mW/kg RF field experiments. The multiplicity problem was controlled by the Benjamini and Hochberg false discovery rate [Benjamini and Hochberg, 1995]. A p-value of less than 0.05 was considered statistically significant.

RESULTS

Expression of phosphorylated hsp27 at serine 82

As shown in Figures 3-1 and -2, the exposure to W-CDMA or CW radiations at a SAR of 80, 250 or 800 mW/kg for 2-48 h resulted in similar measurements of hsp27[pS82] compared to sham exposed controls. The exposure to all of the presented RF fields did not result in a statistically significant change in hsp27[pS82]. The exposure to W-CDMA at a SAR of 80 or 800 mW/kg for 2-48 h did not noticeably change the total hsp27 level in either cell. Moreover, there were no significant changes in total hsp27 expression levels in the cells exposed to W-CDMA signal at 250 mW/kg or CW signal at 80 mW/kg.

Heat shock gene expression

In the RF field exposure experiments, 18,041-24,119 and 18,971-23,180 genes were "present" or "marginal" in A172 and IMR-90 cells, respectively, of 54,675 gene probe sets. We evaluated the changes in gene expression by RF field exposure on their genes that were "present" or "marginal" in A172 or IMR-90 cells. No significant differences were observed between any of the RF field exposure groups and the sham-exposed controls in the gene expression profile, including hsp related genes in either experiments of exposure to W-CDMA or CW signal for 2-48 h.

Cellular localization of hsp27 and hsp70

There was no remarkable effect on the induction of translocation or expression of hsp27 or hsp70 after exposure to W-CDMA or CW signal at a SAR of 80, 250 or 800 mW/kg for 2-48 h. Immunofluorescence staining revealed that some of A172 cells in sham culture expressed a high level of hsp27 and some of IMR-90 cells in sham culture expressed a low level of hsp27. It was found that some of A172 and IMR-90 cells in sham cultures expressed a very low level of hsp70.

Expression of phosphorylated p53 at serine 15

The exposure to W-CDMA or CW radiations resulted in similar measurements of p53[pS15] compared to sham-exposed controls, and resulted in similar values of total p53 compared with sham-exposed controls. The exposure to all of the presented RF fields did not result in statistically significant changes in p53[pS15] (Fig. 4), or the total p53 in each sample. All of the measurements of p53[pS15] protein in the RF field exposure samples were close to the lower limit of the analytical sensitivity of the assay, and almost equal to those in sham-exposed and non-treated samples, or could not be detected with the used p53[pS15] Antibody Bead Kit.

p53-related Gene Expression

There were no noticeable changes of p53 related gene expression levels in A172 or IMR-90 cells exposed to W-CDMA radiation (SARs of 80, 250 or 800 mW/kg) or CW radiation (80 mW/kg). We analyzed the gene expression of TP53, TP53BP2, APAF1, and CASP9 to reconfirm the change of the p53-dependent apoptosis signal cascade on a molecular level by the exposure to RF signals, using a real-time RT-PCR analysis. Relative gene expression was determined based on the threshold cycles of the RF field or sham exposed samples. No noticeable effect on TP53, TP53BP2, APAF1, and CASP9 gene expression was observed after exposure to W-CDMA or CW radiation, as expression ratios were below 2-fold and over 0.5-fold in two independent experiments performed with triplicate RNA samples.

Induction of Apoptosis

The exposure to W-CDMA or CW radiations resulted in a similar percentage of apoptotic cells compared to sham-exposed controls (1.1-3.7 % compared to 1.2-3.0 % in the case of A172 cells, and 2.4 or 4.1 % to 2.4 or 4.7 % in the case of IMR-90 cells). No statistically significant differences were observed between any of the RF field exposure groups and the sham-exposed controls in percentage of apoptotic cells, in either the 2.1425 GHz W-CDMA or CW radiation exposure experiments.

CONCLUSION

Hsp27 and p53 phosphorylation in A172 cells and IMR-90 fibroblasts are not induced by exposure to W-CDMA or CW RF radiation. Furthermore, changes in gene expression levels of hsp family and p53-related genes, and the frequency of apoptotic cell death were not induced by any of the RF exposure.

The results confirm that RF exposure to W-CDMA and CW at 2.1425 GHz cannot be associated with apoptosis or cancer via induction of the p53 pathway or hsp response at the limit of the average whole-body SAR level (80 mW/kg) as defined by the ICNIRP guidelines.

Abstract

Few studies have directly observed brain microcirculation during exposure to radio frequency electromagnetic fields (RF-EMF). The aim of present study was to investigate whether RF-EMF exposure induces acute effects on brain microcirculation being transiently observed only during RF-EMF radiation period. Male Sprague-Dawley rats (8 weeks old) were subjected to cranial window implantation prior to the exposure experiments and fluorescent intravital-microscopic observation under anesthesia. To simultaneously perform a microcirculatory observation and RF-EMF exposure, we developed and used an “8”-shaped loop antenna. Rat's head was locally exposed to 1,457MHz electromagnetic near-field TDMA signal for PDC systems by the “8”-shaped loop antenna. RF-EMF exposure intensity was maintained at 2.0 W/kg of the averaged SAR in parietal targeted area. During experimental period including RF-EMF exposure, four microcirculatory parameters (BBB-function, plasma velocities, leukocyte behaviours, and arterial vasomotion) were measured. No changes in any of the four microcirculatory parameters were elicited by RF-EMF exposure. The results revealed that there were no RF-EMF exposure effects on brain microcirculatory parameters, at least on BBB-function, plasma velocities, leukocyte behaviours, or arteriolar vasomotion under the present exposure conditions.

Introduction

Few studies have directly observed brain microcirculation during exposure to radio frequency electromagnetic fields (RF-EMF). Our previous study showed no effects of RF-EMF exposure on blood-brain barrier (BBB), plasma velocity or vessel diameter, as microcirculatory parameters in rat brain using a cranial window method [1]. However, the changes in these parameters were measured just after RF-EMF exposure, but not during exposure. To simultaneously perform measurements of rat brain microcirculation and RF-EMF exposure to a local cerebral region just under the cranial window, we developed a new type of antenna, “8”-shaped loop antenna [2]. The aim of present study was to investigate whether RF-EMF exposure induces acute effects on brain microcirculation being transiently observed only during RF-EMF radiation period.

Male Sprague-Dawley rats (8 weeks old) were used. The rats were divided into two groups: RF group was exposed to RF-EMF and Sham group was not exposed to any RF-EMF. All rats were subjected to cranial window implantation and intravital-microscopic observation under pentobarbital anesthesia with a cocktail of ketamine and xylazine. The pial microcirculation within cranial windows was observed using a fluorescent microscope equipped with an EBCCD camera. In order to measure four microcirculatory parameters, BBB function, plasma velocities, leukocyte behaviours, and arteriole vasomotion, we used rhodamine 6G for leukocyte behaviours and FITC-Dx (70k or 2000k) for the other three parameters.

Rat heads were locally exposed to 1,457MHz electromagnetic near-field TDMA (time division multiple access) signal for PDC (Personal Digital Cellular, Japanese cellular telephone standard) systems by the “8”-shaped loop antenna placed 4 mm upward to the cranial window. RF-EMF exposure was maintained at 2.0 W/kg of the averaged SAR in parietal targeted area.

Arteriolar vasomotion was observed during 12 min experimental period including 3 min RF-EMF exposure. The other three microcirculatory parameters, BBB-function, plasma velocity, and leukocyte behaviour in pial venules were measured every 10 min during 80 min experimental period including 50 min RF-EMF exposure. The results were compared between RF and Sham group. The statistical analysis was performed by Student's t-test or ANOVA.

Using an intravital fluorescence microscopy and the “8”-shaped loop antenna enable us to observe rat pial microcirculation directly, and expose RF-EMF to rat, simultaneously (Fig. 1). Plasma image flowing in microvessels of the pia mater was visualized by FITC-Dx injected into vein.

Fig. 1. Real-time measurement system

Blood-brain barrier permeability was evaluated by extravasation of FITC-Dx (70k) molecules injected into a rat venule. Although fluorescence intensity of pia mater area decreased through an experimental period, there were no significant difference in the fluorescence intensity between sham and RF group.

Velocities of plasma flowing in pial venules were measured by a dual-slit method and indicated as a relative (%) velocity of initial value. No significant difference in the percent velocities between two groups were showed until the end of experiment.

Leukocyte behaviours were evaluated by the numbers of rolling and sticking leukocytes stained with rhodamine 6G at 0, 10, 20, 40 min after beginning of the exposure. No significant difference in these numbers was found between two groups.

The arteriole vasomotions were monitored pre-, during, and post- RF exposure (Fig. 2). As an index for dynamic changes in the vasomotion, we calculated the mean value of arteriolar diameter for each experimental period and showed them as a relative (%) diameter of pre-exposure. As a result, no significant difference in the arteriolar diameter was found between two groups.

Summary

Our developed new type of loop antenna, the “8”-shaped loop antenna succeeded to concentrate SAR distribution into the target area just under the cranial window. This was convenience to evaluate dynamic changes in microcirculatory parameters in the target area during RF-EMF exposure. In present experiment, we focused on four microcirculatory parameters, BBB-function, plasma velocities, leukocyte behaviours, and arterial vasomotion. However, no significant differences of these parameters were recognized between sham and exposed group even in during exposure period. The results revealed that there were no RF-EMF exposure effects on brain microcirculatory parameters, at least on BBB-function, plasma velocities, leukocyte behaviours, or arterial vasomotion under the present exposure conditions.

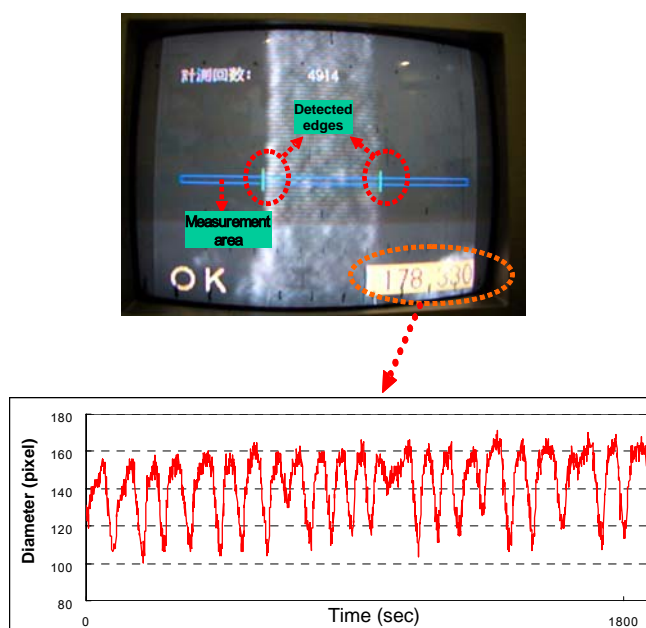

Fig. 2. The changes in pial arteriole diameter were measured using an automatically edge detection camera.

Abstract

Currently, a number of scientific researches are conducted on potential health hazards of electric and magnetic fields. There is a non-objective and psychological belief that they are harmful. However, no scientific and objective proof exists. The ELF magnetic field (MF) has become one of the Korea's social issues due to MF's possible harmful health effect, especially for children under 17 years of age. Therefore, in order to evaluate the magnetic field exposure levels of those children in their general living environment, personal MF exposures of 347 subjects were measured in 2005 with government funding. This study developed the calculation program 16MAGEXPO based on the above measured database to predict personal MF exposure. This program can serve as a valuable tool in estimating 24-hour personal MF exposure without directly measuring the exposure. Three types of personal MF exposure estimation formulas - a formula for infants and preschool children from 1 to 7 years of age, a formula for elementary school children from 8 to 13 years of age and a formula for junior high school students from 14 to 16 years of age - were developed by applying evolutionary computation method to the measured database. Genetic algorithm (GA) and genetic programming (GP) were used among evolutionary computations. After tuning the database with the above methods, final three formulas with the smallest estimation error were selected. The target estimation error was approximately 0.3 mG. The seven parameters of each formula included gender (G), age (A), house type (H), house size (HS), distance between residence and power line (RD), power line voltage class (KV) and the usage and condition of electrical appliances (RULE).

I. Introduction

There is an increasing concern on possible health hazard caused by exposure to power frequency EMF, a part of electro-magnetic interference that is considered the 4th environmental pollution. The concerns over potentially negative biological effects produced by power lines and other sources began in 1979 when Wertheimer and Leeper reported that children living in the vicinity of high-voltage transmission lines had an increasing risk for developing cancer than other children. Although a number of researches were conducted on this subject, biological effects of EMF still remain a heated technological and medical controversy.[1, 2, 3] Therefore, this research developed a method to indirectly estimate the EMF level generated by using electrical energy for participants under 17 years of age. Exposure estimation formulas and calculation program (16MAGEXPO) will provide a method of epidemiological survey for the EMF's biological effects. The 347 participants, ranging from infants to junior high students, were divided into three age brackets to establish EMF exposure estimation formulas. The evolutionary computation was used as an optimization method.

II. Participant Database

The measured personal MF exposure database could be secured by participants who resided near transmission lines up to 345kV. These participants were categorized by the radial distance from the power line and age groups. The subjects included 62 infants to preschool children (1-7 years old), 261 elementary school children (8-13 years old) and 24 junior high students (14-16 years old). In Figure 1, junior high students and preschool children wore a MF measurement meter (Model EMDEX-Lite, Enertech, USA).

Fig. 1 Surveying personal MF exposure for junior high students and preschool children

III. Evolutionary Computations as Optimization Method

A. Evolutionary Computations

Evolutionary computations (ECs) have received significant attention during the last decade, although ECs were originally introduced in the late 1950's [4, 5]. ECs are search algorithms based on the mechanics of genetics and natural selection. ECs combine the survival of the fittest mechanism among string structures with a structured, yet randomized, information exchange to form a search algorithm. ECs efficiently exploit historical information to speculate on new search points with improved performance. In another words, ECs are search methods combining elements of directed and stochastic search, which can strike a remarkable balance between exploration and exploitation of global and local search capability. This research describes the GA and GP application procedures in developing personal MF exposure estimation formulas. The GA was developed by John Holland in the early 1970's. It finds the best solution for the environment by searching the solution space with a probability method and a hierarchical exchange of information between each individual (string or chromosome). GA does not use real parameters but uses chromosomes composed of string coded genotype. GA simulates crossover and mutation of natural systems, thus giving it a global searching capability. GP follows the trend of the GA paradigm but uses trees to represent genotypes. Trees provide a flexible representation for creating and manipulating programs. GP starts with an initial population of randomly generated computer programs (S-expressions) composed of functions and terminals appropriate to the problem domain. Each individual computer program in the population is measured in terms of how well it performs in the particular problem environment. This measure is called the fitness measure. [5, 6]

B. Applications to Develop Formulas

The ECs optimization method was applied to the measured database to develop personal MF exposure estimation formulas. During the development, the following key techniques were employed

1) Types and characteristics of parameters

The 6 main parameters included Gender (G), Age (A), House Type (H), House Size (HS), Radial Distance (RD), and Power Line Voltage (KV). However, occupation was excluded from the parameter. We also added a supplemental parameter called the 'RULE' to increase the estimation accuracy. This RULE represents the length and pattern of electrical appliances usage such as PC and electric heat mat. On the other hand, variables with negligible effects such as sleep, school, commute to and from school and TV watching have not been included in the rules.

2) Radial distance

In order to measure the distance between the power line and the residence, Radial Distance (RD-1), which is considered the real distance, was used instead of Lateral Distance (LD). A digital laser distance meter was used to measure the distance. If distance is difficult to measure, distance RD-2 between tower and the residence was applied.

3) Power line voltage

This research used transmission and distribution line voltage as a parameter instead of load current that directly decides MF level of the power line. The voltage was chosen because the load current fluctuates tremendously by day and season. This research also revealed that there is a significant similarity between increase in transmission line voltage and increase in average MF.

4) Code table of main parameters

Table 1 outlines the main parameter codes and input values during database (DB) tuning.

Table 1. Codes and input values of main parameters

Gender (G)	Age (A)	House Type (H)	House Size (HS)	Radial Distance (RD)	Power Line Voltage (KV)
·Male: 10 ·Female: 20	·1~16	·Apt.: 10 ·Etc.: 20	·the square footage of the unit	·0~30m: 10 ·31~50m: 20 ·51m or more: 30	·Line Voltage

5) Applications of ECs

Table 2 describes the DB tuning parameters of each method based on ECs. Equation 1 illustrates the general objective function for genetic algorithm.

Table 2. Tuning parameters of genetic optimizations

ECs	Generations	Population Size	Crossover Probability	Mutation Probability
GA	2,000	100	0.95	0.05
GP	200,000	1,000	0.8	0.08

$$MFExposure = k1 \log(G) + k2 \log(A) + k3 \log(H) + k4 \log(HS) + k5 \log(RD) + k6 \log(KV) + Rule \quad (1)$$

IV. The Results of Formulas Development

A. Development Conditions

The conditional criteria and functional evaluation characteristics for developing MF exposure estimation formula are as follows:

- 1) Six parameters: G, A, H, HS, RD and KV
- 2) Supplementary rules were applied to reduce estimation error.
- 3) Target error value: mean absolute estimation error below 0.3mG, or tuning and verification errors below 30%.
- 4) KV: Actual power line voltage. However, if RD is over 100m, '1' is inputted to bring KV term to '0'.
- 5) Database was tuned with GA and GP first. Then, formulas with the smallest estimation error or ones that incorporated the most parameters were chosen for each case.
- 6) When the formula produced a negative value due to a peculiar problem between the formula parameters under normal condition, a penalty was issued to the fitness of string (chromosome) during DB tuning.
- 7) HS: For apartments, the square footage of the unit was used. For houses and villas, the square footage of the floor which the participants live was used.

B. Resulting Formulas and Their Applicable Conditions

1) Types of formulas

This research developed six types of formulas as below.

- Formula for infants and preschool children: 1 type (Equation 2)
- Formula for elementary school children: 1 type
- Formulas for junior high school students: 2 types
- Supplementary formulas for elementary school children and junior high school students : 2 types

2) Sample result of personal MF exposure estimation formula for infants and preschool children and their applicable conditions

$$\#1MFExp = -0.002 \log(G) + 0.003 \log(A) + 0.94 \log(H) - 0.24 \log(HS) - 1.22 \log(RD) + 1.09 \log(KV) + Rule \quad (2)$$

• Applicable condition

- A: Ages between 1 and 7
- KV: 22.9~345 kV

C. Estimation Error

Table 3 combined the estimation errors of each formula; thus, displaying the reliability of each formula. Most estimation errors satisfy the target error of approximately 0.3mG (~30%). Yet, supplementary formulas exceeded

PROGRAM TO CALCULATE PERSONAL MAGNETIC FIELD EXPOSURE

the target error due to their DB characteristics. The supplementary formulas are applicable only if participants' power line voltage (KV) does not meet the criteria. Figure 2 is the graphic representation of the DB tuning and verification trend in case of elementary school children.

Table 3. Collection of MF exposure estimation formula errors

Formula type	Tuning percentage error (Tuning error/ average measurement value)	Verification percentage error (Validation error/ average measurement value)		
Formula for infants & preschool children	32.1 % (0.36/1.12 mG)	29.6 % (0.37/1.25 mG)		
Formula for elementary school children	26.2 % (0.43/1.64 mG)	22.8 % (0.45/1.97 mG)		
Formulas for junior high school student	25.0 % (0.28/1.12 mG)	27.9 % (0.29/1.04 mG)		
Supplementary formulas for elementary school children & junior high school student	41.3 % (0.66/1.60 mG)	Elementary school children & junior high school students 39.7 % (0.71/1.79 mG)	Elementary school children 40.6 % (0.8/1.97 mG)	Junior high school students 33.7 % (0.35/1.04 mG)

V. MF Exposure Calculation Program 16MAGEXPO

A. 16MAGEXPO Features

The measurement of MF exposure is rather complicated, and it may be impossible according to circumstances. 16MAGEXPO allows accurate estimation of the personal MF exposure level without directly measuring. The following is the main features of 16MAGEXPO.

- 1) Calculates personal MF exposure level by incorporating all MF sources commonly found in daily living environment.
- 2) Applies to children younger than 17 years old, including infants.
- 3) Any person, including non-experts, can predict personal MF exposure level if six personal parameters such as gender, age, house type, house size, distance between the residence and power line, and power line voltage and daily lifestyle of rules are known.
- 4) Rules are variables decided by electrical appliances usage such as PC and electric heat mat. Rules are introduced to enhance the prediction accuracy.
- 5) This program contains 6 types of personal MF exposure estimation formulas, and the prediction can be made as accurate as mean absolute error below 0.4mG.
- 6) This program will serve as a valuable tool in surveying and evaluating ELF MF's epidemiological effects.

B. Calculation Modules of 16MAGEXPO

16MAGEXPO has three calculation modules, infants and preschool children, elementary school children and junior high school students as shown in Figure 3. Figure 4 is the screen shot of the main menu. When you select a module button (for example: Infant and preschool child), a detailed calculation screen appears as shown in Figure 5. In the calculation screen, enter the calculation condition first and execute to display the 24-hour personal MF exposure result. If calculating multiple computation cases, use the output files as described in Table 4.

C. Main Calculation Functions of 16MAGEXPO

The following is the main calculation functions of 16MAGEXPO.

- 1) Calculates personal MF exposure level based on personal traits such as gender and age and living environment conditions such as house size, residence condition, and power line voltage.
- 2) Enhances the estimation accuracy by integrating daily usage pattern of electrical appliances such as electric heat mat that generate high magnetic field.
- 3) The user maintains the input file by entering above parameters in a menu-driven method.
- 4) Personal traits, rules, and calculation results are stored and maintained as an output file of Table 4.

VI. Conclusions

The human health problem caused by ELF magnetic field has become one of Korea's most debated social issues. The possible health effect on children less than 17 years of age is especially a matter of primary concern. Therefore, this paper proposed the 16MAGEXPO software that can estimate personal MF exposure levels of the above children in their general living environment. The key features and significance of this software development are as follows:

- 1) The data used to develop estimation formulas were collected from 347 participants.
- 2) Since the program was designed to estimate the effects of MF near power lines, participants living close to power lines were selected. As a result, as much as 24% of the participants lived within 50m from power lines.
- 3) Total of six formulas was developed, including a formula for infants and preschool children.
- 4) The program chose gender, age, house type, house size (square footage), radial distance between residence and power lines and line voltage as parameters. This research revealed that the voltage, distance, and age parameters are highly relative to the MF exposure level.
- 5) First time in the world, the evolutionary computation suitable for this problem was used as an optimization method. This computation showed that these estimation formulas yielded approximately 0.4mG mean average errors. However, the supplementary formulas, which have limited use, resulted in higher estimation errors. The target estimation error was approximately 0.3 mG.
- 6) This research developed the personal MF exposure estimation program, 16MAGEXPO, by utilizing the previously mentioned estimation formulas and daily living patterns (rules). The program based on LabView can be used to calculate personal MF exposure for children less than 17 years of age.
- 7) 16MAGEXPO can serve as a valuable tool in estimating 24-hour personal MF exposure in children without directly measuring.
- 8) This software marks the suggestion of a new MF exposure estimation method since the introduction of the wire code in late 1970's. In addition, this software will provide an effective and practical means to study MF's effects on human health, especially the epidemiological study on correlation between magnetic field and childhood cancer.

Abstract

In this study, magnetic field exposure of human body near an induction heating (IH) cooker is numerically evaluated using Scalar Potential Finite Difference (SPFD) method. The maximum induced current densities are compared among three kinds of anatomical human body models of the Japanese adult male/female and the American adult male. The induced current densities are averaged over one square centimeter in the area, and they are compared with the guideline of International Commission on Non-Ionized Radiation Protection (ICNIRP). As a result, it is found that the maximum induced current densities are considerably different among these three models of the human body, and the induced current exceeding the guideline of ICNIRP may not flow inside human body in the case with a portable type IH cooker and a pan designed for the IH cooker. In addition, reducing the computation load and the computer resource by dividing the model is considered. As a result, the difference of calculation result by dividing the model is almost negligible, and computation load is decreased.

Introduction

Recently, people have been concerned about the effect of the electromagnetic field on the human body. Because the IH cooker is widespread in Japan, the Japanese especially has the interest of influence on health by the leakage magnetic field. The basic restrictions for exposure to electromagnetic fields in each frequency band are determined by ICNIRP. At the frequency of 20 kHz (internal frequency of the IH cooker used in this study), the basic restriction for the exposure to the induced current density is 40 mA/m² (for the general public exposure) and 200 mA/m² (for the occupational exposure)[1].

In this study, we use the small loop as a magnetic source equivalent to the IH cooker. We calculate the potential and the induced current density inside the body by SPFD method which is useful for the low frequency magnetic field exposure problem. We use the male and the female models of National Institute of Information and Communications Technology (NICT) as Japanese standard human models[2], and the male model of the Air Force Research Laboratory (AFRL) of Brooks City-Base as a reference[3]. We calculate the induced current density distribution for these models, average them over a cross-section of 1 cm² perpendicular to the each direction of axes, and compare those magnitude with the guideline of ICNIRP.

Methods

SPFD method:

The SPFD method is a numerical technique used for calculating potential and the induced current inside conductor under the low frequency magnetic field[4]. At first, we digitize the subject to three dimension cells. The edge conductance s is posited to the each edge of the cell. The scalar potential Ψ is assumed to each node. A simple finite difference equation is given as

$$\left(\sum_{r=1}^6 s_r \right) \Psi_0 - \sum_{r=1}^6 s_r \Psi_r = i\omega \sum_{r=1}^6 (-1)^{r+1} s_r l \vec{A}_r, \quad (1)$$

where r is the local node index (1~6) and target node is labeled 0. The symbol l denotes the length of the edge, and A_r is the magnetic vector potential tangent to the r -th edge. The set of equations are arranged to the simultaneous equations of unknown Ψ , and solved by SOR method or conjugate gradient method.

Numerical models and source:

In this study, we use three kinds of anatomical human models (Figs.1-3). Figs.1 and 2 are the Japanese male and female models, respectively, developed by NICT. The cell size is 2 mm. Fig.3 shows the male model developed by AFRL. The cell size of the model which we used is 3 mm. The conductivities of the tissues in all models are obtained from Gabriel's report[4].

INDUCED CURRENT INSIDE A HUMAN BODY NEAR AN IH COOKER

Fig.1 NICT male model and magnetic source.

Fig.2 NICT female model and magnetic source.

Fig.3 AFRL male model and magnetic source.

A small loop is posited to 0.939 m in height and the distance 0.19 m as a magnetic source equivalent to the IH cooker. The axis of the loop is z-direction. The magnetic moment is 1.07×10^6 wbm when we use a portable IH cooker and a pan designed for the IH cooker, and the frequency is 20 kHz.

Averaging filter:

According to the guideline of ICNIRP, the current densities should be averaged over a cross-section of 1 cm^2 perpendicular to the current direction[1]. We calculate the running average using 2D filter like Fig. 4 in the perpendicular plane for each component of current. The cell at the center of the filter represents the tissue after averaging. When the cell size of the model is 3 mm, an equivalent area is adjusted to 1 cm^2 by weighting as shown in Fig. 5.

Fig.4 Averaging filter for 2 mm model.

Fig.5 Averaging filter for 3 mm model.

Dividing of models:

When a magnetic source is replaced with small dipole, the current doesn't have z component in the x - y plane including the source since the external magnetic field has only z component in that plane. Therefore, we can calculate the induced current density independently by dividing the body into the upper and the lower half by that plane. The saving of the computer resource is expected by dividing the models. We investigate whether the computation load can be reduced by dividing as shown in Fig. 6.

AFRL male model:

Figure 11 shows the comparison between the raw value and averaged value, concerning the maximum induced current density in each tissue for AFRL male model. Figure 12 shows the distribution of averaged current densities in the cross section of the same height as the source.

Fig.11 Comparison of induced current density for AFRL male model.

Fig.12 The distribution of averaged current density for AFRL male model.

According to Figs. 7, 9, and 11, the averaged current densities do not exceed the basic restriction 40 mA/m² of ICNIRP for the general public. Generally, the model with a fat body has the trend with large averaged current density.

Reduction of computation load by dividing of models:

Comparing the maximum value of the division model with the value of the whole body model, they are almost corresponding (Figs. 13, 14). Tables 1 and 2 show the required computer resource in our computation of the induced current densities. The computing time is proportional to the multiplication of the memory usage with the number of repetitions. Convergence in the upper half model has quickened due to dividing of the model, and the computing time could be saved

Table 1 Reduction of computer load by dividing of the NICT male model.

	No. of reputation N	Memory usage M (MB)	Load ratio of N*M (%)
Whole body	24466	1532	100
Upper half	9311	707	17.6
Lower half	21664	837	48.4
Division model			66.0

Table 2 Reduction of computer load by dividing of the NICT female model.

	No. of reputation N	Memory usage M (MB)	Load ratio of N*M (%)
Whole body	17797	1423	100
Upper half	6812	598	16.1
Lower half	17727	836	58.5
Division model			74.6

Summary

We have replaced the IH cooker by the small loop, and provided the magnetic vector potential required by the SPFD method theoretically. The induced current densities have been obtained using Japanese anatomically models and the SPFD methods. As a result, it is found that the averaged current densities of them is lower than that of the American male model. The induced current exceeding the guideline of ICNIRP may not flow inside human body in the case with a portable type IH cooker and a pan designed for the IH cooker.

Abstract

The Greek Atomic Energy Commission (EEAE) is the competent national authority for the protection of the general public and the environment from artificially produced non-ionizing radiation. To this end, EEAE carries out measurements in the vicinity of all kinds of sources emitting ELF electric and magnetic fields (e.g. power lines and substations), in order to monitor whether the general public exposure limits are being adhered to. The limit values for the ELF fields in Greece are set exactly the same as those in ICNIRP's guidelines. EEAE has conducted many measurements regarding the levels of ELF electric and magnetic fields in Greece around the elements of the electric power grid where the main interest of the public is focused. Theoretical estimations and typical values based on actual measurements of the fields in the vicinity of all the power lines used in Greece are presented. Measurement results in the vicinity of substations are also presented. In general, the levels of the magnetic field in the vicinity of the power grid elements are well below the established limits; whereas the levels of the electric field may reach values comparable to the safety limits very close to extremely high voltage lines. However, there is no case where the measured values of electric or magnetic fields were higher than the safety limits.

Introduction

Extremely low frequency or ELF electric and magnetic fields are omnipresent in modern societies. The possibility that long-term exposure to these fields might cause adverse health effects is a source for concern, especially for those people residing or working nearby high voltage lines or substations. Competent international scientific committees are watching the scientific developments in order to reach general conclusions about the health effects of these fields, [1].

In 2002, Greece put into force a legislative act, [2], implementing the recommendation, [3], of the Council of the European Union, adopting ICNIRP's limit values, [4], for the protection of the general public. The competent national authority for the protection of the general public and the environment from artificially produced non-ionizing radiation in Greece is the Greek Atomic Energy Commission (EEAE). To this end, the EEAE carries out measurements in the vicinity of all kinds of facilities emitting ELF electric and magnetic fields (e.g. power lines, high voltage substations) in order to monitor whether the general public exposure limits are being adhered to. The EEAE has been accredited in accordance with the requirements of the EN ISO/IEC 17025 standard for performing this kind of measurements. Figure 1 shows the number of annual audits conducted by the Non Ionizing Radiation Office of EEAE in the vicinity of ELF sources. There is an incremental tendency in these measurements reflecting the increasing interest for them.

Fig. 1. Annual audits conducted by the Non Ionizing Radiation office of EEAE concerning ELF sources.

In the next paragraphs the main sources of ELF electric and magnetic field exposure of the general public are presented. Domestic sources as the electrical appliances, internal wiring and currents on large grounded metallic objects as water pipes, drains and rails are presented. Also, the exposure resulted from the electric power transmission and distribution system is examined. Special emphasis is given to the situation in Greece and its particularities in relation to other parts of the world. That is because the levels of the electric and magnetic fields are to an important extent depending on the practices applied at electrical installations and on the electric power grid construction and operation, which might be quite different from country to country, [5].

Domestic Sources

In domestic environments the most common sources of ELF fields are the electric appliances, the internal wiring as well as the currents in large grounded objects as water pipes, drains and rails. These sources mainly create magnetic fields in their vicinity, because the created electric field is small due to the low voltage and is further attenuated by closures, walls etc.

The magnetic fields produced by appliances are rapidly attenuated with increasing distance from them and are noteworthy at distances much lower than 1 meter. The field at the surface of the appliance might be very strong, reaching values of hundreds μT . However, in most practical cases the human exposure takes place at much greater distances. Exceptions to this are devices that require their operator to be in close vicinity as electric shavers and hair driers. However, these devices are usually used for short time-periods each day and so the exposure of their operators is limited. Furthermore, exposure from these devices is locally focused in a small area of the body and the coupling of the field with the human body is weak. Taking into account these special exposure situations it is rather impossible that exposure from these sources might be capable to stimulate the neural or muscle cells.

The internal electrical wiring usually does not create important magnetic field levels in its vicinity. The involved practices applied at the construction of these installations are described in the electrical safety codes for the avoidance of the electrocution and other dangers. According to the safety code in Greece, [6], but also in many other parts of the world, the currents at the internal wirings create magnetic fields that at a great extent cancel each other. However, in the rare cases of installations not complying with the terms of the safety code, it is possible to find unusually strong magnetic fields, due to faulty connections or leakage currents. The existence of strong magnetic fields from the internal wiring might be an indication of an installation not complying with electrical safety codes and even hiding risks for electrocution or other dangers (as initiation of a fire).

It is noteworthy that in Greece the main supply is 50Hz and 220V ac voltage (as in the rest of Europe). That means that the currents used in electric appliances and the magnetic fields associated with them are roughly half of those that are used in other parts of the world (as the North America) where 110V are used. Furthermore the 50Hz magnetic fields in Europe induce 20% less internal fields and currents in the body of an exposed individual in relation to the 60Hz used in North America.

Another important source of domestic ELF magnetic fields might be the existence of ground currents at large grounded objects as water pipes, drains and rails. These currents create elevated levels of background magnetic

fields, i.e. fields that decay relatively slowly with the distance from their source. These currents are actually a portion of the returning currents normally located at the neutral conductor. However, the multiple ground connections of the neutral conductor allow alternative paths for the flow of the returning currents back to the power grid through large grounded metallic objects as water pipes, figure 2. Ground currents typically flow if there is a fault on the power system or they can be a normal condition, if there are many connections of the neutral conductor to the ground. However, the use of non-conductive parts at the water supply system significantly reduces the levels of the return currents.

Fig. 2. Mechanisms for the creation of ground return currents. The connection of the neutral conductor with the protective earth (ground) at the beginning of each consumer installation is either prohibited or imperative in Greece, depending on the geographic area.

Electric power distribution

The electric power distribution network is consisted of the low and medium voltage network used for the delivery of the electric power as well as the medium to low voltage substations. In Greece the low voltage is at the nominal level of 220/380V. The medium voltage is at various nominal levels but the last years it is being standardized to 20kV.

The low voltage network is the final piece of the electric network used for the delivery of the electric power at home level. This network consists of overhead and underground lines. These lines create mainly magnetic fields in their vicinity. The created magnetic fields may reach values up to a few μT close to the conductors and attenuate at much lower levels a few meters away from the lines. However, the low voltage loads are usually not well balanced on the three phases of the system and that causes the appearance of currents on the line neutral conductor. A portion of this current might flow on large grounded metallic objects in the vicinity of the line but in special circumstances also far from it, with the results described in the previous paragraph. That also means that there is a net current on the line producing magnetic fields that decay relatively slow with the distance from it.

The medium voltage network is used for the power supply of the substations feeding the low voltage network as well as for the immediate supply of large consumers. The voltage in this network is many times higher than that in low voltage network and so the currents are many times lower for the same amount of transferred power. Table 1 includes typical EMF values found in the vicinity of medium voltage lines in Greece. It is noteworthy that the medium voltage lines do not suffer from the unbalances mentioned for low voltage lines, because the medium voltage loads are usually well balanced and the medium to low voltage substations act as barriers not allowing the low voltage unbalance to pass on the medium voltage side.

The medium to low voltage substations are usually sources of public concern. The attention is mistakenly focused on the transformer, which is used for power transmission from one voltage level to another. However, the transformer itself is not producing any significant levels of electric and magnetic fields in its vicinity. It is the medium and low voltage conductors connected to the transformer that create the electric and magnetic fields. Typically, the medium voltage equipment is the dominant source of the electric fields and the low voltage one is the dominant source for the magnetic fields close to a substation. The electric and magnetic fields produced by these substations does not extent further than a few meters from it. However, the current on the low voltage lines, which are fed by the substation, is higher close to the substation than far from it, as the electric power is dispatched to the various consumers along the line's way.

Electric power transmission

High and extremely high voltage lines are used to carry vast amounts of electric power. In Greece the main centers for electric power generation are located at the north part of the country; whereas the main consumption is occurring at the south part nearby Athens metropolitan area. Three double circuit 400kV (extremely high voltage) power lines are used to carry the electric power from the north to the south. Also, 400kV power lines are used for the interconnections with the neighbour countries at the north. The rest of the transmission is mainly accomplished with 150kV (high voltage) single or double circuit power lines.

Figure 3 shows typical levels of the electric and magnetic fields in the vicinity of the 150kV overhead power lines used in Greece. The magnetic field calculations refer to 50MVA apparent transferred power, which is considered typical for this level of voltage. The capacity for power transmission of these lines reaches 202MVA per three-phase circuit. In the 3rd row of this figure the fields in the vicinity of compact single circuit line are shown. This line creates the least field levels in its vicinity as it was also shown in [7].

Similarly, figure 4 shows typical levels of the electric and magnetic fields in the vicinity of 400kV power lines used in Greece. For these lines the magnetic field calculations refer to a typical level of apparent transferred power of 350MVA (typical capacity is 1400MVA per three-phase circuit). In the 2nd and 3rd row of this figure the fields in the vicinity of a double circuit line with different phase arrangements are shown. The double circuit 400kV power lines in Greece used to be constructed with the symmetrical phase arrangement on the two circuits (2nd row). However, for the barrel type double circuit lines used in Greece, this phase arrangement is not the optimum for the reduction of the produced electric and magnetic fields (actually for the parallel operation of the two circuits this phase arrangement is the worst one) and this led to elevated levels of electric and magnetic fields. The new 400kV double circuit lines are now constructed with opposite phase sequence on the two circuits, which is the optimum phase arrangement (3rd row) for this type of lines and leads to reduced electric and magnetic fields, [7]. Also, the phase sequence on the existing power lines of this kind were switched to the optimum one causing significant reduction of the produced fields,[8].

In Greece there are about 10000km of overhead high voltage power lines (400kV and 150kV) as well as 200km of underground high voltage power lines (150kV). The later are used for transferring high voltage power in the dense populated urban areas. Underground cables do not produce any electric field above the ground. Comparing the magnetic fields produced by an overhead and an underground high voltage line, carrying the same power, the underground cable produces a higher magnetic field value in a narrow area right above it (figure 5).

Table 2 shows worst-case values (based on theoretical estimations) and typical values (based on actual measurements) of electric and magnetic fields in the vicinity of the power lines used in Greece. The levels of the magnetic field are, as a rule, much lower than ICNIRP's reference level for general public exposure to 50Hz magnetic fields (100 μ T), [4]. The levels of the electric field can reach values close to 5kV/m (ICNIRP's reference level for general public exposure to 50Hz electric fields) under 400kV lines and under worst-case considerations. However, in no case the measured values for the electric field were higher than ICNIRP's reference level.

High Voltage Substations

Regarding the electric and magnetic fields produced in the vicinity of high voltage substations the measurements conducted by EEAE have shown that the equipment installed into the substation does not produce any significant values of electric and magnetic fields outside the substation. It is the power lines connected to it, that produce the levels of electric and magnetic fields measured in the vicinity of the substations. Figure 6 shows a satellite photo of Agios Stefanos 400kV substation of the Greek power transmission system. EEAE was called upon to examine the levels of the produced fields outside this substation and performed measurements around the perimeter of it. The routes of the power lines connected to the substation as well as the measurement points are indicated in figure 6. These measurements verified that far from the power lines there are insignificant levels of fields, whereas close to the power lines the typical electric and magnetic field levels in the vicinity of the corresponding lines are found.

Table 1. Electric and magnetic field levels at the vicinity of the power lines used in Greece. The values refer at a distance of 2m above ground level in the vicinity of overhead lines and at ground surface in the vicinity of underground cables.

Arrangement		Magnetic field (μT)	Electric field (V/m)
400 kV lines	Worst-case scenario	25	5000
	Typical (underneath the conductors)	1 – 4	2000 – 4000
	Typical (25m aside from line)	0.5 – 2	200 – 500
150 kV lines with lattice towers	Worst case scenario	15	2000
	Typical (underneath the conductors)	0.5 – 2	1000 – 2000
	Typical (25m aside from line)	0.1 – 0.2	100 – 300
150 kV compact lines on poles	Worst case scenario	10	1200
	Typical (underneath the conductors)	0.3 – 1.5	500 – 1000
	Typical (25m aside from line)	0.05 – 0.2	50 – 100
150 kV underground cables	Worst case scenario	20	-
	Typical (above the cable)	3 – 6	-
	Typical (25m aside from cable)	< 0,01	-
20 kV overhead lines (medium voltage network)	Worst case scenario	5	700
	Typical (underneath the conductors)	0.2 – 0.5	50 – 200
	Typical (25m aside from line)	0.01 – 0.05	10 – 20

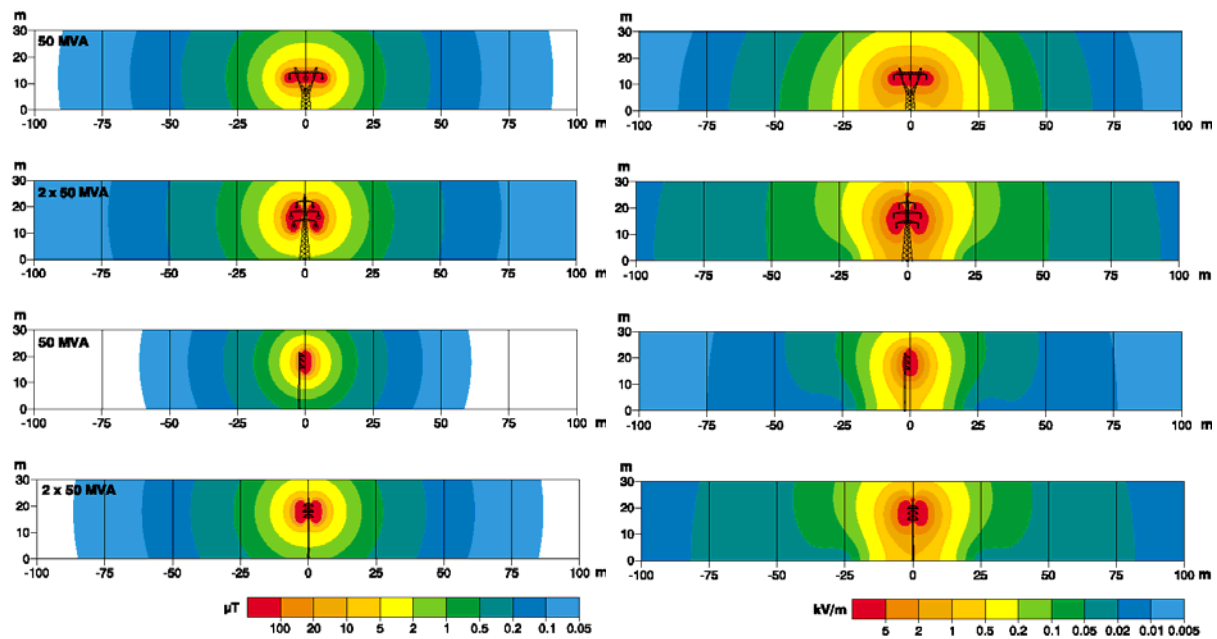

Fig 3. Typical levels for the magnetic field (on the left) and electric field (on the right) in the vicinity of the 150kV overhead power lines used in Greece. The considered clearance of the conductors to the ground was 12m and the indicated power line types are:

- 1st row: single circuit line on steel lattice towers
- 2nd row: double circuit line on steel lattice towers
- 3rd row: compact single circuit line on poles
- 4th row: compact double circuit line on poles

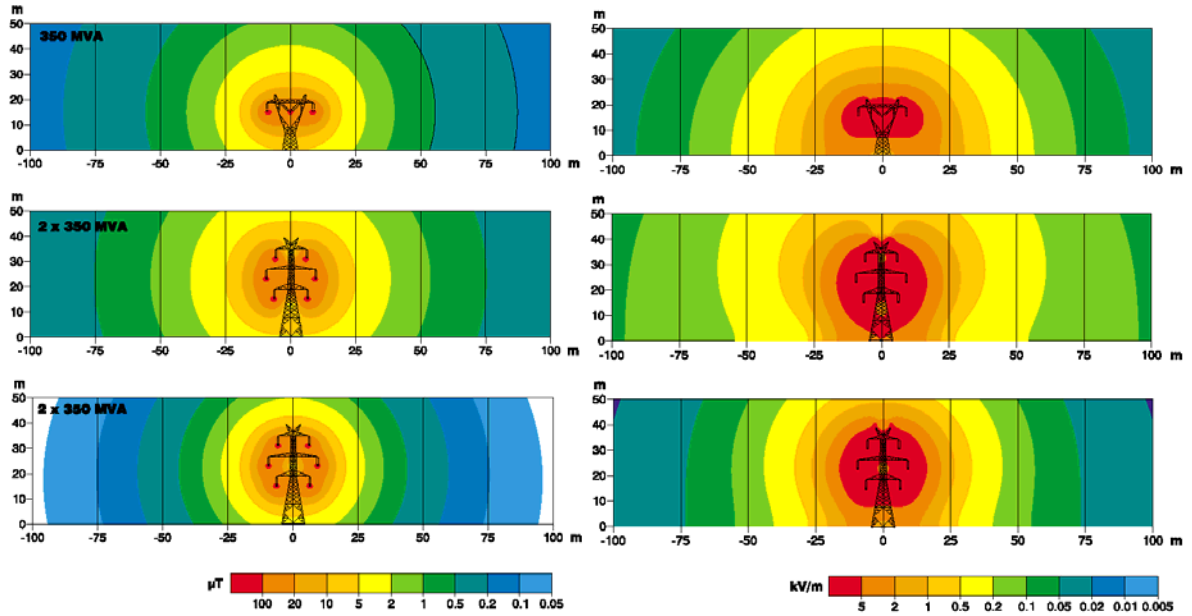

Fig 4. Magnetic field (on the left) and electric field (on the right) in the vicinity of the 400kV overhead power lines used in Greece. The considered clearance of the conductors to the ground was 15m and the indicated power line types are:

- 1st row: single circuit line
- 2nd row: double circuit line with the symmetrical phase arrangement
- 3rd row: double circuit line with the optimum phase arrangement

Fig. 5. Magnetic field in the vicinity of a 150kV underground cable carrying 50MVA. The considered cable is buried at 1.5m depth and the distance between the neighbor pole centers is 25cm.

Fig. 6. Satellite photo of Agios Stefanos 400kV substation (Greece) where the routes of 150kV and the 400kV power lines connected to it and the locations where EEAE have conducted measurements outside its perimeter are indicated.

Conclusion

The main sources of ELF magnetic field exposure of the general public in domestic environments are the electrical appliances, the internal wiring and the return currents on large grounded metallic objects as water pipes, drains and rails. The electrical appliances produce fast decreasing fields with distance that typically are considered important only for those devices where the operator must be in the close vicinity of them. The internal wiring normally does not produce any significant levels of magnetic fields, unless there is a faulty connection or a leakage current. The return currents on large grounded metallic objects as water pipes, drains and rails cause elevated levels of background magnetic fields.

Unbalanced loads at low voltage lines might cause net currents on them creating magnetic fields that decay relatively slowly with the distance. The medium voltage network does not suffer from these unbalances. The medium to low voltage transformer does not actually produce any fields in its environment. It is the lines connected to it that produce the electric and magnetic fields in its vicinity.

The electric and magnetic fields in the vicinity of high and extremely high voltage power lines depend on the type of line, its load and the distance from it. In Greece the application of the optimum phase arrangement at double circuit 400kV power lines caused a significant reduction of EMF levels around them. Furthermore, the use of compact lines also reduces the produced fields in relation to lines with normal dimensions. Underground cables create magnetic fields that decay very fast with distance from them. However, the magnetic field might be higher than that of an overhead line in a narrow zone above the cables.

SOURCES AND LEVELS OF RF ELECTROMAGNETIC FIELDS IN GREECE

**E. KARABETSOS G. FILIPPOPOULOS D. KOUTOUNIDIS
CH. GOVARI N. SKAMNAKIS**

***NON IONIZING RADIATION OFFICE
GREEK ATOMIC ENERGY COMMISSION
P. O. BOX 60092, 15310 AGIA PARASKEVI, GREECE***

Abstract

The Greek Atomic Energy Commission (EEAE) is the competent national authority for the protection of the general public and the environment from artificially produced non-ionizing radiation. To this end, EEAE carries out measurements in the vicinity of all kinds of sources emitting RF electromagnetic fields (e.g. audio, radio and television antennas, mobile phone base stations, radar and satellite earth stations and other microwave communication systems), in order to monitor whether the general public exposure limits are being adhered to. The safety limits in Greek legislation for the electromagnetic fields emitted by antenna stations, were recently set to 70% of the ICNIRP's values and to 60% of them if the antenna station is closer than 300m from the perimeter of kindergartens, schools, hospitals or eldercare facilities. There are a few exceptional cases where measurements of RF fields conducted by EEAE in the vicinity of radio and TV broadcasting antennas have revealed excess of ICNIRP's reference levels. The results of one such case are presented. About 70% of the RF measurements conducted by EEAE concern cellular phone base stations. EEAE has conducted measurements in the vicinity of 1200 such stations and virtually in all measurements the results are from tens to thousands times below ICNIRP's reference levels for general public protection.

Introduction

The proliferation of wireless communication technologies caused a radical change on the modern society. In Greece the penetration of cell phones is about 80% that is close to the average of the developed world. At the same time there is an increasing concern among people residing nearby cell phone base stations about adverse health effects caused by the presence of the station.

In order to protect against known effects of the exposure to electromagnetic fields, competent committees as ICNIRP have developed exposure guidelines, [1]. In the recommendation, [2], issued in 1999, the EU Council adopted ICNIRP's guidelines for the protection of the general public. Implementing this recommendation, Greece put into force a national legislative act concerning the protection of the public from exposure to electromagnetic fields emitted by all kinds of land-based antenna stations, [3] in 2000. The limits in Greek legislation were set to 80% of the European Recommendation values. Recently, however, the Greek Parliament has voted the Law [4] setting the Greek limit values at 70% of the European Recommendation values, in general, and 60% of them, if the antenna station is closer than 300m from kindergartens, schools, hospitals or elder-care facilities.

The competent national authority for the protection of the general public and the environment from artificially produced non-ionizing radiation in Greece is the Greek Atomic Energy Commission (EEAE). To this end, the EEAE carries out measurements in the vicinity of all kinds of facilities emitting RF electromagnetic fields (e.g. audio, radio and television antennas, mobile phone base stations, radar and satellite earth stations and other microwave communication systems), in order to monitor whether the general public exposure limits are being adhered to. The EEAE has been accredited in accordance with the requirements of the EN ISO/IEC 17025 standard for performing this kind of measurements. Figure 1 shows the number of annual audits conducted by the Non Ionizing Radiation Office of EEAE regarding RF sources. There is an incremental tendency in these measurements reflecting the increasing interest for them.

Fig. 1. Annual audits conducted by the Non Ionizing Radiation office of EEAE concerning RF sources.

In the next paragraphs results of measurements conducted by EEAE in the vicinity of the most common types of antenna stations are presented. Though the use of mobile phones is the major source of exposure to RF electromagnetic fields, mobile phones are not treated in this paper. That is because the measurements conducted by EEAE generally concern fixed antenna stations as mobile phone base stations, radio and TV broadcasting stations radar and satellite earth stations and other microwave communication systems. The purpose of these measurements is to check compliance with the limits set in the Greek legislation. Figure 2 shows the percentage of the measurements conducted in the vicinity of mobile phone base stations, radio and TV broadcasting antennas as well as radar facilities. The majority of measurements concern mobile phone base stations. This big ratio is due to the constantly increasing relevant requests from municipal authorities, individual citizens and even the mobile phone network operators.

Fig. 2. Percentage of the measurements conducted by EEAE regarding mobile phone base stations, radio and TV broadcasting antennas and radar facilities.

Mobile phone base stations

Mobile phone base station antennas in Greece are, as everywhere else, placed either on top of large metal pylons (in rural places) or on poles on top of buildings (in urban areas). Nowadays, it is also common to find micro antennas in the interior of big buildings such as airports, metro stations, stadiums, etc, where a lot of people are assembled. Throughout the country there are about 6000 base stations installed until now, including the new UMTS stations. The EEAE has conducted measurements in the vicinity of almost 1250 such stations and practically in all cases the results were found to be from tens to thousands times below ICNIRP's reference levels for general public exposure. Table 1 shows typical maximum levels of the electromagnetic fields measured in the vicinity of mobile phone base stations in Greece. It is noted that these values refer to the maximum value at worst-case selected areas in the vicinity of the base station. These areas are usually on the roofs of nearby tall buildings in the main lobe directions of the base station's antennas. The levels of the electromagnetic fields caused by these stations at areas where people normally dwell or work are, as a rule, much lower.

Table 1. Typical maximum values of electromagnetic radiation in the vicinity of mobile phone base stations and the reference levels imposed by the Greek legislation for the frequencies used in mobile phone systems.

		Electric field (V/m)	Magnetic field (A/m)	Equiv. Power Density (W/m ²)
Typical maximum values		0.25 – 5	0.0005 – 0.01	0.0002 – 0.05
Reference levels for GSM-900*	70%	34.5	0.0929	3.1
	60%	31.9	0.0860	2.7
Reference levels for GSM-1800*	70%	48.8	0.1313	6.3
	60%	45.2	0.1216	5.4
Reference levels for UMTS* (2100MHz)	70%	51	0.1339	7
	60%	47.2	0.1239	6

* The Greek limits are set to 70% of ICNIRP's values for the electromagnetic fields in the vicinity of antenna systems further than 300m from the perimeter of day nurseries, schools, hospitals or elder-care facilities and to 60% of ICNIRP's values closer than 300m from these facilities. The Greek reference levels are calculated from corresponding basic restrictions set to 70% and 60% per case of ICNIRP's basic restrictions.

Radio and TV broadcast stations

In many cases, a great number of powerful radio and TV broadcasting installations have been assembled in one place forming an antenna park. In some of these places, measurements conducted by EEAE have revealed excess of ICNIRP's reference levels. Usually, the excess is limited a few meters away from the antenna installations. In a specific and exceptional case, the side lobe of a powerful installation in an antenna park near Herakleion, Crete Island radiates a nearby, elevated area where an army camp is situated, causing excess of ICNIRP's reference levels in almost half of the camp (see figure 3).

EEAE was called upon to examine the levels of the electromagnetic radiation caused by this antenna park. The measurements performed by EEAE revealed levels of electromagnetic fields much in excess of Greek reference levels (and ICNIRP reference levels as well). After that, the area where the excess occurs was defined and special signs were temporally set in order to warn the personnel of the high EMF levels, until the competent authorities take all the appropriate remedial actions. Figure 3 indicates the area where the electromagnetic fields exceed the Greek reference levels and the points where measurements have been taken. Besides measuring the levels of the electromagnetic fields spectral analyses were also performed in order to specify the contribution of each source to the measured levels. Figures 4 and 5 show the results of spectral analyses per service and per FM radio station, respectively, conducted at point M1 (a typical point). These analyses revealed that the major contribution at the measured fields came from FM radio stations and particularly from a single radio station operating at 97.5MHz.

Fig 3. A sketch of the camp and the surrounding area showing the points of measurement (M1- 12) and the area in red where the RF radiation exceeds the Greek reference levels. The photo shows the radio station antenna causing the high radiation levels.

Fig. 4. Spectral analysis per service for the electromagnetic radiation at point M1.

Fig. 5. Spectral analysis per FM radio station for the electromagnetic radiation at point M1.

Radar Stations

EEAE has also conducted measurements in the vicinity of radar installations. Despite the powerful emitted pulses the exposure in the vicinity of these installations is in general some hundreds to thousand times lower than ICNIRP's reference values for general public protection. It is noteworthy that the measurement process in these cases is much more difficult and time requiring because the instrument's response to pulsed modulated fields has to be taken into account and the peak and average exposure has to be calculated.

Conclusions

EEAE carries out measurements in the vicinity of all devices emitting RF electromagnetic fields throughout Greece in order to check compliance with the limits imposed by the Greek Legislation. To that end over one and a half thousand audits have been performed. It is noted that the Greek limits were recently set to 70% of ICNIRP's values in general, and 60% of ICNIRP's values for exposure caused by antenna station at a distance lower than 300m from the perimeter of day nurseries, schools, hospitals or elder-care facilities.

The results of RF electromagnetic field measurements show that there might be cases where powerful radio or TV broadcasting antennas cause levels of these fields greater than the established reference values for human exposure, if proper care were not shown during their design and installation phases. Regarding the electromagnetic field levels in the vicinity of mobile phone base stations, the measurements conducted by EEAE show that the maximum values of electromagnetic fields are typically hundreds to thousand times lower than ICNIRP's reference levels.

ABSTRACT

The use of mobile connection that relates to electromagnetic saturation is rapidly increasing during the recent 10 years in Latvia. People who carry mobile phones constantly subject themselves to the action of an electromagnetic field (EMF). And in the process of talking the mobile phone EMF exceeds the standards admissible by a factor of 10 times.

The number of children who always use mobile phones rapidly augments too. According to our data (2005) every tenth pupil of the first form has a mobile phone. Moreover, at the age of the secondary school nearly every pupil has a mobile phone.

The main tasks of the studies were the EMF influence on the development of the children motor and psychological function. The intensity of the EMF influence determined on the children neuropsychic development peculiarities was studied.

A complex of motor and psychological parameters was found.

The studies were performed every year on 112 children in 2 schools of Riga from 1996 and will be finished in 2008. Tests were carried out with every child determining their motor functions (taping-test, reaction time on sound stimuli were given binaurally or bilaterally with stereo earphones and light stimuli presented at the centre of table and on the left or right sides), psychological IQ—by Raven's test, capacity for attention switching was tested according to a modified Shulte's procedure, stability and capacity to focus attention were studied using an "entangled line" test, and memory was tested by the capacity to remember numbers functions.

The paper presents the preliminary results of experiments on a possible interdependence between EMF and children motor and psychological functions development.

Key words: children, development, mobile phone, IQ, attention, reaction time, tapping-test.

INTRODUCTION

Children, like adults, are subjected to the effect of harmful environmental factors, including also those generated by electromagnetic fields (EMF) of modern communication systems. At the same time, recent reviews demonstrate that there has been little research on the EMF effects on children.

The literature data available contain no common opinion on the mechanism of EMF effect on human health. There are studies on the heat effect of high frequency EMF on human health (Maier *et al.*, 2000; Kumar, 2001; Liesenkotter, 2002; Lin *et al.*, 2002; Walton, 2002; Evans-Pughe, 2003; Hocking, 2003), human body (Schonborn *et al.*, 1998; Nesse *et al.*, 2001; Lin, 2003; Toropainen, 2003), nervous system (Croft *et al.*, 2002; Hamblin and Wood, 2002; Hietanen *et al.*, 2002; Hossmann and Hermann, 2003; Huber *et al.*, 2003; Salford *et al.*, 2003), and psychological function (Lee *et al.*, 2001; Edelstyn and Oldershaw, 2002; Haarala *et al.*, 2003;); however, the data available are on contradictory. The number of children who persistently use mobile phones has rapidly increased as well. The studies were performed with a psychophysiological diagnostic system “Polytest-8802 (Produced by Engineering Center of Latvian Academy of Science, Latvia). The “Polytest-8802” is a specialized computer that uses psychophysiological reactions to determine human functional state. In total, 11 tests were made for each child. A rest break was included and the test duration was 70 minutes. Each test included twenty measurements that were used to obtain the arithmetical mean, standard deviation, and standard error of the mean (Kolodynski and Kolodynska, 1996, 2006). The studies were performed on 112 children (57 boys and 55 girls) in 2 schools of Riga in 1996–2003 (Table 1).

Tapping-test. To evaluate the functional state of the neuromuscular system, a tapping-test was used. The children examined had to press two keys with their right and left hands at maximum rate for 30 seconds. The rate of key pressing per second was registered for each hand separately.

Reaction time Red light diodes were used to present light stimuli at the centre of the table and on the left and right sides. The visible diameter of the light was 2.5 mm and the stimulus duration was 40 ms. Sound stimuli were given with stereo earphones (intensity, 60 dB; stimulus duration, 100 ms; frequency, 1 kHz). The interval between both light and sound stimuli was randomized (2.5–4 s). Children had to rapidly press and release keys after stimuli. Presentations of stimuli from the table centre or binaurally required the child to press both keys simultaneously. When the stimulus was presented from the side of the table, or in one earphone, the subject had to press the key on the side corresponding to the stimulus. In the cross variant of the test, the subject had press the key at the side opposite that of the stimulus. The response time, duration of press contact, and the number of errors were registered.

Attention. The capacity for attention switching was tested according to a modified Shulte’s procedure. The procedure used a double-colored table of 64 squares. Each square consisted of two numbers: large black and small red colors (index), as well as a response button. At the beginning of the test the monitor displayed a number which the child was required to find among the black numbers. When the required black number was found, the child was required to press the appropriate key and memorized the associated red number. This new number was then searched for among the black numbers and the process was repeated 20 times.

The stability and capacity to focus attention were studied with the “entangled lines” test. The test table was covered with entangled lines. Each line began with a number on the left side and finishes with another number on the right side. The child was required to rapidly follow each line visually and press the key at its finish. The time taken to follow every line and the number of errors were registered.

Memory. Memory was tested by the capacity to remember numbers. During the experiment, a series of numbers of increasing complexity was presented, beginning with three digits and ending with nine. White digits of 6 x 10 mm, on a dark-grey background were presented on the computer monitor. During one test, three numbers were displayed on a monitor at 1 second intervals. The child then entered the three numbers on the keyboard. This was repeated seven times, progressively increasing the number of numbers displayed from three to nine. One volume of operative memory was determined according to the formula $V = A + (m/n)$ where A is the largest numbers of digits in the operation which was successfully reproduced by the child in all experiments, n is the number of experiments, m is the number of correctly reproduced number series.

DEVELOPMENT OF MOTOR AND PSYCHOLOGICAL FUNCTION ON CHILDREN AND ELECTROMAGNETIC FIELD

Test of Raven's (Q I). The data obtained were transferred to the Wexler's scale, where the mean parameter value was equated to 100 points and a deviation from the mean value for one standard deviation – to 15 points.

Statistics. Statistically significant differences were evaluated by Student's criteria for quantitative variables and Pearson's coefficient was used for analysis of correlations.

Results. In each age group were tested 55 girls and 57 boys (Table 1). The duration of talks using mobile phone increased with age from 3 min/day (7 years old children's) to 21 min/day (14 years old children's). Mean power of mobile phone 0.6 W (GSM-900).

Table 1

MEAN AGE \pm STANDARD ERROR (YEARS) IN FEMALE AND MALE CHILDREN

Forms	Sex	Mean age \pm SE, years
1st form	Female	7.3 \pm 0.04
	Male	7.4 \pm 0.03
2nd form	Female	8.2 \pm 0.02
	Male	8.5 \pm 0.03
3rd form	Female	9.4 \pm 0.03
	Male	9.6 \pm 0.05
4th form	Female	10.3 \pm 0.03
	Male	10.5 \pm 0.04
5th form	Female	11.5 \pm 0.03
	Male	11.6 \pm 0.02
6th form	Female	12.3 \pm 0.04
	Male	12.4 \pm 0.03
7th form	Female	13.5 \pm 0.05
	Male	13.6 \pm 0.03
8th form	Female	14.4 \pm 0.03
	Male	14.5 \pm 0.03

The rates of all motor reaction (tapping-test end reaction time) tests in boys were better then in girls Table 2 and Table 3).

The rates of all attention (attention switching and attention concentration) tests in girls were better then in boys.

No differences in the volume of operative memory and the time required to fulfil the test for the rate of the attention switching were detected (Table 4).

A weak negative correlation dependence was observed between the duration of daily conversations using MT and intellect $r = 0.37$ ($P < 0.01$) and concentration of attention $r = 0.29$ ($P < 0.05$).

The pupils began to use mobile telephones at different time. Therefore, the analysis of the data obtained was started from the analysis of separated cases. In example, the testing results of one girl aged 7 to 14 (Fiig.1 and Fig.2) during eight years. The start of the persistently MT use – in the 5th form. Figures 1 and 2 demonstrate a worsening of some motor and psychological parameters during the first year of using MT, later these parameters gradually become more equable. On the basis of this observation 2 groups of pupils were chosen for the analysis: those who use MT during the first year and those who use MT during more than one year.

It turned out that the highest worsening of the parameters is observed during the first year of MT use, and the parameters improve more quickly in the children who started to use MT later (Fig.3 and Fig.4.).

Fig.1. Mean ± SE time to perform the test for IQ. The development of IQ in girl was testing.

Fig.2. Mean \pm SE time to perform the test for attention concentration. The development of attention in girl was testing.

Fig.3. Mean \pm SE of IQ. The differences are significant ($P < 0.05$) between the mobile phone users and control groups in children of 5th-6th forms and ($P < 0.01$) in children of 7th-8th form for MT >12 month group with control..

Unexpectedly, IQ differences were found between the mobile phone users and control groups in children of 5th-6th forms and in children of 7th-8th form for “MT >12 month” group with control..

DEVELOPMENT OF MOTOR AND PSYCHOLOGICAL FUNCTION ON CHILDREN AND ELECTROMAGNETIC FIELD

Fig.4. Mean \pm SE time (s) to perform the test for attention concentration. The differences are significant ($P < 0.05$) between the mobile phone users of 5th-6th forms and ($P < 0.01$) in children of 7th-8th form for MT > 12 month group.

Younger children using mobile phone are more sensitive to the EMF radiation than oldest and have worse results to IQ and attention tests (Fig.3. and Fig.4).

SUMMARY

The highest shifts in motor and psychological parameters are detected during the first year of MT use, and later they gradually improve.

The improvement of parameters proceeds more rapidly in the children who started to constantly use MT at an elder age.

The improvement of parameters proceeds more rapidly in the children who started to constantly use MT at an elder age.

The analysis of the data obtained will be continued basing on the working hypothesis on that the oldest children organism, being adapted to the EMF chronic influence better, responses by the increase in the IQ and attention after 12 month of mobile phone using..

Children are more sensitive to the EMF radiation than adults, and on the basis of the data available, the Independent Expert Group on Mobile Phones (IEGMP) in the United Kingdom came to the conclusion that children may be more vulnerable because they have a developing nervous system, children's brain tissue is more conductive than that of adults since it has a higher water content and ion concentrations, children have a greater absorption of RF energy at mobile telephone frequencies in the tissues of the head, and that children would have a longer lifetime of exposure. The IEGMP also recommended that, as a precautionary approach, mobile phone use by children should be for non-essential calls only, and that the mobile phone industry should refrain from promoting mobile phones to children.

The authors of the paper support the point of view of the IEGMP.

The research should be continued in this direction, including the individual dosimetry and analysis of each separate case.

DNA-damaging effects of UMTS electromagnetic fields in human cells *in vitro*

Elisabeth Kratochvil¹, Claudia Schwarz¹, Petra Hartbauer¹,
Marietta Weninger¹, Alexander Pilger¹, Franz Adlkofer²,
Hugo W. Rüdiger¹

¹ Medical University of Vienna, Division of Occupational Medicine, Vienna, Austria

² Verum Foundation, Munich, Germany

Our previous research demonstrated that radiofrequency electrsignals have genotoxic properties *in vitro*¹; there are no corresponding data concerning the recently introduced European mobile communication standard UMTS (Universal Mobile Telecommunication Standard) as yet. A putative genotoxic potential of UMTS signals was investigated in cultured human cells using the alkaline comet assay and the cytokinesis-blocked micronucleus assay.

Materials and Methods

Cultured human fibroblasts (diploid fibroblasts obtained from a male 6 year old healthy donor) were continuously exposed to UMTS test signals (carrier frequency 1950 MHz) in a temperature-controlled exposure setup² specially designed for blind *in vitro* exposures of cell monolayers and provided by the IT'IS foundation (Zurich, Switzerland). Various exposure conditions (specific absorption rate SAR: 1 and 2 W/kg; exposure time: 4, 16 and 24 hours) were tested. Each exposure condition was tested in duplicate. Positive (comet assay: 5 min UV light/254 nm, which equals 0,6 kJ/m²; micronucleus assay: 3 µg Bleomycin/ml - time corresponding to the exposure time) and negative controls were included in each set of experiments to check for effective operation of the method. DNA damage was assessed in terms of DNA strand breaks (alkaline comet assay, evaluated by visual classification³) and micronuclei (cytokinesis-blocked micronucleus assay⁴).

Summary

Exposure to UMTS signals resulted in a twofold increase in DNA strand breaks after 16 and 24 hours for both SAR investigated. In addition, a corresponding doubling in micronuclei frequency was detected.

Preliminary experiments using peripheral blood lymphocytes showed no increase in DNA strand breaks after UMTS exposure (not shown).

In conclusion, UMTS signals may have genotoxic effects in certain cell systems *in vitro* below and at the current European safety limit (2 W/kg).

ABSTRACT

Reports of biological effects of low-energy electromagnetic field (EMF) have increased in recent years. Particularly debated is the question of the epidemiological evidence of adverse effects of an extremely low frequency magnetic field (ELF-MF) generated by 50-60 Hz high voltage power transmission lines, video display terminals, electric blankets and other home appliances, which raise the possibility of deleterious health effects from exposure to radio frequency or low frequency fields. A valid objection is that field intensity is many orders of magnitude below the noise threshold so that selective, cooperative, or amplifying mechanisms must be postulated. The therapeutic potential of magnetic field can be seen in the proven efficacy of low-energy, pulsed magnetic fields in non-union bone fracture healing (Bassett, 1993), confirming that under certain conditions non-ionizing electromagnetic energy can influence physiological processes in organisms. Low frequency magnetic fields at 50 or 60 Hz are also reported to stimulate nerve regeneration (Rusovan and Kanje, 1992) alteration gene transcription (Phillips et al., 1992), and they may also play a synergic role in cellular processes that are already activated, such as cell proliferation and cell differentiation (Walleczek, 1992; Manni et al., 2002., Lisi et al 2005).

The possible mechanisms of the induced effects are not known, although a number of theoretical models have been proposed (Glaser, 1992., Liburdy, 1992., Barnes, 1996).

In this work we have studied the effect of EMF radiations on human mesenchymal Stem Cells (hMSC) differentiation

In literature is well described that this cells are able to differentiate to osteoblast following treatment with chemical agents such as dexamethasone. Regulation of osteoblast differentiation its an important fenomena that must occur to maintain the continuos supply of mature osteoblast needed for bone growth, remodelling, and in particular for bone repair.

INTRODUCTION

Culture and differentiation of mesenchymal stem cells. Height- ten ml of bone marrow, obtained from iliac crest, was mixed with one volume of phosphate-buffered saline and nucleated cell fraction was enriched for mesenchymal stem cells by density-gradient centrifugation over Lympholyte-H cushion. The cells at the medium- Lympholyte-H interface were collected, washed three times with culture medium and seeded into culture flask. Confluent monolayers of adherent cells were obtained about one week after the start of cell division. Subcultivation was performed by replating at 6×10^3 cells per cm^2 flasks. To promote osteogenic differentiation

cells were stimulated during subpassages by cultivation in standard medium supplemented with 100nM dexamethasone or by exposure to extremely low frequency electromagnetic field (50Hz 1mT) under controlled condition.

Cells were continuously exposed to a sinusoidal 50 Hz magnetic field at a flux density of 1 mT (10 G) (rms) in a temperature regulated solenoid. Temperature regulation (37 ± 0.2 °C) and 5% CO₂ was provided. Temperature was continuously recorded by a Hanna HI 9274 OC printing thermometer, within the centre of the solenoid and was in the $37^{\circ}\text{C} \pm 0.2$ range. In a control experiment the sample was placed in an identical cell incubator containing the solenoid with no field, in the same conditions as the exposed one. All experiments were under blind conditions. The solenoid manufacture has been published elsewhere (Santoro et al, 1997; Lisi et al, 2000; Manni et al, 2004, Lisi et al, 2005).

The main body of the solenoid is a cylinder in concrete-asbestos 2 cm thick and has a diameter of 20 cm and a height of 40 cm. It is made of 1200 turns of 2 mm diameter copper wire wound in three layers in continuous forward-backward fashion. It is driven from the 50 Hz power mains through a variable autotransformer and generates a flux density of 1 mT (rms) for an applied voltage of 6 Volts (rms). The solenoid is then placed into a cell incubator with its centre ventilated by the fan for appropriate air circulation. The modest heat due to Joule effect is efficiently dispersed by the continuous forced ventilation in the total mass of the CO₂ incubator. Field density measured with a calibrated Hall probe, is within – 5% of centre value inside the cylindrical exposure volume of 11 cm by 17 cm along the solenoid axis. The measured geomagnetic ambient field is 32 μT (vertical component) and 16 μT (horizontal component). Stray ambient ac fields are below 0.1 μT . An often overlooked fact related to solenoids is the presence of an almost homogeneous electric field oriented parallel to the magnetic field (Chute et al., 1981) unless adequate electric shielding is used (Stauffer et al., 1994). An approximate estimate of this field may be obtained from the voltage across the extremes of the inner of the six layers and its length. The corresponding field induced by capacity coupling in the culture medium will be in the order of 0.01 $\mu\text{V}/\text{cm}$ (Foster et al., 1995).

SUMMARY

Exposure to low frequency electromagnetic field for 5 days resulted in a change in plasma membrane morphology and this modification were also accompanied by a rearrangement in actin filaments as showed by confocal microscopy analysis after cells labeling with FITC-phalloidin.

In particular, mesenchimal cells exposed to the field showed the same actin organization found in cells after treatment with dexamethasone. The differentiating effect of dexamethasone were potentiate by exposure to the field.

After 5 days of exposure, the mRNA expression for osteoblast markers differentiation such as Alkaline Phosphatase (AP), Osteocalcin (OCL) and Osteopontin (OPN) increase (Fig.1) this result were further confirmed by indirect immunofluorescence assay for osteopontin. Osteopontin showed an increase in exposed and dexamethasone-exposed cells with respect to control (Fig. 2).

In conclusion our finding demonstrated that exposure to ELF can act as a differentiating agent on mesenchymal human cells outlining the relevance of low frequency electro-magnetic field as a terapeutical agent suggesting a possible use of ELF as support in medicine for different pathologies therapy.

THE NATIONAL REGISTER OF RF WORKERS (UK): A LONG-TERM FOLLOW-UP STUDY

Ian Litchfield, Tom Sorahan.

*The Institute of Occupational and Environmental Health, The University of
Birmingham, Edgbaston, Birmingham, England B15 2TT*

AIMS AND OBJECTIVES: In 1999, the Minister of Public Health asked the Radiation Protection Division of the Health Protection Agency (formerly the National Radiological Protection Board (NRPB)) to set up an independent expert group to examine the possible effects on health from the use of mobile phone telecommunication technologies. The group, under the chairmanship of Sir William Stewart, published its report in May 2000 [1]. One of the main conclusions was that there was no evidence to suggest that exposures to radiofrequency (RF) radiation below the guidelines of the NRPB and the International Commission on Non-Ionising Radiation Protection (ICNIRP) cause adverse health effects. Nevertheless, a key recommendation was that a register of occupationally exposed workers be established to facilitate studies into cancer incidence, mortality or other potentially harmful effects.

The Health and Safety Executive (HSE) responded to this recommendation by holding a consultation meeting on 9 January 2001 in Birmingham to which independent experts and those with an interest in telecommunications were invited. At this meeting, a decision was made to establish a Working Group to discuss how the recommendation should be implemented. In an attempt to ensure involvement across the whole industrial sector, representatives from the broadcast companies, mobile phone operators (FEL), contractors, the Ministry of Defence, National Grid, Trade Unions, and HSE were included.

The Working Group agreed to set up a register of exposed workers with a potential for exposure to radio-frequency radiation, and that the register would be confined to people whose work brings them in close proximity to transmitting antennas on telecommunication, broadcasting masts or other similar structures. Information about the workers would be retained and maintained in a centralised database or register. The Institute of Occupational and Environmental Medicine (IOEM) was contracted to administer the database. Now in its second phase, the register is guided by a Steering Group consisting of representatives from the HSE, the Institute of Occupational and Environmental Medicine and industry.

The study described here seeks to obtain important new information on the topic of long-term health effects of occupational RF exposure by examining data from the on-going National Register of RF workers.

MATERIALS AND METHODS: Analyses will be based on data from the on-going National Register of RF workers. The Register was first supported by the Health and Safety Executive (HSE) for the two-year period 2003-2004. It was always the intention of the HSE to support the start-up costs but then seek industry support for later years of data collection and analysis. Industry support is currently in place for the three-year period 2005-2007.

STUDY POPULATION

The cohort available for analysis currently comprises 604 male employees. All employees have some period of employment working in close proximity to transmitting antennas on telecommunication, broadcasting masts or other similar structures in the period 1961-2004. Work continues on increasing the size of the Register and in the next twelve months it is estimated that the Register will comprise some 2000 employees.

In order to account for the variation in exposure between different occupationally exposed jobs the participants are asked to supply their job title. This is then placed in one of five job categories (Antenna Support, General Maintenance Worker, Occasional Climber, Rigger and Satellite Support). The level of exposure typically experienced by each job category is informed by the five-year study carried out

by the Institute of Occupational and Environmental Medicine in conjunction with the Radiation Protection Division of the Health Protection Agency. This work, titled 'A Feasibility Study for an Epidemiological Investigation into the Health Effects of Radiofrequency Fields and Radiation' [2] produced a job exposure matrix for job titles relevant to the Register.

The National Register of RF Workers follow-up study will seek the approval of the Office for National Statistics (ONS) to receive follow-up particulars (copies of death certificates and cancer registration (incidence) details from the National Health Service Central Register (NHSCR) of the ONS). Underlying cause and multiple-cause coding will be supplied by the ONS for all deaths according to the tenth revision of the International Classification of Diseases (ICD-10).

STANDARDISED MORTALITY RATIOS AND STANDARDISED REGISTRATION RATIOS

The mortality experience of the cohort will be compared with that which might have been expected to occur if rates of mortality for the general population of England and Wales had been operating on the study cohort, having due regard to the composition of the study cohort by sex, age (five-year age groups), and calendar year (five-year calendar periods). Expectations based on person-years-at-risk (pyr) will be calculated using the PERSONYEARS computer program.[3] Individuals enter the pyr on the date of consenting to join the National Register. Individuals leave the pyr on the date of death, date of emigration, date last known alive or the closing date of the study, whichever is the earlier. Individuals will be "censored" on reaching their 85th birthday - that is, they will make no further contributions to expected or observed numbers past this age. Standardised mortality ratios (SMRs) will be calculated as the ratio of observed to expected numbers of deaths expressed as a percentage. In calculating P-values and confidence intervals, it will be assumed that deaths occur as a Poisson process [4]. Any significance tests will be two-tailed. Similar analyses will be performed on the cancer registration data to calculate standardized registration ratios (SRRs). Overall SMRs and SRRs will be calculated for individual sites of cancer (3-digit ICD codes) as well as SMRs for broader non-cancer causes (ICD chapters). Causes of special interest will be selected on the basis of significantly elevated SMRs or SRRs obtained either from this study or from similar studies of RF workers in other parts of the world. For causes of special interest, SMRs and SRRs will also be calculated by industry sector (telecommunications or broadcast), job type (1-5 names) and period from first RF work (ten-year intervals). In addition SMRs and SRRs for causes of special interest will also be calculated separately for workers reporting any high exposure incidents.

COLLABORATION: The National Register of RF Workers seeks to collaborate with international bodies undertaking similar research with the aim of contributing data and expertise and increasing understanding of the issue for the benefit of those occupationally exposed to RF radiation.

Abstract

The aim of this study is to evaluate the efficiency of two exposure set up realized for *in vitro* experiments purposes. Maximum dimensions of these systems are 198x99x27 mm, with an exposure zone of 80x99x27 mm in order to allow the simultaneous insertion of four Petri dishes 35 mm of diameter, or other shape flasks. The set up efficiency was been evaluated at the frequency of 900 MHz and 1820 MHz by means of SAR calculations (local and average) on cell cultures. To this scope a commercial software package (CST Microwave Studio) based on Finite Integration Technique (FIT) was used. Cad drawing tools allowed the parameterization of the structure made up of culture medium thickness contained in plexiglas dishes or flasks inserted between two metallic plates fed by 1 W power.

All materials employed were electromagnetically characterized by appropriate values of dielectric permittivity and conductivity. SAR calculation accuracy was improved by defining a refining mesh in the cell culture volume. SAR distributions on the exposed samples were investigated, and several SAR calculations were made employing flasks of various forms and with different quantity of culture medium.

The study was developed in the frame of activities referring to the European Project EMF-NET, Main Task 2, Work Package 12 (focused on numerical calculations for occupational exposure).

I. Introduction

The study of the effects of radio frequency radiation on biological systems is a topic of great concern due to the rapid spreading of mobile communication systems in the recent years and the identification of the mobile phone as a potential source of risk for people. Then a wide number of research has been and is presently carried out with particular reference to the frequencies employed by the Global System for Mobile Communications (GSM) standard, that is frequencies near 900 MHz and 1800 MHz.

This paper presents a numerical efficiency evaluation of two exposure set up designed in such scenario for *in vitro* experiments purposes.

The efficiency of the systems was investigated through numerical SAR evaluation inside cell cultures, performing *in vitro* tests based on the employ of flasks and dishes of different size and culture medium content. The effects of the number of samples exposed at the same time on SAR were also investigated.

Basing on the equipment present in our laboratory, an experimental characterization of the efficiency of the two set up were also performed by means of the ratio between direct and reflected power. The results of measurements indicated that the frequencies giving the best performance of the two systems (minimum reflected power) are centred respectively at 900 MHz and 1820 MHz.

These frequencies were then selected for the simulations.

Both experimental and numerical characterization was carried out at the ISPESL Research Centre in Monte Porzio Catone (Rome).

II. Exposure set up

The exposure set up under test consisted of two parallel metallic plates T-modelled as shown in Figure 1.

Figure 1 – Exposure set up operating near 1800 MHz

Both set up were designed to generate an RF electric field, one at 900 MHz and the other one at 1800 MHz, as much as possible uniform between the two metallic plates and orthogonal to them.

To this aim the systems consisted of two contiguous zones. The first one (the basis of the T), the so called adaptive section, was designed in order to maximize the power transfer from the feed to the exposure zone by means of a gradual change of the wave impedance. A coaxial connection allowed to feed the systems.

The second zone (the head of the T), the so called exposure zone, was the volume available for the exposure of the biological samples. In this regard the final part of this zone was open (see Figure 1), while the side walls were closed by two layers of absorbing material covered by thin plastic sheets.

The dimensions of the exposure zone were the same for both set up, that is about 80×99×27 mm, inside of which 80×80×27 mm were available for exposure (between the two panels of absorbing material). On the opposite, due to the different working frequencies, the dimensions of the adaptive sections were different for the two systems and are the following:

- 118×69×27 mm for 900 MHz set up
- 80×99×27 mm for 1800 MHz set up

III. Numerical method and SAR evaluation

Computational simulations have been carried out by employing the electromagnetic commercial simulator Microwave Studio (MWS) by CST-Germany [1], based on the Finite Integration Technique (FIT) [2]. This numerical method, developed by Weiland in 1977, provides a discrete reformulation of Maxwell's equations in their integral form suitable for computers and it allows simulating real-world electromagnetic field problems with complex geometry. In order to numerically solve Maxwell's equations, a finite calculation domain is defined. By creating a suitable mesh system, this domain is split up into small cubes, so-called grid cells.

In combination with the FIT, MWS employs the Perfect Boundary Approximation (PBA) for the spatial discretization of the simulated structure that allows an accurate modelling of bend-shaped structures also [3].

In order to simulate *in vitro* tests, the exposure set up were simplified. In fact in the numerical model only the exposure zone of the two set up was modelled, presuming that the detailed description of the adaptive section was not relevant for SAR evaluation purposes. Each exposure set up was then represented as two parallel metallic plates of (80 × 99) mm size, at 27 mm of distance.

Figures 2 show the various simulations performed inserting different Petri dishes or flasks between the plates. In particular Figure 2 a) refers to exposure to 900 MHz electromagnetic field of one plexiglas dish of 54 mm diameter, height of 11 mm and of 1 mm of thickness. Culture medium was then parameterized as dish of 52 mm of diameter, height of 2.4 mm for a total liquid volume of 5 ml.

Figure 2 b) refers to simultaneous exposure to 900 MHz electromagnetic field of four plexiglas dishes of 35 mm of diameter, height of 8 mm and 1 mm of thickness. Each culture medium was then parameterized as dish of 33 mm of diameter and 3.5 mm of height for a total liquid volume of 3 ml.

Figure 2 c) refers to simultaneous exposure to 1820 MHz electromagnetic field of two plexiglas flasks. Each flask was represented by means of a plexiglas parallelepiped of (35 x 35 x 20) mm size and of 1 mm thickness for each wall. Consequently each culture medium was parameterized as a parallelepiped of (33 x 33 x 3.7) mm size, for a total liquid volume of 5 ml.

Fig 2 a

Fig 2 b

Fig 2 c

All simulations have been carried out feeding exposure systems through an electromagnetic pulse of 1 W. All materials were characterized, on the basis of data literature, with their particular values of dielectric permittivity (ϵ_r), conductivity (σ) and density (ρ) at the frequency of 900 MHz and 1820 MHz as shown in Table 1.

Table 1 - Properties of materials used in the simulations

	frequency 900 MHz		
Materials	ϵ_r	ρ [kg/m ³]	σ [S/m]
Plexiglas	2.6	1200	neglectable
Cell Culture (culture medium)	80.5	1000	1.55
	frequency 1820 MHz		
Plexiglas	2.6	1200	neglectable
Cell Culture (culture medium)	76.8	1000	2.21

To perform dosimetric evaluation with better accuracy, a refined mesh in the culture medium volume was adopted. This involved a not uniform spatial discretization of the calculation domain ensuring a good compromise between the need of accuracy in the volume of interest and the simulation time.

As MWS evaluates both local and total average SAR through closed routines, in order to be sure regarding the mass involved in the calculation, we adopted a suitable numerical procedure made up of two steps [4].

The first one was aimed to produce electric field peak values on the whole domain by MWS, with higher accuracy in the sample volume. As second step, a mesh refinement limited in the cell cultures volumes was carried out, and the electric field values were recalculated. In this way the volume of each culture medium was discretized with spatial resolution of about (0.5 x 0.05 x 0.5) mm corresponding to 157248 mesh nodes. Finally, the electric field values were exported to commercial SW and post-processed to compute local spatial SAR (W/kg) values according to the relation:

$$SAR = \frac{\sigma E_{(i)}^2}{2\rho} \quad (\text{Eq. 1})$$

where:

$E_{(i)}$:	internal electric field in an elementary volume of the cell culture (peak value) [V/m]
σ	:	conductivity of culture medium [S/m]
ρ	:	density of culture medium [kg/m ³]

The total average SAR was evaluated by summing every SAR spatial contribution on the basis of relation:

$$\langle SAR \rangle = \frac{1}{N} \frac{\sigma}{2\rho} \sum_{k=1}^N E_{(i)k}^2 \quad (\text{Eq. 2})$$

where:

$E_{(i)k}$:	internal electric field in an elementary volume (k-elementary cell) of the cell culture (peak value) [V/m]
σ	:	conductivity of culture medium [S/m]
ρ	:	density of culture medium [kg/m ³]

IV Results

900 MHz

Figures show the most relevant results for electric field calculations. Figures 2 (a) e (b) show a chromatic 3D scalar representation of the absolute value of electric field distribution (peak values) in the exposure set-up and in the culture medium, as calculated by MWS.

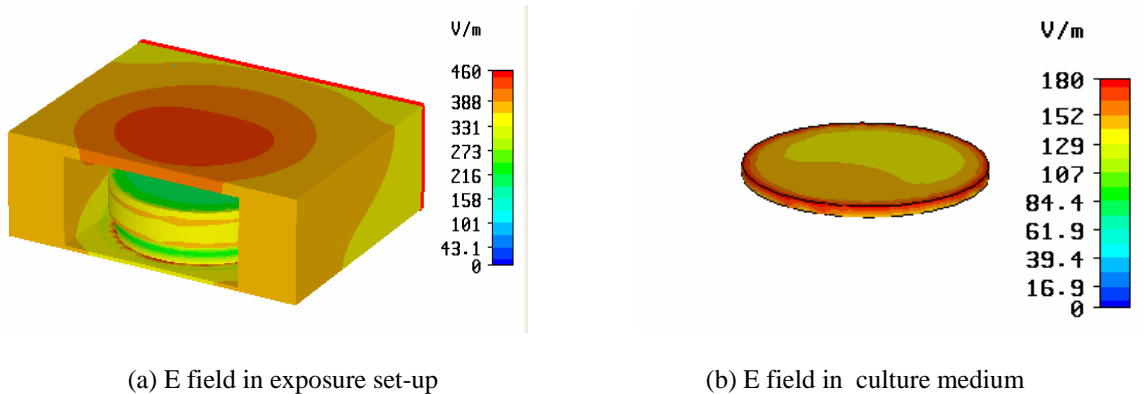

Fig.2 - 3D scalar representation of the electric field inside the structure (peak values)

Figures 3 show the SAR distribution histogram inside the culture medium and a chromatic power loss density (PLD) distribution inside the cell cultures. The local spatial SAR values inside the cell culture as calculated from our numerical procedure previously described. The total average SAR calculated from these distributions is 0.1 W/kg .

Power Loss Density is supplied by MWS and it is related to the electromagnetic power locally delivered into the sample. PLD is described by

$$PLD = \frac{d}{dt} \left(\frac{dU}{dV} \right) \quad (\text{Eq. 3})$$

where dU is the incremental energy dissipated in an a volume element dV . The PLD values are expressed in units of W/m^3 .

Fig. 3 -SAR and Power loss density distribution histogram in the culture medium

Figures from 4 to 7 show the most relevant results of the 4 disks case.

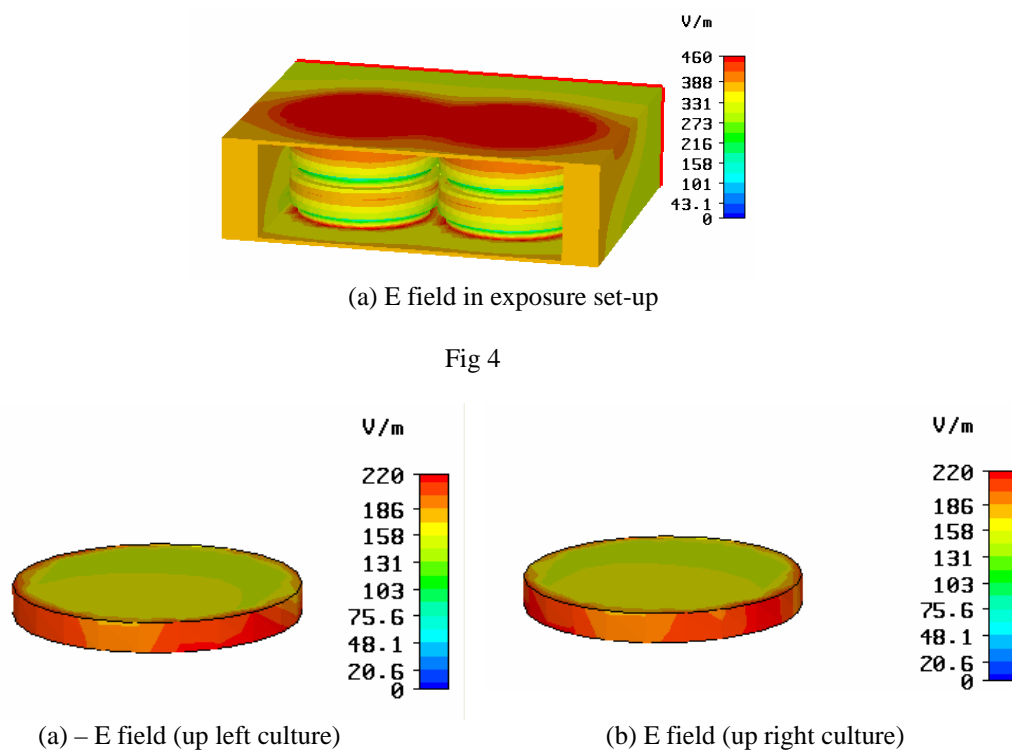

Fig 4

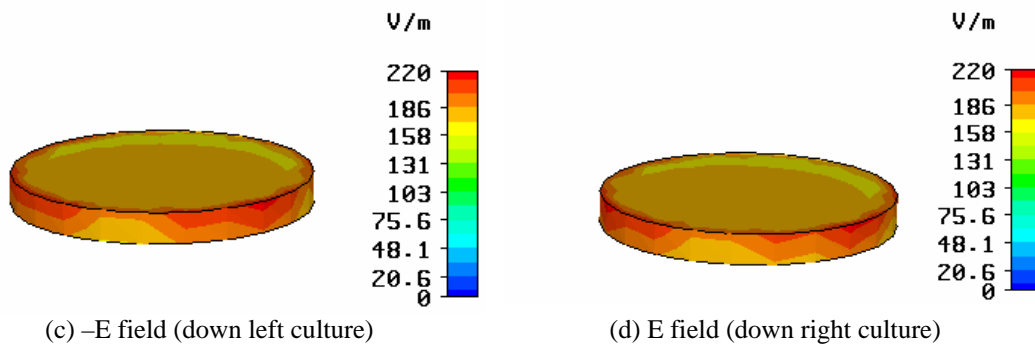

Fig 5

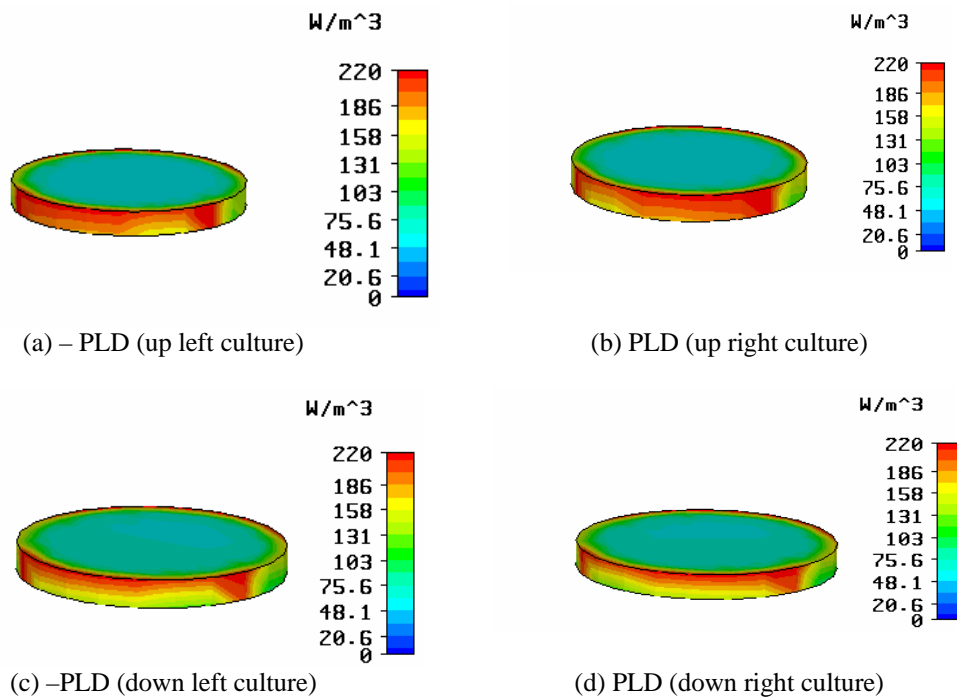

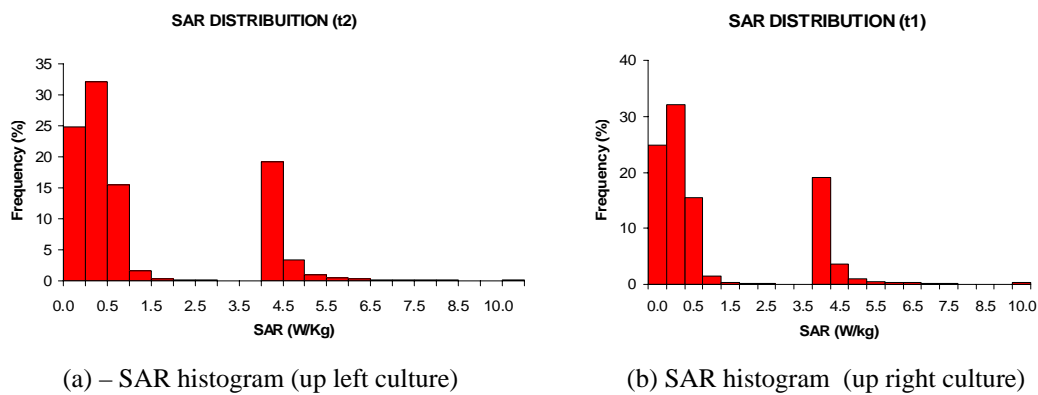

Fig 6

Fig 7

The total average SAR calculated from these distributions is:

CULTURE POSITION	SAR (W/kg)
up left	1.1
up right	1.1
down left	1.4
down right	1.4

1820 MHz

Figures from 8 to 11 show the most relevant results, as calculated by MWS at the frequency of 1820 MHz. At this frequency, there are some modes of field propagation. For each mode, we have calculated SAR contribution. Only first an second mode have a significant value. However, in our calculations, we have considered ten modes.

(a) E field in exposure set-up

Fig 10

Fig 11

The total average SAR calculated is 3.5 W/Kg for the left culture and the right culture

V Concluding Remarks

This study was carried out in the frame of activities referring to the European Project EMF-NET, Main Task 2. In fact our group is leader of the Work Package 12 focused on numerical calculations for occupational exposure.

Variability of the efficiency depending of the shape of terrain culture container (flask o dish), number of samples exposed at the same time, their positions, has been investigated.

Separately, for the various numerical calculations performed, the results can be summarized as follows:

- 900 MHz average SAR and distribution depend on quantity of culture medium (3 o 5 ml) and depend on number of culture exposed.
- 900 MHz average SAR and distribution depend on positions of the culture medium
- 1820 MHz average SAR doesn't depend on positions, because we have a symmetry in our set up.
- All simulations show that the spatial distribution of SAR inside each sample is not homogeneous, and local SAR values may be highly variable

Acknowledgments

The authors would like to thank Vincenzo Brugaletta for his precious support in experimental characterization of the exposure set up.

EFFECT OF SIGNAL MODULATION ON THE LINEAR RESPONSE OF ELECTRIC FIELD PROBES USED TO DETERMINE SPECIFIC ABSORPTION RATE

BENJAMIN LOADER, DANIEL BOWNDS.

NATIONAL PHYSICAL LABORATORY,
HAMPTON ROAD, TEDDINGTON MIDDLESEX, UK, TW11 0LW

Abstract

Electric field probes used to assess the specific absorption rate (SAR) of energy in human tissues due to radio transmitters are largely based on diode detectors. To determine the accuracy of SAR measurements, it is necessary to characterise the effect of the signal modulation on the linear response of these probes. This paper describes the system developed at the National Physical Laboratory to assess the linearity of SAR probes to different signal modulations, and gives results for four commercially available SAR probes. There was a wide variation in the linearity of the probes to pulse modulated signals, and this highlights the need to assess the linearity to the signal modulation to be measured. The results show that the tests in the IEEE 1528-2003 [1] give a conservative estimate for the linearity error in most cases.

Introduction

SAR is the specific absorption rate of radio frequency energy in a material and has the unit watts per kilogram. SAR forms part of the basic restriction limiting exposure of humans to radio-frequency fields over the frequency range 100 kHz to 10 GHz. The SAR resulting from the use of mobile radio transmitters is assessed by measuring the electric field in a liquid phantom that approximates the electrical properties of the biological material of interest. For a dielectric, SAR is then calculated by

$$SAR = \frac{E^2 \sigma}{\rho} \quad (1)$$

where E is the electric field in the liquid, σ its conductivity and ρ its density. The electric field probes used to assess SAR contain three orthogonal electric field sensors, and these commonly use Schottky diode detectors. Below the diode compression point the output voltage from the diode is proportional to the average power during the measurement (square law region). At high powers the output voltage is proportional to the r.m.s voltage during the measurement period (linear region). There is a transition region between the linear and square law region. Since the diodes are operated beyond the square law region, the output voltage (V) must be corrected to obtain a linear response (V_{LIN}), using

$$V_{LIN} = V \left(1 + \frac{V}{DCP} \right) \quad (2)$$

where DCP is the diode compression point. For pulse-modulated signals, the sample rate of the probe may be too slow to correctly sample the modulation, and in this case the V_{LIN} is obtained using

$$V_{LIN} = V \left(1 + \frac{CF \times V}{DCP} \right) \quad (3)$$

where CF is the crest factor of the signal. Linearity is defined as the maximum deviation over the measurement range of the measured quantity from the closest linear reference curve defined over a given interval [2]. The linearity of each sensor in the probe must be assessed to determine the uncertainty for SAR measurements. This paper describes the system developed at NPL for testing the linearity of SAR probes, and gives the measurement results for probes from three manufacturers to a range of communications signals.

Description of the measurement system

Linearity is measured by placing the sensor in an electric field and recording the diode output voltage as a function of input power to the system used to generate the field. This can be done with the sensor in air or liquid, but air is preferable since the conductivity of liquids will change with temperature, introducing non-linearity to the field generating system. Figure 1 shows a schematic of the system used. The probe is placed into IEC-R22 (UK WG8) waveguide through an aperture in the broad-wall with its axis at an angle of 54.7° to the axis of the waveguide, so that rotation of the probe about its axis allows each sensor in turn to be aligned with the polarisation of the field. This is necessary to avoid over-range errors occurring. The signals were generated using an Agilent ESG vector signal generator, which can produce a wide range of communications signals. A 5 W low noise linear amplifier allowed sensors to be tested up to a sensor output voltage that is equivalent to 100 Wkg^{-1} .

EFFECT OF SIGNAL MODULATION ON THE LINEAR RESPONSE OF ELECTRIC FIELD PROBES USED TO DETERMINE SAR.

A power sensor monitors the input power to the system via a high directivity coupler and step attenuator. The step attenuator was adjusted to keep the burst average power readings in the range -20 dBm to 0 dBm, as this limits the uncertainty due to the linearity of the power sensor. Note that changing the attenuation step does not alter the power transfer between the signal generator and the waveguide, and this is an important requirement for such a system.

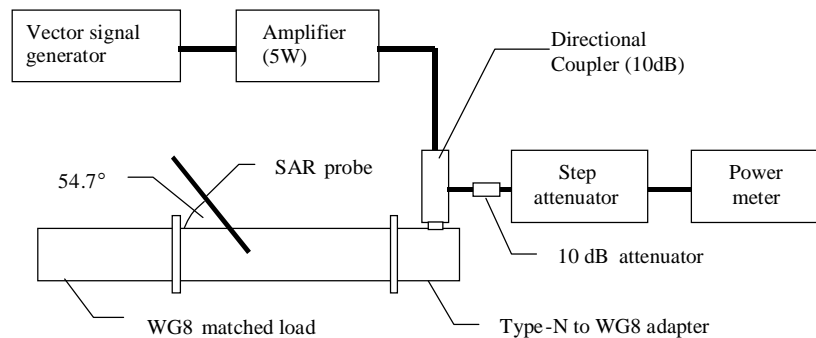

Figure 1: Schematic of linearity measurement system.

The linearity measurements were made at 1800 MHz. Table 1 lists the modulation frequency and crest factor for the signals used. UMTS 1 has a single carrier (5 MHz bandwidth), and UMTS 4 has four carriers (20 MHz bandwidth). Pulse 1 and Pulse 2 correspond to the linearity tests specified in [1].

Table 1. Signal characteristics

Signal type	Crest factor	Modulation frequency
CW	1	0 Hz
GSM	8	217 Hz
DECT	12	100 Hz
TETRA	4	17.6 Hz
Bluetooth	3.25	($625\mu\text{s}$ per slot)
WCDMA-1	1	0 Hz
WCDMA-4	1	0 Hz
Pulse 1	10	11 Hz
Pulse 2	25	1 kHz

Measurement results

The linearity of the probes was measured for peak SAR readings over the range 0.02 Wkg^{-1} to 100 Wkg^{-1} . Table 2 gives the maximum linearity error of the probes over this range. Figures 2 to 5 show the SAR reading against the ratio of average input power to the system. All of the probes over-read at high SAR levels when measuring pulse-modulated signals. The extent of the linearity error varies considerable between probes from different manufacturers. The linearity error for UMTS signals is similar to that for CW signals. Table 3 gives the maximum change in the relative sensitivity of the three sensors in each probe over the range 0.02 Wkg^{-1} to 100 Wkg^{-1} . This corresponds to the change in isotropy due to differences in linearity of the three sensors in the probe.

Table 2: Linearity over the peak SAR range 0.02 Wkg^{-1} to 100 Wkg^{-1} .

Signal type	Maximum linearity error (\pm dB)				
	Power sensor	Probe A	Probe B ¹	Probe C	Probe D

Pulse 1	0.28	0.69	0.33	0.94
Pulse 2	0.14	0.44	2.53	1.21

Conclusions

The linearity performance of four commercially available probes for measuring SAR was tested for a variety of communications signals over the range 0.02 Wkg^{-1} to 100 Wkg^{-1} . The linearity performance of the probes to CW signals and UMTS signals was found to be good. The low-level detection limit of one probe was limited to around 0.05 Wkg^{-1} . For pulse-modulated signals, the equation used to compensate for diode compression (Eq 3) was found to cause the probes to over-read at high peak SAR levels. The extent of this error varied considerably between the probes tested. For one probe, this correction did not give a linear response for pulse-modulated signals. Differences between the linear responses of the three sensors in the probes were also observed. It is therefore essential to characterise the linear performance of SAR probes to determine the measurement uncertainty. Each sensor should be tested separately, as differences in linear response between the sensors change the isotropy of the probe. In most cases, the tests specified in the [1] gives a conservative estimate for the linearity error for the range of pulse modulation schemes, but will over-estimate the measurement uncertainty for many real signals. Ideally, the linearity should be tested to the actual signal modulation to be measured.

Abstract

Acute effect of electromagnetic fields (EMFs) and induction of genes, with no thermal stress, have been reported but remain controversial. In previous studies we have found neuronal activation markers (c-fos) in the brain of rats pre-treated with subconvulsive doses of picrotoxin, after 2hs exposure to 900 MHz GSM radiation, at intensities similar to those emitted by mobile phones. In this study we analyzed in 50 adult male Sprague-Dawley rats the time course effects of induction of c-fos immunochemical testing of relevant anatomical areas with acute experimentally model induced by picrotoxin, after 60 minutes, 24 hours and 3 days of exposure to EMF radiation. C-Fos positives cells were counted in cortical and hippocampal areas, using a morphometric software, having expressed counts per field as means \pm s.e m.. 60 m and 24 hs after the radiation (AR), the c-Fos positive cells were increase on cortical and hippocampal areas; after 3 days the counts were similar in the same areas of the exposed–and–treated and non–exposed–and–treated animals. After 3 days, none of them showed differences. The time course of the effects after the GSM radiation on the CNS showed to be recovered after 3 days.

1. Introduction

The modulation of gene expression can be initiated by external events, acting through intracellular signalling pathways triggers changes in differentiation of cells, cell growth and programmed cell death. It

is well know that the induction and up-regulation of immediate-early genes (IEGs) precede degenerative process of central nervous system (CNS). Induction of c-fos has been associated with cellular injury and even cellular death (1, 2) c-fos is also easily induced under non-pathogenic environmental conditions and can be used as a sensitive marker of neuronal activation (3, 4). The expression of genes called proto-oncogenes can be increased by tumor-promoting agents, ultraviolet radiation and X-rays.

In relation with gene activation by exposure to non-ionizing radiofrequency electromagnetic radiation on CNS is controversial topic that normally it is explain normally by thermal influence. The results of studies of gene expression in mammals have been variable and generally negative (5). Studies of changes in the expression of the early response gen c-fos (6, 7, 8, 9) in the brain of rats and mice exposed to RF radiation and in vitro exposure (10,11) generally find no effects following at thermally insignificant levels. In any case, c-fos expression is known to increase enter sham and exposure animals of the expression levels proto-oncogene c-fos after exposure to RF and suggest the acute genomic response detected was due to immobilisation (12) of an animal or to increase simply as a result of stress (13). In previous study in rats that have been made seizure-prone by subconvulsive doses of picrotoxin, GSM radiation can trigger seizures and induce changes in cerebral activity reflected by high levels of c-Fos-positive neurons in certain brain areas (14). The brain tissue of seizure proneness can be especially sensitive to the effects of mobile-phone type radiation (15). In this paper the time course of the effects of radiation were evaluated by immunochemical testing of relevant brain areas for a marker of neuronal activation c-Fos expression at 60m 24 hs and 3 days after 2h of GSM-modulated 900 MHz radiation at intensity similar to that emitted by mobile phones.

2. Material and Methods

2.1. Animals and experimental procedure

72 adult male Sprague-Dawley rats weighing 230-270 g were housed during exposure under standard environmental conditions (12:12 h light/dark cycle, 22°C) with food and water available *ad libitum*. Twelve groups of eight rats were given the following treatments:

EXPERIMENTAL GROUPS	
Group 1:	Picrotoxin Treated (PT)+ irradiated (IR) studied to 60m
Group 2:	PT+ Non-Irradiated (NIR) studied to 60m
Group 3:	PT+ IR studied to 24hs
Group 4:	PT+ NIR studied to 24hs
Group 5	PT+ IR studied to 3 ds
Group 6	PT+ NIR studied to 3ds
Group 7	Non-Treated with Picrotoxin (NTP) + IR studied to 60m
Group 8	NTP + NIR studied to 60m
Group 9	NTP + IR studied to 24hs
Group 10	NTP + NIR studied to 24hs
Group 11	NTP + IR studied to 3 ds
Group 12	NTP + NIR studied to 3 ds

Table 1. This table showed experimental groups used in this experiment

Immediately following intraperitoneal administration of 2 mg/kg of picrotoxin (Sigma), used in groups 1-6, each animal was immobilized in a methacrylate tube and placed in a 150×46×70 cm³ radiation cage that had previously been calibrated to enable measurement of the radiation absorbed by the animal.

C-FOS EXPRESSION ON BRAIN AFTER ACUTE EXPOSURE TO 900 MHz GSM RADIATION OF PICROTOXIN MODEL OF EPILEPTIC RATS IS RECOVERING AFTER 3 DAYS

2.2. Determination of exposure

Animals belonging to groups 1 and 4 (2 and 5) were irradiated with GSM-modulated (non-modulated) 900 MHz radiation, and the power absorbed by the animal was correspondingly determined (see [14]). The irradiation power level ± 1000 MW, was chosen to be somewhat lower than the average power radiated by a GSM mobile phone. In the metallic cage all the animals were videotaped to record their behaviours while radiated; after 2 h they were removed from the cage and sedated with pentobarbital to transfer them to the histochemistry laboratory. In the radiation cage, the experimental animal in its methacrylate tube was located between a radiating antenna and a receiving antenna with its head at an electromagnetic field maximum (as calculated by finite-difference time domain (FDTD) calculations [16] for the cage plus radiating antenna set up).

2.3. Immunohistochemistry, quantification and statistical analysis of immunohistochemical findings

Approximately 1 h after removal from the radiation cage, the rats were given an overdose of pentobarbital, as said above, and prefixed by transcardial perfusion with physiological saline followed by formaldehyde in phosphate buffer (pH 7.4). Their brains were immediately removed and processed in sections of 40 μ . The free-floating sections were used for polyclonal sheep anti-Fos antibody immunochemistry tests (from Cambridge Research Biochemicals, Billingham, UK).

For each rat, c-Fos positivity was evaluated in cerebral cortex (frontal motor, parietal motor, piriform olfactory and entorhinal olfactory areas), in hippocampal structures (dentate gyrus, CA1 and CA3). For each area, three or four sections were examined. c-Fos-positive cells were counted in a 0.30 mm² field magnified 20 \times . Counts per field were reported for each group of rats as means \pm SEMs. The significance of between-group differences was estimated by two-way analysis of variance (*picROTOXIN status*: PT vs NTP \times *radiation status*: IGSM vs INM vs NI). *Post hoc* comparisons were made using Scheffé-type tests. Differences with $p > 0.05$ were considered not to be statistically significant.

3. Results and Discussion

3.1. SAR Results

The parameters of radiation absorbed power, incident power, for the calculus of average SAR_{exp}, Peak SAR values calculated for picROTOXIN-treated and untreated irradiated rats are listed in Table 1. Every values are lower thermal level (5 W/kg)

3.2. Morphological Results

In picrotoxin-treated animals, c-Fos-positive neurons appeared systematically in the thalamus and cortical areas, and some animals also showed more-or less scattered c-Fos positivity in the hippocampus, amygdale, or putamen-caudate complex, and/or in hypothalamic and pontomesencephalic nuclei c-Fos-positive neuron counts.

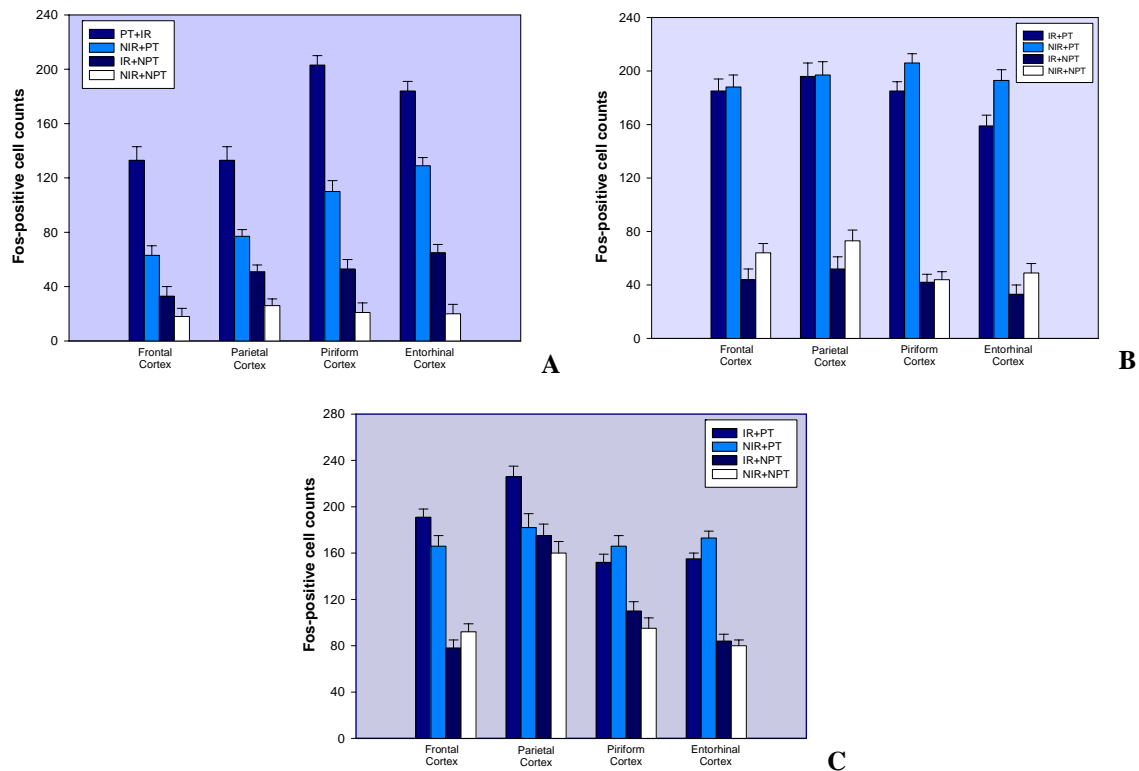

Figure 1. C-fos-positive cell counts in the frontal, parietal, piriform and entorhinal cortex (A) 60 minutes (B) 24 hours (C) 3 days after irradiation. (means of seven or eight rat groups; whiskers indicate SEMs).

3.2.1. Cortical Areas:

- Sixty minutes after radiation neuron counts in irradiated picrotoxin-treated rats were almost double those found in non-irradiated picrotoxin-treated rats. In rats without picrotoxin treatment, counts were lower than in picrotoxin-treated animals and may were in relation with cortical area. In almost all the areas examined analysis of variance showed that both picrotoxin and radiation had statistically significant effects on counts, and that the effect of each was significantly modified by the other.

Irradiated picrotoxin-treated animals had significantly higher counts than non-irradiated picrotoxin-treated animals in both the frontal cortex ($p < 0.001$) and the parietal cortex ($p < 0.004$). There were no significant differences for counts in frontal cortex but in parietal cortex we found significant differences ($p < 0.05$) between irradiated and non-irradiated rats that had not received picrotoxin. In the piriform cortex there is statistically significant difference in picrotoxin-treated irradiated and non irradiated ($p < 0.001$) and non treated irradiated and non irradiated animals ($p < 0.003$), in this area there is important interaction between radiation and treatment ($p = 0.002$). In entorhinal cortex did radiation per se have a statistically significant influence on counts ($p < 0.001$) and in this area it significantly modified the effect of picrotoxin ($p < 0.01$) but there is not a statistically significant interaction between both variables; In both areas there was a statistically significant difference in counts between irradiated and non-irradiated rats that had not received picrotoxin ($p < 0.05$).

Twenty-four hours after radiation neuron counts in irradiated picrotoxin-treated rats values were similar found in non-irradiated picrotoxin-treated rats. In cortical areas examined analysis of variance showed that picrotoxin had statistically significant effects on neuron counts. However both variables picrotoxin and radiation had statistically significant effects on counts alone in Entorhinal cortex ($p < 0.001$). In neither the frontal, parietal and piriform cortex did radiation per se have a statistically significant influence on counts, but in this areas the

C-FOS EXPRESSION ON BRAIN AFTER ACUTE EXPOSURE TO 900 MHz GSM RADIATION

OF PICROTOXIN MODEL OF EPILEPTIC RATS IS RECOVERING AFTER 3 DAYS

counts it significantly modified for the effect of picrotoxin. In neither cortical area was there a statistically significant difference in counts between irradiated and non-irradiated rats that had not received picrotoxin.

Three days after radiation in cortical areas there are a statistically significant effects on counts in relation with treatment picrotoxin but the statistically significant interaction effects between radiation x picrotoxin it happen on frontal cortex alone. C-fos positive neurons in irradiated-treated rats showed statistically significant difference in non-irradiated picrotoxin-treated rats on frontal ($p < 0.026$) and parietal ($p < 0.05$) cortex. In neither cortical areas there were a statistically significant difference in counts between irradiated and non-irradiated rats that had not received picrotoxin.

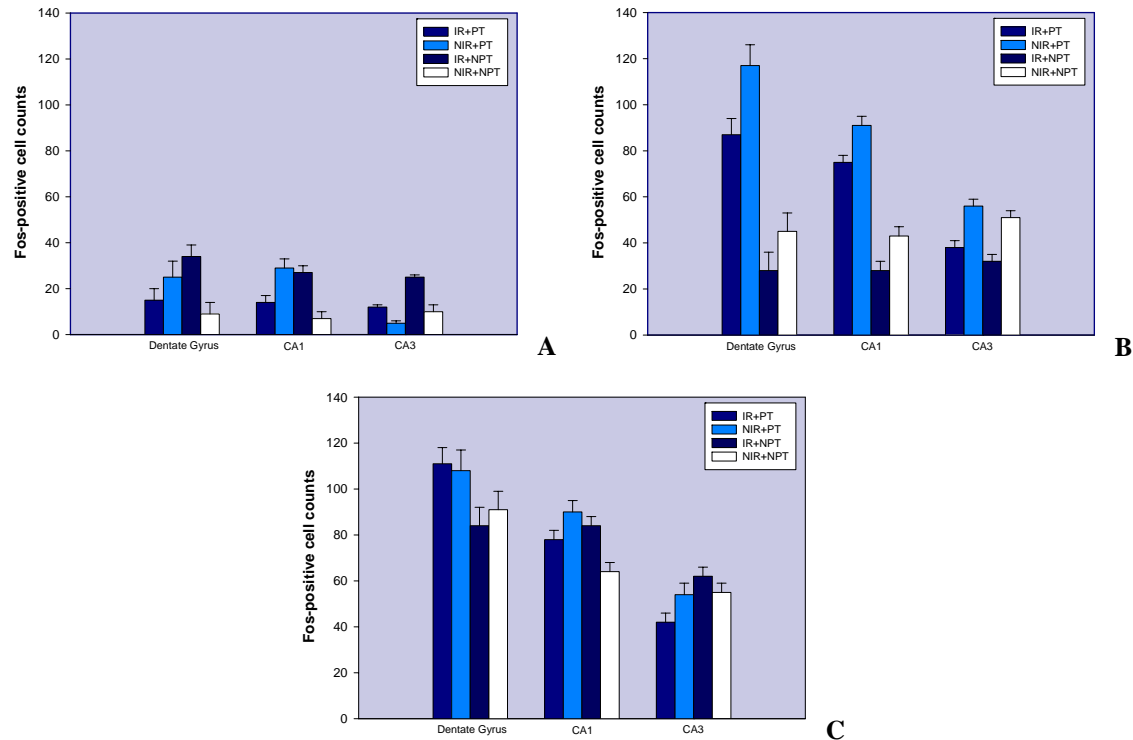

Figure 2. C-fos-positive cell counts in Gyrus dentate, CA1 and CA3 in Hippocampal areas (A) 60 minutes (B) 24 hours (C) 3 days after irradiation. (means of seven or eight rat groups; whiskers indicate SEMs).

3.2.2. Hippocampal Areas:

-Sixty minutes after radiation neuron counts in hippocampal areas showed the highest levels c-Fos in rats without picrotoxin treatment and irradiated. The two way analysis of variance showed that there is a statistically significant interaction between radiation and treatment in hippocampal areas and generally a major effect of radiation in untreated animals. In Gyrus dentate untreated and radiated animals showed significance differences with treated and radiated animals ($p < 0.013$) and untreated and non radiated animals ($p < 0.002$). C-Fos positive neuron counts in non picrotoxin treated and irradiated animals had statistically significant difference with picrotoxin treated and irradiated animals in CA1 ($p < 0.009$) and CA3 ($p < 0.013$). Irradiated and untreated animals and non-irradiated and untreated animals showed significance differences in both areas CA1 ($p < 0.001$) and CA3 ($p < 0.001$). Treated animal irradiated and non irradiated showed significant differences in CA1 alone ($p < 0.012$).

- Twenty-four hours after radiation neuron counts in the most animals unirradiated showed higher levels of c-fos positives neurons than irradiated animals. The same way picrotoxin treatment animals showed important levels in the counts neurons respect to animals without treatment. Non-irradiated picrotoxin-treated animals had significantly higher counts than irradiated picrotoxin-treated animals in GD, CA1 and CA3 ($p < 0.05$, $p < 0.05$, $p < 0.001$). Non irradiated animals without picrotoxin showed significance differences with irradiated animals in three cortical areas.

-Three days after radiation disappear the major differences in the counts in picrotoxin treated and irradiated animals and non picrotoxin treated and non-irradiated animals except in CA3 area where there is a significance differences in counts enter two groups ($p < 0.05$). The animals without picrotoxin treatment showed significant differences in irradiated and unirradiated animals in CA1 hippocampal area alone.

3.3. Discussion

We have studied the time course of effects of RF radiation on the CNS in two relevant anatomical areas: cerebral cortex and hippocampal areas. Within the CNS, the cerebral cortex is the part of the brain that is most vulnerable to the electromagnetic field (EMF) [17] exposure as it is a peripheral anatomical structure that received most of SAR of microwave radiation at non thermal levels (see table). However, a very low level of radiation may produce effects due to the vulnerability of cerebral cortex, altering the activity of the nervous system [18]. Hippocampal areas are in the middle of the brain and the low level SAR did not explain the direct effect of GSM radiation in this area. The radiation seems to act as a periodic peripheral stimulus that increases the vulnerability of neuronal circuits that, in the case of GABA-ergic circuits, have already been weakened by picrotoxin [14]. Sixty minutes after radiation there is high expression of c-Fos in cortical areas. Neuronal changes are not persistent and 24 hs after irradiation both groups, picrotoxin-treated rat irradiated and picrotoxin-treated and non radiated, had similar levels. Finally 3days after irradiation there was a compensation in most of the groups. The progressive time course recovering of c-fos levels in this acute model of seizure-proneness indicate no altered functionally physiological normal mechanism after acute radiation.

4. Conclusions

The time course of the effects after the GSM radiation in rats that have been treated by subconvulsive doses of picrotoxin showed induced changes in cerebral activity. These are reflected by high levels of c-Fos-positive neurons in certain brain areas after 60m. The differences between the irradiated and non irradiated groups are shown to be minor after 24 hs from radiation and finally they be recovered after 3 days.

Abstract

Rat thyroid gland was exposed in vivo to 2.450 MHz microwave fields using a commercial set up (GTEM). Heat shock protein Hsp90 is constitutively expressed in most cells under normal physiological conditions and is induced in cells upon cellular stress. The purpose of this work is to explore the expression of chaperone Hsp-90 as a biological marker that determines the sensitivity of thyroid gland to whether acute or repeated microwave exposures.

Twenty-six female Sprague-Dawley rats were studied with an irradiating microwave experimental system subject to: 1) 30 minutes acute exposure to whether 1,5 or 3,0 W and 2) Repeated exposure of 30 minutes per day during 10 days to 3,0 W. Rats were perfused with 4% paraformaldehyde, and thyroid gland removed 90 min and 24 hours post-exposure. Finally the thyroid glands were studied with histochemistry techniques: Hematoxylin-Eosin and immunocytochemical analysis of Hsp90

These results suggest that microwave radiation provokes a stress stimulus for thyroid gland with both thermal and non-thermal mechanisms. In acute exposures they showed response to functional activity changes, but with chronic exposure the physiological mechanism of the gland suffered a certain degree of adaptation to this type of stress.

1. Introduction

The heat shock proteins (Hsps) are a cytoprotective cellular system which has different physiologic functions for homeostatic cellular balance and in response to cellular stress. Hsps have been shown to function in protein maturation events such as protein folding, unfolding and translocation across membranes [1] [2]. There are two cytoplasmic isoforms mains: Hsp90 α (inducible form/major form) and Hsp90 β (constitutive form/ minor form) [3][4].

Hsp90 is an abundant and highly conserved molecular chaperone that is essential for viability in eukaryotes [5], comprises as much as 1%-2% of total cellular protein under basal conditions and increase to 4%-6% of cellular

proteins under stress [4]. Therefore, it is constitutively expressed in most cells under normal physiological conditions and is induced in cells upon exposure to elevated temperatures or other forms of cellular stress [6] as hypoxic/anoxic injury, radiations, heavy metals, viral infections, drugs ... Then Hsp90 is a main functional component of an important cytosol chaperone complex, and is involved in different cellular processes, such as cell proliferation, differentiation and apoptosis. It is also associated with various cellular proteins such as steroid-hormone receptors, aryl hydrocarbon receptor, MyoD, oncogen tyrosine kinases, haem-regulated aukariotic initiation factor 2 α kinase, casein kinase II, actin and tubulin [7]. Hsp90 expression is higher in proliferative cellular process than in normal tissues [8] and allow tumor cells to tolerate alterations that would be lethal.

A lot of years before ionizing radiation has been proven to cause genetic damage, which can lead to cancer and thyroid gland is one of the organs most sensitive to radiation [9][10]. In the last years the investigation of anti-cancer therapy is direct to specific proteins as Hsp90 [11][12][13].

Heat shock protein is released after exposure to microwave at levels causing, or not, heating [14][15]. And thyroid gland function change in response to environmental temperature and can be directly stimulated by microwave heating changed the activity [15].

Although non-ionizing radiation like microwaves have not been established as a cancer-causing agent, we like to explore the expression of chaperone, Hsp90 as a biological marker that determines the sensitivity of thyroid gland to whether acute or repeated microwave exposures. And we like to check if existed differences between thyroid gland exposed to microwaves and non exposed (controls).

2. Material and Methods

2.1. Animal exposure

Twenty-six female Sprague-Dawley rats, weighting between 168,7 and 248,5 gr. were exposed in vivo to 2.450 MHz microwave fields using a commercial set up GTEM 250: twenty-two rats were exposed during 30 minutes one day, acute exposure to 1,5 or 3,0 W and four rats were exposed during 30 minutes/day for 10 days, chronic exposure to 3,0 W. Radiation was direct to left front leg. During exposure, rats were housed in transparent cylindrical perspex jigs that did not allow them to move.

GROUP	TIME EXPOSURE -MICROWAVE POWER - PERFUSION		
1	EXPOSURE 30',	P= 1,5 w ,	PERFUSION 90'
2	EXPOSURE 30',	P= 1,5 w ,	PERFUSION 24 h
3	EXPOSURE 30',	P= 3 w,	PERFUSION 90'
4	EXPOSURE 30',	P= 3 w,	PERFUSION 24 h
5	EXPOSURE 30'/10 days, P=3 W,		PERFUSION 10 d

TABLE 1. Exposure groups relative to time of exposure, microwave power applied and time elapsed until perfusion with 4% paraformaldehyde.

2.2. Tissue processed

Rats were anesthetized with dose of pentobarbital 40 mg/Kg and sacrificed 90 minutes or 24 hours after exposure. Were perfused with 4% paraformaldehyde in phosphate buffer during 20 minutes through transcardiac cannula and thyroid glands removed 90 minutes and 24 hours post-exposure and were introduced in post-fixed (10% paraformaldehyde) during 12-24 hours.

The tissues were passed for different alcohols for dehydrate (OH 70° one hour, OH 96° two hours, OH 100° two hours, and finally Toluol two hours), following paraffin embedding during six hours and 4 μ sections were taken for Hematoxylin-Eosin and immunocytochemical analysis of Hsp90.

The same process was realized regarding to control groups.

All tissues were observed with optical microscope for different magnification (20x, 40x and 100x) of the constitutive structures and a quantitative model was established between exposure rats and control rats.

EXPOSURE OF RAT THYROID GLAND TO 2450 MHZ MICROWAVE INDUCES CHANGES IN EXPRESSION OF HSP-90

3. Morphological Results

In thyroid glands the structures studied were: connective tissue of capsular membrane; interlobule connective tissue; follicular cell and parafollicular cell.

In acute microwave exposure of thyroid glands, Hsp90 proteins expressed increase at all structures respect to controls and this increase was greater with high potency. But this increase was lesser in thyroid removed 24 hours respect to 90 minutes post-exposure. In chronic microwave exposure we observed a decreased of Hsp90 expression respect to the control in all structures studied.

In table 2 we can see the representation of data. Results concerning SAR will be presented in the poster.

ACUTE EXPOSURE 1,5 W		ACUTE EXPOSURE 3,0 W		CHRONIC EXPOSURE 3,0 W	
PERFUSION		PERFUSION		PERFUSION	
90 minutes	24 hours	90 minutes	24 hours	90 minutes	
+++	+++	+++	+	+	CONNECTIVE TISSUE CAPSULAR MEMBRANE
++	++	+++	++	+	CONNECTIVE TISSUE INTERLOBULE
+	+	++	+	-	FOLLICULAR CELL
+	+	++	+	-	PARAFOLLICULAR CELL

TABLE 2. In this table we group the results about all types of radiation (acute and chronic) power, exposure time and perfusion time after radiation.

- - Without expression
- + Poor expression
- ++ Moderate expression
- +++ High expression

The Hsp90 expression in different structures of thyroid gland respect corresponding controls:

- **Capsular membrane:** Hsp90 expression is high whether for 3.0W or 1.5W, for the animals sacrificed 90 minutes after exposure. But for animals sacrificed 24 hours after exposure there is a decrease in the Hsp90 expression, and such a decrease is more pronounced in animals exposed to 3.0W including expressed levels below the control group. For exposures chronics the Hsp90 expression were poor for all samples with respect to the control group.
- **Interlobule:** The levels Hsp90 expression are higher with 3.0W than with 1.5W for animals sacrificed 90 minutes after exposure. With 3.0W Hsp90 expression was higher than with 1.5W. But when animals were sacrificed 24 hours after exposure the expression is equal for both 1.5W and

3.0W. And for chronic exposed animals Hsp90 presented a decrease with respect to the control group with a poor expression at the same mode than capsular membrane.

- **Follicular cell:** Hsp90 expression was higher for groups exposed to 3.0W (moderate expression) than for groups exposed to 1.5W (poor expression), all of them sacrificed 90 minutes after exposure. The expression was very marked at the periphery follicular cells. 24 hours after exposure, to whether 3.0 W or 1.5W, a poor expression persisted (with respect to control group). And in the other hand in follicular cells of thyroid glands exposed with chronic radiation did not express Hsp90, while the control group presented a minimal expression.
- **Parafollicular cell:** The expression of these cells is similar to that of follicular cells. In thyroid gland removed 90 minutes after exposure, the group exposed to 3.0W presented a higher Hsp90 expression compared to the group exposed to 1.5W, respect to control group. When thyroid glands were removed 24 hours after exposure, Hsp90 expression was the same for two groups (3.0W and 1.5W). And in contrast to chronic exposure control (minimal expression of Hsp90) the chronic exposure group did not present Hsp90 expression.

PHOTOS

CONTROL ACUTE EX. (3.0W)

Figure 1. In thyroid glands exposed to acute radiation, the HSP90 expression increase in cellular membrane and intracellular structures with respect to control.

CONTROL CHRONIC EX. (3.0W)

Figure 2. In thyroid glands exposed to chronic radiation, the HSP90 expression in chronic exposure is lower than in control.

4. Discussion

With these results we can observe that the use of microwave power at whether 1.5w or 3.0W stimulated Hsp90 production, compared to control groups, because this radiation constitutes a stressing factor for thyroid gland, in acute exposure. In chronic exposure Hsp90 expression decreased, perhaps due to adaptation of the cells to this type of stress. M. Brennan and colleagues observed the effects of body temperature during exercise training on myocardial, and they described that Hsp90 increases with exercise in cold run; and at the end of 9 weeks training Hsp90 levels were no longer significantly increased, which may indicate that a certain degree of adaptation to this type of stress occurs [17]. By contrast, in animals adapted to some stressor, such as anoxia, Hsp90 expression does increase after acute stress exposure; and in chronic exposure Hsp90 experiment a rapid increase. It is possible that such an increase in the expression of stress proteins is part of a rescue mechanism, triggered at the survival limit, similar to a behaviour observed in the experiment with the western painted turtle *Chrysemys picta belli*, which is the most anoxia-tolerant vertebrate known [18].

EXPOSURE OF RAT THYROID GLAND TO 2450 MHZ MICROWAVE INDUCES CHANGES IN EXPRESSION OF HSP-90

5. Conclusions

These results suggest that microwave radiation is a stressful stimulus for thyroid gland in acute exposure with power of 1.5 and 3.0 watts. Nevertheless, with chronic exposure the gland suffers a certain degree of adaptation to this type of stress revealed by the Hsp90 expression decrease.

Abstract

Microwave radiation can switch certain genes in response to stressful challenges to the cell. Heat shock protein 90 (HSP-90) are immediately expressed as marker of stress injury and play a protective role on central nervous system. Moreover, HSP-90 is preferentially expressed in neuronal cell populations in the unstressed mammalian brain. We explore the expression of molecular chaperone HSP-90 on brain neuronal circuits of rats using high-power microwaves with no-thermal or thermal radiation.

Twenty adult males Sprague-Dawley were exposure to radiation (1.5 and 3 W at 2.45 GHz) using a commercial set up GTEM-250. (1) In acute exposures during 30'; (2) Repeated acute exposures (30') during ten days. Control-rats were immobilized in set up considering the same elapse time but with no exposure to microwave.

Approximately 90' and 24 h after removal from the radiation cage, the rats were prefixed by transcardial perfusion saline followed by formaldehyde (4%). Their brains were cut with a vibrotome in transverse 40 µm sections. Finally, the sections were processed with blue toluidine and were tested with HSP-90 immunochemistry on hypothalamus, thalamus, hippocampus and cortical areas.

Acute exposure to microwave increases the HSP-90 expression in subregions of hypothalamus, thalamus, hippocampus and cortical areas; and these changes persist with repeated exposure.

1. Introduction

In the last years a great social and scientific concern has arisen for the possible adverse effects of the electromagnetic fields in the living organisms, in short of the radiofrequency, given the great technological advance of the last years, mainly in the field of the mobile telephones. However, already for many years that one comes applying the radiofrequency, in short the microwave, in the human being. A clear example is the medical-therapeutic application of high frequency radiation microwave (2,45 GHz)

MICROWAVE EXPOSURE OF RATS TO THERMAL AND NON-THERMAL 2450 MHz RADIATION PRODUCES CHANGES IN NEURONAL EXPRESSION OF HEAT SHOCK PROTEIN (HSP-90)

in processes osteoarticulars (diathermy for microwave) at different powers, usually between 25 and 200 watts (w). Microwave treatment is applying in humans directly over the anatomical treatment part about 15-30 minutes during 10-20 sessions. There is recently experimental evidence that the interaction of the radiofrequency with the living organism could produce effects not cause by heating biological tissue (D. Pomerai, 2003; E.Diem, 2005). There by, there are describe two types of biological effects: thermal and not thermal. Thermal effects make reference to secondary effects of energy deposited in the organism which cause an increase of temperature in the biological body and secondarily stimulates the thermoregulation mechanisms; and non-thermal effects are caused by the microwave radiation which does not increase the temperature in the organism (J. L. Franco and cols, 2006).

Heat shock proteins are constitutively expressed under normal conditions in cells and they intervene in a routine way in the metabolic processes essentials for the cell, like the “*novo*” proteins folding (D. Picard, 2002). But it is also known that under stressful conditions these proteins are overexpressed (induced HSP) to have a protective role in cells (D. S. Latchman, 2004), and even several studies showed that HSP synthesis is responsible for the protective effect of preconditioning by mild stressful stimuli (V. Amin et al, 1995). Recent studies have demonstrated than heat shock protein 90 (HSP-90) is expressed under physiologic conditions in more quantity in neural tissue that not neural (P. Gass, 1994; S. M. D’Souza and I. R. Brown, 1998), and that overexpression of HSP-90 plays an important role in the maintenance of the survival neuronal (G.S. Jeon and cols, 2004; R.G. Ahmed, 2005), for what we conclude that HSP-90 constitutes a biomarker that will help us to know the effects at level neuronal of different types of cellular stress, in this case of the radiation microwave.

The aim of this study was to explore the expression of molecular chaperone HSP-90 on brain neural circuits of rats, using whether thermal and non-thermal acute high-powered microwave (HPM) radiations (2,45 GHz) at 3.0 and 1.5 W respectively, and also after repeated-acute radiation exposure.

2. Material and Methods

2.1. Animals and Experimental Procedure

16 female Spragüe-Dawley rats were exposed to a HPM radiation (2.45 GHz) by using a GTEM250 commercial chamber. Rats were assigned to one of this two treatment groups: Acute and Chronic. “Acute group” rats were radiated, only one time, at 1.5 w or 3.0 w, for 30 minutes, and “Chronic group” rats were exposed to repeated acute HPM at 3.0 w for 30 minutes during 10 sessions (1 per/day) (see Table 1).

Table 1. Radiated Experimental Groups

Group	Microwave Power (watts)	Time Exposure (minuts)	Time Postradiation	Repeated Sesions (days)
Acute (n=16)	1,5 (n=8)	30	90 m	—
		30	24 h	—
	3 (n=8)	30	90 m	—
		30	24 h	—
Chronic (n=4)	3 (n=4)	30	90 m	10

The issuing field of the radiation was directed toward the upper left leg. Besides, control-rats were immobilized during 30 minutes similar that radiation animals, but not exposed to radiation, in set up the same time (see Table 2).

Table 2. Non Radiated Control Groups

Group	Time post-inmovilization	N
Control Acute	90 m	5
	24 h	5
Control Chronic	90 m, 10 days	4

2.2- Tissue Preparation and Immunohistochemistry

Rats were deeply anesthetized with pentobarbital sodium and then, they were perfused transcardially with heparinized physiological saline followed by a solution of 4% paraformaldehyde in fosfate buffer, 90 minutes (m) and 24 hours (h) postradiation in acute group, and 90 m post radiation in chronic group. Following, rats were sacrificed, their brains were immediately removed and cryoprotected in sucrose for

approximately 24 hours. Subsequently, brains were frozen and cut into 40 µ coronal sections using a cryostat. These sections were processed using immunohistochemical techniques for demonstrating HSP-90 expression.

Finally, we evaluated HSP-90 positivity under an optic microscope Nikon Eclipse E2000 in 12 selected encephalic anatomical areas which nomenclature are from Paxinos and Watson: Hypothalamus (nucleus periventricular, PV; nucleus paraventricular, Pa; Lateral of Hypothalamus, LH and nucleus Arcuate, Arc), Hippocampus (Dentate Gyrus, DG; CA1, CA2 and CA3) and Cortex (frontal, Fr; parietal, Parl; piriform, Pir and entorhinal, Ent). We compared acute and chronic radiated groups with their respective control-rats.

3. Results and Discussion

3.1 HSP-90 Expression in Acute 1.5 W Group

90 minutes after HPM exposure resulted in increases HSP-90 expression in all studies anatomical rat brain areas respect control, except PV of hypothalamus, where expression was similar to controls-rats. This expression still remained high after 24 hours microwave exposure in the same areas except in LH where the expression was similar to controls (see Table 3). HSP-90 expression was similar in hippocampus and cortex after 24 hours than after 90 minutes post radiation. Several studies have been observed that heat shock stress produced upregulation throughout the brain (Tynell M, 1993; Goldbaum O. & Ritchter-Landsberg, 2001), however, heat shock response depends on different factors, such as stress stimulus, and little is known about HSP-90 response to microwave at 2.45 GHz in the brain of rats, thereby we cannot compare our results.

3.2 HSP-90 Expression in Acute 3.0 W Group

HSP-90 expression in 90' postradiation group was greater than control-rats in subregions of hypothalamus (Pa and Arc) and hippocampus (CA1, CA2, CA3). The PV and LH expression were decrease and there were not different with controls in GD and cortex. After 24 hours, hsp-90 expression increase in more areas (nucleus arcuatus, hippocampus, and cortex), however, there were not significant changes in PV, Pa and LH (see Table 3).

Table 3. Expression of HSP-90 following exposure acute power (1.5 and 3 W) microwave radiations compared with control groups.				
Anatomical Areas	1.5 W		3.0 W	
	Post-irradiation time		Post-irradiation time	
	90 m	24 h	90 m	24h

MICROWAVE EXPOSURE OF RATS TO THERMAL AND NON-THERMAL 2450 MHz RADIATION PRODUCES CHANGES IN NEURONAL EXPRESSION OF HEAT SHOCK PROTEIN (HSP-90)

We observed that brain areas exposed to 3.0 W power microwave radiation are as much stimulated as brain areas exposed to 1.5 W; and HSP-90 expression at 3 W even was decreased with respect to 1.5 W acute group in some areas, such as hypothalamus and cortex.

3.3 HSP-90 Expression in Chronic Group

We observed that HSP-90 expression decreased in DG of hippocampus, hypothalamus (PV, Pa and LH) and piriform and entorhinal cortex (see Table 4). There were not differences in Arc, CA1, CA2, CA3 and frontal and parietal cortex.

Table 4. Expression of HSP-90 following repeated acute exposure to high-power microwave radiations (3 W, during 10 days) compare with controls.	
Anatomical Areas	
<i>Hypothalamus</i>	
PV	↓↓
Pa	↓
LH	↓↓
Arc	—
<i>Hippocampus</i>	
DG	↓
CA1	—
CA2	—
CA3	—
<i>Cortex</i>

Pir	↓
Ent	↓
PV, periventricular nucleus; Pa, paraventricular hypothalamic nucleus; LH, lateral hypothalamus; Arc, arcuate nucleus; DG, dentate gyrus; Fr, frontal cortex; Parl, parietal cortex; Pir, piriform cortex; Ent, entorhinal cortex.	

We noted that the less stimulated area in all the groups corresponds to hypothalamus, and even in chronic group the expression in this area spreads to diminish. Loones and cols. (2000) have shown that HSP90 is most abundant in hypothalamus, preoptic areas, pons and medulla in the central nervous system of unstressed mouse.

Both the SAR values and the morphological thermal-SAR results will be presented on the poster, at the Symposium.

4. Conclusions

Acute high power (1.5 and 3.0 Watts) 2.45 GHz microwave radiation produces an upregulation heat shock response in subregions of central nervous system. Moreover, we observe that HSP-90 expression decrease when the delivered power increases in animals that are subject to acute exposure. Nevertheless, the repeated acute exposure causes decrease of the HSP-90 expression in hypothalamus and limbic areas, whereas keeps unchanged (compared to control groups) in several cortex and hippocampal areas.

Abstract

Exposure evaluation to radiofrequency and microwave non-ionizing radiation of both general public and workers is considered an emerging sector in environmental and safety work surveys. Nevertheless, radars are typically rarely analyzed, due to difficulties in measuring such kind of source, but also inaccessibility or even secrecy of some installations.

Aim of this study was to analyze the emissions of a meteorological doppler radar, placed in the Province of Trento (North Italy), working in C band, with a wavelength of about 5 cm and nominal peak power of 250 kW.

The survey involved: i) electric field monitoring around the radar, to assess the general public and operators exposure, and ii) test measurements on radar functioning, such as evaluation of the antenna's radiation pattern.

In the first case measurements were performed with electric field probe and spectrum analyzer, while in the second case only with spectrum analyzer in far field conditions. The signal was characterized both in frequency domain, to analyze operating frequency and frequency stability, and time domain, to acquire radiation patterns in the principal planes as well as pulse duration and duty cycle.

The obtained results are compared to standard limits, with particular reference to the EU Directive 2004/40/CE.

Introduction

Starting from the 1980s radar networks have become extensively used in meteorology for determining the location of rain and storm activity. The radar under analysis is one of the North-Italian network and consists of a DSWR-2500C (EEC) pulsed-doppler radar, which means that it is not only capable of detecting target's location (bearing, range, and altitude), but also measuring its velocity. In particular, velocity is determined by transmitting many radar pulses towards each target (hydrometeor in this specific case) over a very short period of time, and thus measuring relative target movement between each pulse. The frequency in which the pulses are emitted are usually referred to as Pulse Repetition Frequency (PRF). The radar operates at 5.8 GHz (C-band), with a wavelength of 5.5 cm; its nominal peak power is 250 kW, thus guaranteeing a coverage range of about 120 km.

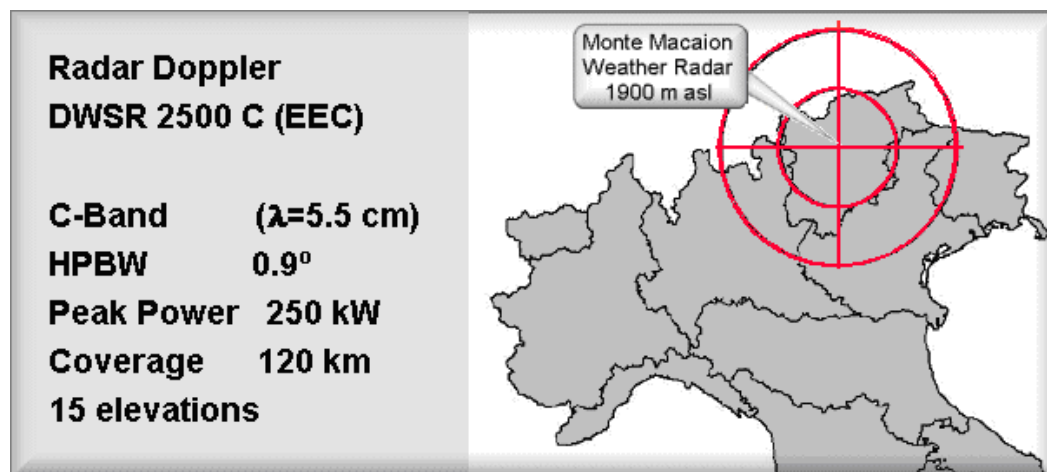

Figure 1: Location and main technical specifications of the weather radar system under analysis (Northern Italy).

The weather radar systems are generally designed and located to ensure that power densities that humans could be exposed to, fulfil the exposure limits. In order to assess this, measurements have to be carried out when the system is installed and operating in fully functioning conditions.

In particular, the two principal aspects investigated in this work were:

- the electric field values monitoring in the proximity of the radar (in near field conditions), in order to assess the exposure of both population and maintenance workers. Besides the radar personnel, exposed people could be only hikers, considering that in the area neither residential buildings nor commercial concerns are present.
- the measurement of the antenna's radiation pattern, being this latter crucial to predict the far field exposure. It is worth noting that the radar is located at a high altitude (1900 m a.s.l.), which permits a good extension of its horizons, otherwise limited by the mountainous orography. Therefore, the closest built-up areas are out of the radar's optical visibility, whilst those areas satisfying this condition are several kilometres far from the source, and at a significantly lower altitude.

In the first case, both the broadband electric field sensor and the spectrum analyser were used in proximity of the radar. Conversely, in the second case measurements were performed on a mountain 15 km south of the radar's location, since this ensured at the same time the fulfilling of the far field conditions (at a distance from the emitter larger than 700 meters), the good optical visibility, as well as a higher altitude (necessary for the characterisation of the antenna's lobe along the vertical direction). In this case only the spectrum analyser with the suitable antenna was used.

Afterwards, the results of the radioprotectional survey were compared to the limits provided by the EU Directive 2004/40/CE on workers' exposure to electromagnetic fields [1], to the thresholds reported by the ICNIRP [2] referred both to general public and workers, and also with the limits imposed by the national Italian law concerning general public exposure [3].

Site Description

The site housing the radar system lies on the top of a mountain (Monte Macaion, 1865.5 m a.s.l.; longitude WGS84: 11°12'32.6", latitude WGS84: 46°29'35.7"), characterised by a ridge gently descending towards west and by a rocky vertical front in east direction. The radar is mounted on a metallic tower 10 m high, with, at its bottom, two shelters housing the electronic equipment connected to the antenna. The radiating system consists of a 4.27 m diameter paraboloid antenna installed on a motorised pedestal, which enables orientations along whatever azimuth angles and elevations from -2° and 90°. Moreover, the antenna is covered by a 6.25 m diameter glass-reinforced plastic radome (Figure 2).

Figure 2:

The Monte Macaion summit, housing the weather radar. Measurement points 2 and 3 are also indicated.

In east direction with respect to the radar's tower there are some ruins and a redoubt, whose roof represented the highest measurement point of the area. Proceeding a few tens of meters in north-east direction, the terrain is

gently descending and without trees, forming a panoramic site rather frequented by hikers, especially during the summertime. About 350 m in 160° north direction there is another hill, at the same level of Monte Macaion, housing several broadcast antennas which contribute to the overall RF exposure level in this area.

Measurement points, instruments and technique

The measurement points for radioprotectional purposes were chosen at ground level and providing that optical visibility of the source was satisfied. In the absence of such a condition—even when the sight was obstructed only by leafy branch—a so considerable attenuation of the field was indeed registered, that exposure levels became insignificant from a radioprotectional point of view. The reason of such behaviour could be easily found in the highly absorptive character of high water content media in the microwaves frequency range.

Four different measurement points were chosen:

1. The radar equipment room, where personnel stands occasionally. The measurements were carried out with the radar in operating conditions, in order to assess possible dispersions from the cases containing the generation apparatuses.
2. The roof of the redoubt visible in Figure 2, as it is an interesting and comfortable place to stay for hikers, which also corresponds to the closest approaching point to the emission beam of the paraboloid antenna. During the measurements the most conservative conditions for the exposure were reproduced, by choosing an elevation of -2° and keeping an azimuth angle fixed along the receiving antenna direction. It is worth mentioning that such angle choices are not likely in normal operating conditions. In particular, the chosen elevation value produces images highly disturbed by orography and the fix azimuth angle is meaningless for meteorological purposes, even though manually selectable. In correspondence of this point the difference in height between the electric centres of the antennas (receiving antenna and radar) was 7 m, their distance was 30 m in 30° north direction, and the radar observation angle was +10°.
3. The panoramic site (see Figure 2) in north-east direction from the radar. In this case the difference in height between the electric centres of the antennas was 13 m, their distance was about 80 m in 40° north direction, and the radar observation angle was +9°.
4. The summit of the mountain Monte Roen, 14.9 km far from the radar. Its altitude is 2065.5 m a.s.l., that is 200 m higher than the Monte Macaion; its longitude WGS84 is 11°11'12.6", its latitude WGS84 46°21'41.8". The receiving antenna was placed 3 m above the ground, thus resulting in a difference in height of about 195 m between the electric centres of the antennas. The radar could see this point setting a theoretical azimuth value of 185.1° north with an elevation equals to +0.75°.

The measurements were performed by using:

- a spectrum analyser Agilent Technologies ESA-E4407B, which operates in the frequency range 100 Hz–26 GHz;
- a doubled ridge horn antenna EMCO 3115, linearly polarised and operating in the frequency range 1–18 GHz;
- a power density sensor General Microwave RAHAM (RAAdiation HAZard Meter), Model 495. It features a six minute power density averaging function which automatically computes and displays the average exposure measurement over the six minute period as required by safety standards;
- an isotropic E-field probe General Microwave Model 94, operating in the frequency range 200 kHz–40 GHz and characterised by a wide dynamic range of 46 dB (from 0.005 to 200 W/m², or correspondingly from 1.37 to 274 V/m).

Being the radar signal composed by a succession of pulses, each of which lasts about 1/1000 of the time occurring between one pulse and the successive, the linearity of the response of the broadband sensors was initially checked. This was performed at the ITC-first laboratory, before any measurement on site. The instruments used in this case were:

- a pulse generator (Philips PM5705) 0.1 Hz–10 MHz;
- a voltage variable attenuator (Mini Circuits ZFAS-15);
- a synthesised RF generator (HP8660C) from 10 kHz to 2600 MHz;
- a high power RF amplifier (PST-BHE, 500W);
- a biconical antenna (EMCO 3109);

In particular, the attenuator received the signal from the two generators (RF and pulse), mixing them into a new “composed” signal which was then amplified and used to feed the biconical antenna, placed in an anechoic chamber (Siemens-Matsushita). In this way, in the proximity of the antenna, pulses with E-field peak values of hundreds of V/m and a duty cycle typical of the radar (1/1000) were obtained. In these conditions, the satisfactory linearity of the sensor RAHAM 495 with its probe 94 was verified, at least up to values of about 10 V/m, corresponding to E peak values of 320 V/m. This led to the conclusion that, in the aforesaid E field range, the displayed value actually corresponded to the time-averaged field and the sensor was hence suitable for on-site radar signal measurements.

The electric field measurements for radioprotectational purposes were generally performed by the only use of the broadband sensor, with the exception of point 2, which was analysed also in narrow band with spectrum analyser and horn antenna. In correspondence of point 4 (far field) the only narrow band characterisation was instead performed.

While operating with the broadband sensor, it was placed at the three different heights (1.1, 1.5 and 1.9 m above the ground) prescribed by the Italian CEI 211-7 guide [4]. Considering the fact that the radar was remotely controlled, pointing the antenna towards the measurement point and keeping constant the signal emission conditions, the results obtained with the two operational modes ‘Normal’ (for direct reading of power density) and ‘Average’ (for computing the average power density over a six minute period) were equivalent. In fact, this assumption neglected the possible magnetron power fluctuations, but these were found to be insignificant with respect to those characteristic of the measurement point itself, such as the unpredictable signal scattering due to the foliage waving in the breeze. Consequently, the ‘Normal’ mode was used, which refreshed the power density values every 1.5 s.

The measurements with spectrum analyser were carried out in time domain (zero span), in peak detection mode and selecting a resolution bandwidth of 5 MHz, in order to filter as little as possible the impulsive nature of the signal. Furthermore, the chosen sweep time (20 μ s) was the shortest selectable for the acquired points number. The signal was acquired in max-hold mode, which provides the envelope of all the maxima observed during the acquisition time, so that the snapshot of each pulse was frozen on the display as soon as it appeared in the measurement time window.

The horn antenna was placed with its electric centre at 1.5 m above the ground, in conformity with the CEI 211-7 guide [4] prescriptions. The polarisation of the antenna was horizontal, like that of the radar. During the measurements, the neglectability of the vertical component of the signal was also assessed: while in optical visibility of the radar, it always remained 15–20 dB lower than the horizontal.

Finally, the measurements performed in correspondence of point 4 (Monte Roen, 14.9 km far from the radar) were carried out with the only use of the spectrum analyser, following the same set-up just described, with some variations/additions. In particular:

- the horn antenna was placed at the highest possible height (3 m) on the roof of an off-road vehicle, in order to minimise the contribution of signals scattered from the ground;
- measurements were carried out also in the frequency domain, setting a 10 MHz span, in order to characterise the magnetron frequency as well as the pulse duration;
- some measurements were devoted to the assessment of the PRF (Pulse Repetition Frequency), by using the same settings described before (zero span), but with longer sweep times (up to 10 ms);
- the radiation pattern measurements were performed with the same settings, but making use of much longer sweep times (up to 100 s), in order to cover the complete azimuth revolution time. Consequently, the number of acquired points per sweep was much higher than before (up to 3600 points), in order to obtain a good angular resolution;
- the radiation pattern in the vertical plane was determined in a similar way. In this case, the radar azimuth angle was set as that maximising the radiation in correspondence of the measurement point; afterwards, the radar was made scan vertically, covering an overall amplitude of 27° (from -1° to +26°).

Results

It is well known that regulations in general define different limit for general public and occupational exposure. Moreover, some of them refer explicitly to only one of these categories: either the general public (like for example the Italian law DPCM 8 July 2003 [3]) or the workers (like for example the European Directive 2004/40/EC [1]). Regarding the general population, both the Italian law and the ICNIRP [2] limits were taken into account in the present work. In the first case, the E-field limit imposed in the frequency range under analysis is 40 V/m, expressed as rms value, which must not be exceeded in any case. The same law, as a cautionary measure to protect against any possible long-term effects, adopts a more conservative ‘attention value’ of 6 V/m in correspondence of children’s playgrounds, residential dwellings, school premises and in general in those areas where people could stay for 4 hours or more per day, as well as in outdoor annexes that may be used as residential environments, such as balconies, terraces, courtyards, but excluding roof pavings. Therefore, this second limit was suitable only for residential buildings, far from the radar source. Both these values must be averaged over any six-minute period in an area equivalent to the vertical cross-section of the human body.

Yet while the Italian Law does not discriminate between pulsed and not-pulsed sources, the ICNIRP guide establishes a peak value limit for the pulse, which must not exceed—in the considered spectrum range—1000 times its average value in terms of density power (S). Another aspect, which is taken into account in the ICNIRP guide while is lacking in Italian regulation, concerns the safeguard from annoying auditory effects, possibly caused by a thermoelastic interaction in the auditory cortex of the brain [5, 6, 7]. In order to avoid the onset of such kind of effect, the ICNIRP guide fixes a limit on the Specific Absorption (SA—energy per mass unit), which is however impossible to assess directly, being it related to quantities internal to the body. In addition, the guide indicates a

threshold for perception of about $100\text{--}400 \text{ mJ m}^{-2}$ for pulses of duration less than $30 \text{ }\mu\text{s}$ at 2.45 GHz (corresponding to an SA of $4\text{--}16 \text{ mJ kg}^{-1}$). However, other publications identify more conservative values: a threshold of 20 mJ m^{-2} , always for pulses of duration less than $30 \text{ }\mu\text{s}$, is stated in [8], while in [9] RF hearing has been reported also for energy density per pulse values lower than 90 mJ m^{-2} for pulse widths from 3 to $5000 \text{ }\mu\text{s}$. Furthermore, the Australian Radiation Protection and Nuclear Safety Agency in its Standard [10] establishes, on the basis of the considerations exposed in [11], a limit for the spatial peak SA of 2 mJ kg^{-1} (for general public) and 10 mJ kg^{-1} (for workers) in the head within any $50 \text{ }\mu\text{s}$ interval.

On the other side, regarding the occupational exposure, there is not a specific Italian regulation, so that the normative reference has been the European Directive 2004/40/EC, which assumes in its turn the same limits established by the ICNIRP guideline for the workers.

Summing it up, the limits taken into account in this work were:

- Electric field: 40 V/m (averaged) for the general public–DPCM 8 July 2003;
 1952 V/m ($61 \text{ V/m} \times 32$), as peak value, for the general public–ICNIRP;
 137 V/m (averaged), for the workers–ICNIRP and 2004/40/EC;
 4384 V/m ($137 \text{ V/m} \times 32$), as peak value, for the workers–ICNIRP and 2004/40/EC
- Energy density per pulse: 20 mJ m^{-2}

Finally, the compliance with the ‘attention value’ of 6 V/m of the DPCM 8 July 2003 were also verified, in correspondence of the residential places at far distance from the radar but in optical visibility of it. Considering the minimum elevation of the radar (equals to -2°), at least 10 km are necessary to the radar beam for reaching the altitude of the closest villages (1500 m a.s.l.).

In evaluating the electric field values, conservative hypotheses were applied, in order to eventually overestimate the field. Similarly, during the measurements, conservative parameters were adopted. For instance, it is customary to estimate the electric field in the antenna boresight (which extends up to $0.2 D^2/\lambda = 70 \text{ m}$) with its time-averaged value, without taking count of its angular-averaged value due to its rotation. Assuming this, it is:

$$E = \sqrt{\frac{Z_0 P dc}{\pi D^2/4}} = 78.6 \text{ V/m}$$

where Z_0 ($377 \text{ }\Omega$) is the free space characteristic impedance, dc is the duty cycle (conservatively chosen as 0.00094), D is the paraboloid diameter (4.27 m) and P is the nominal peak power (250 kW). This averaged E-field intensity corresponds to a peak value of 2563 V/m . The energy density per pulse values are equal to 6.9 , 13.9 and 34.8 mJ/m^2 for the three considered kinds of pulses, corresponding to the ‘velocity’ mode the first two and to the ‘intensity’ mode the last one.

From these results it follows that in the antenna boresight (cylinder which base corresponds to the paraboloid aperture and with an height of 70 m) a worker could occasionally stay in safety conditions according to the Directive 2004/40/EC and the ICNIRP, but with a possible auditory effect (perceived as a noise at 250 Hz) in the ‘intensity’ mode. Furthermore, no site in the antenna boresight is accessible to the general public, whilst the only site accessible to the workers is the platform (with parapet) surrounding the antenna radome.

Considering the first kilometre from the radar, only the broadcast towers in south direction could be interested by considerable exposure levels. However, owing to the minimum elevation value of -2° , the radar beam could only approach them from above, so that only maintenance workers who should climb them could be exposed to the radar primary radiation lobe. In this condition, neglecting again the radar rotation (thus representing the conservative but unlikely condition of fixed azimuth at 160°N and elevation of -2°), the electric field can be estimated as:

$$E = \frac{\sqrt{30 P dc G_n}}{d} = 41.5 \text{ V/m}$$

where $30 = 377/(4\pi)$, G_n represents the numeric antenna gain that is about 30000 , d is the distance (radar–broadcast towers) equals to 350 m . Should the angular average be taken into account, this would introduce a further multiplying factor of $360^{-1/2} = 0.053$, which would make decrease the obtained value to about 2.2 V/m .

Therefore, even maintenance personnel potentially working on the towers facing the radar would operate in safety conditions accordingly to ICNIRP and EU Directive.

While these exposure points were characterised only from a theoretical point of view, those accessible to general public, as well as the equipment room (as described in the third paragraph), were instead actually measured. In particular, Table 1 refers to the results obtained in correspondence of point 2, where measurements were carried out both in broad- and narrow-band. Taking into account the different measurement techniques (in the first case three values at different heights were acquired, each of which represented the 6-minute average value; in the

second case one only intermediate height was considered and the acquisition was detected in peak mode), the difference between the two obtained values (1.2 dB) is widely justified.

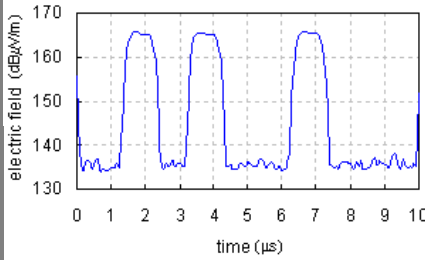

POINT 2 (broadband)	POINT 2 (narrow band)	
Height 110 cm: $E = 8.68 \text{ V/m}$		Height 150 cm: $E \text{ (peak value)} = 165.65 \text{ dB}\mu\text{V/m}$
Height 150 cm: $E = 5.12 \text{ V/m}$		
Height 190 cm: $E = 5.82 \text{ V/m}$		
Spatial average: $E = \sqrt{\frac{8.68^2 + 5.12^2 + 5.82^2}{3}} = 6.72 \text{ V/m}$		Mean value with duty cycle: $E = 10^{-6} \cdot 10^{\frac{165.65}{20}} \sqrt{9.4 \times 10^{-4}} = 5.87 \text{ V/m}$

Table 1: Electric field measurements in correspondence of point 2 (redoubt's roof). On the left the results obtained averaging the values acquired for the three heights, by using the broadband RAHAM sensor, are presented, while on the right, those obtained with the spectrum analyser. The picture in the middle displays the acquired spectrum: the three different peaks are due to the max-hold operating mode, and refer to different repetitions of the radar signal.

In correspondence of the remaining measurement points, the sensitivity limit ($0.5 \mu\text{W}/\text{cm}^2$) of the sensor was never reached, which means that the electric field kept lower than 1.37 V/m

The other set of measurements performed were devoted to the characterisation of the radar antenna radiation pattern in far field conditions. The horizontal plane pattern (alongside the azimuth angle) was acquired by making the antenna rotate with an angular velocity of $5^\circ/\text{s}$ and by setting the spectrum analyser in zero span mode with a sweep time suitable to cover a complete turn. Figure 3 shows the part of the diagram concerning the angular range from -40° to $+40^\circ$ from the radiation maximum, acquired at 1.1° of elevation. In the remaining part of the diagram, the electric field level kept about 40 dB under the maximum and did not rise in correspondence of either the back lobe or possible spillovers.

Figure 3: Electric field diagram by varying azimuth angle (horizontal plane), centred in the main lobe.

Finally, further measurements were carried out to better characterise the main lobe, in particular determining its amplitude in both the azimuth and elevation directions. The knowledge of these quantities (θ e φ , expressed in radiant and calculated at -3 dB from the maximum) enables to determine the antenna gain (G_n), on the basis of the formula:

$$G_n = \pi^2 / (\theta \varphi)$$

which assumes a gaussian profile of the main lobe. The data acquired for different elevation values are shown in Figure 4 together with the parabola, which represents the fit using a quadratic regression. Being the ordinate axis in logarithmic scale, the curve would correspond to a gaussian trend in linear scale, thus confirming the suitability of the previous formula in determining the antenna gain.

The θ e φ angles obtained from the diagrams are 0.93° (azimuth) and 1.14° (elevation), thus giving a $G_n=44.85$ dB. This value is very close to that provided by the manufacturer: 45 dB.

Figure 4: Characterisation of the main lobe by varying the elevation (vertical plane). Points represent the acquired data, while the parabola is the fit obtained by using a quadratic regression.

Furthermore, the peak amplitude is verifiable by means of the following analytical formula, valid in far field condition:

$$E \text{ [dB}\mu\text{V/m]} = 120 + 20 \log_{10} \frac{\sqrt{30 P G_n}}{d} = 150.28 \text{ dB}\mu\text{V/m}$$

where P is the nominal peak power ($2.5 \cdot 10^5$ W), G_n is the numerical gain of the antenna and d is the distance ($1.49 \cdot 10^4$ m). The comparison between this result and the actually measured value (with spectrum analyser, in peak mode detection) shows a discrepancy of 2 dB, with measured values exceeding those estimated. However, some considerations have to be taken into account:

- the directivity of the radar antenna is so high that, even at a long distance, the electric field peak values are important. For instance, at 15 km distance $E=30$ V/m, which however corresponds to 1 V/m provided it is time-averaged;
- also in this case the radar beam was intentionally pointing the measuring point, without rotating. In realistic operating conditions, the radar is continuously rotating, so that further reduction factors representing its movement both in the horizontal and vertical planes should be added.

As a consequence, it is possible to confirm that, even in correspondence of the residential places satisfying the optical visibility requirement and considering direct pointing of the radar beam over them, also the 'attention value' (6 V/m) of the Italian law would be fulfilled.

Conclusions

Regarding both the measurements and the theoretical estimation of electric field for radioprotective purposes, all sites taken into consideration in the present work met the requirements of the Italian law DPCM 8 July 2003 (only concerning the general public), even considering the unlikely and highly conservative operating conditions of the radar, directly and constantly pointing to the measurement point. Moreover, no significant RF dispersion was found inside the equipment room. Also the exposure conditions of the maintenance personnel who could

access on broadcast towers facing the radar were assessed—through theoretical estimations—to comply the safety standards for the workers (ICNIRP and Directive 2004/40/CE), even in case of direct pointing of the radar beam towards their direction. The peak exposure thresholds of the ICNIRP and Directive 2004/40/CE are fulfilled as well, as the multiplying factor to introduce for the continuous exposure corresponds to the inverse of the radar duty cycle. Even the possible access on the platform surrounding the radar radome would comply the occupational limits. The only effect which could be observed in such condition (within the antenna boresight), as reported in literature [8, 9], is the onset of annoying auditory effects, as long as the ‘intensity’ pulse mode had been used. The antenna boresight is reachable by workers in this only situation, while it is never accessible to the general public.

Abstract

Recently, epidemiological studies and researches have proposed a relation between exposure to electromagnetic fields (extremely low frequency, ELF) and the development of several neurodegenerative diseases (WHO and NRPT progress reports 12-4-2004). This has stimulated scientific interest to verify ELF effects on different life forms (Repacholi MH, 2003).

We have analysed the effects of ELF on neuron-like cell lines (PC12 and SH-SY5Y), glioblastoma GL15 as glial model and C2C12 myocytes as muscle model, focusing our attention on the cellular oxidative stress machinery.

We exposed cell cultures to 50Hz ELF (0-1mT) generated by a solenoid or Helmholtz coils adapted to a confocal microscope, and investigated cell proliferation, ROS production, mitochondrial membrane potential, antioxidant enzymatic activities (SOD, Catalase, GSH-Px, etc).

The growth curves of tested cells did not show any differences between ELF-treated cells towards controls. The presence of ELF influenced ROS production in dependence of cell phenotype and of field intensity. Also mitochondrial potential as well as antioxidant enzymatic activities were altered by ELF.

These results show that ELF modified oxidative stress status in excitable cells. These were able, in different way depending on their biological activity, to counteract ELF effects and to adapt themselves without altering their proliferation rate.

Introduction

In 1996, the World Health Organization (WHO) decided to start a world program named “International Electromagnetic Fields (EMF) Project” regarding potential dangerous health effects of the exposure to electric and magnetic fields at extremely low frequencies (ELF-EMF). Such exposures arise mainly from the transmission and use of electrical energy at power frequencies of 50/60 Hz. The International EMF Project is scheduled to complete its health risk assessments of EMF in 2007, since it is likely that current and proposed research should provide sufficient results within this time frame to allow more definitive health risk assessments. While the enormous benefits of using electricity in every day life and health care are unquestioned, the presence of possible inappropriate effects, or health consequence, needs to be clearly identified. The results of research currently available are often contradictory and this adds to people confusion and lack of confidence that supportable conclusions about safety can be reached.

The biological effects in cell lines derived from different modalities of ELF-EMF exposures have been frequently noted but the basic interaction mechanism(s) between such fields and living matter is unknown (Kavet et al., 2001; Foster KR, 2003). Even if some hypotheses have been suggested, none of these is adequately supported by experimental data (Repacholi and Greenebaum, 1999; Preece et al., 2000). Various cellular components, processes, and systems can be affected by ELF-EMF exposure, e.g. cell membrane (both internal and external) and signal transduction pathways (Czyz et al., 2004), cell cycle regulation and cell proliferation and/or differentiation (Simko and Mattsson, 2004; Frahm et al., 2006). Also direct or indirect DNA damage can be measured in different substrates but this does not directly lead to genotoxic effects (Villarini et al., 2006; Stronati et al., 2004). If the biological effects induced by ELF-EMF exposures are not easy to understand, the possible physiological effect of power frequency fields is still a hotly debated issue. In living organisms, above all in vertebrates, some tissue constituted by excitable cells (neurons and muscle fibres) are more sensible to the presence of perturbation of electric fields present around their cell membranes (Sieron et al., 2004). Some recent papers seem to confirm this assumption, in fact short-time exposure (5 days) to ELF-EMF radiations showed, by the cytotoxic glutamate (Glu) pulse test, a 30% decrease of cell survival in primary neurons, prepared from newborn rat cerebellum (Nikolova et al., 2005) and ELF-EMF exposure of neural progenitor cells transiently affects the transcript level of genes related to apoptosis and cell cycle control (Blackman et al., 1993). Also “in vivo” experiments seem to confirm the peculiar responsiveness of this particular cell typology to ELF-EMF presence. It has been found, in fact, that ELF-EMF exposure for 14 days (1 h daily) did not influence the level of the biogenic amines and their metabolites, but increased the rate of synthesis of DA and 5-HT in rat frontal cortex as compared to control (Jenrow et al., 1998). Several investigations have revealed that electrical activity within the central nervous system (CNS) can be affected by exposure to ELF-EMF. Many of these studies have concerned CNS structures exhibiting endogenous oscillations and synchrony as optimal sites for field coupling. In this regard, a particularly well characterized structure is the rat hippocampus whose rhythmic slow activities (necessary to some pathways of memory procedures) are exclusively susceptible to field-mediated perturbation suggesting that the sensitivity of these networks to ELF-EMF exposure may be really significant (Wolf et al., 2005).

In conclusion, the various modifications measured in several laboratories utilizing different substrates showed the presence of real biological effects (acute and chronic) derived from ELF-EMF exposure even if not without troublesome questions, these responses can be associated with detectable changes in cell physiology. This last consideration suggests that somehow, compensatory mechanisms at the translational and posttranslational level could exist.

Also for this reason, it is necessary to suggest the hypothesis regarding a possible initial cellular event affected

by exposure to ELF-EMF, an event which is present in a large number of effects observed as consequence of ELF-EMF exposure. Based on an extensive reviewed literature, Simko and Mattsson (2004) recently suggested that ELF-EMF exposure is able to perform such activation by means of increasing levels of free radicals. Such a general activation is compatible with the diverse nature of observed effects. Free radicals are intermediates in natural processes and they could be the stimulus to induce an "activated state" of the cell which then enhances the release of free radicals, in turn leading to biological events such as, in the CNS, an inhibition of the effects of the melatonin release and, as consequence of this, an alteration of biological rhythms or the deregulation of the neurotransmitter synthesis. In general, reactions in which radicals are involved become more frequent, increasing the possibility of DNA damage and therefore, to an increased risk of tumour development.

The purpose of this paper is to provide information about the effects of ELF-EMF applied to excitable cell lines. In particular, we focused our attention on the generation of radical oxygen species (ROS) and on the antioxidant system correlated with "in vitro" cell exposure to ELF-EMF having different intensities and duration using pheochromocytoma- and neuroblastoma-derived cell lines (PC12 and SH-SY5Y respectively) as neuronal models, glioblastoma GL15 as glial model and C2C12 myocytes as muscle substrates.

Results. To verify if the "in vitro" cell exposure to ELF-EMF influences cell proliferation rate, the cells were grown for 4-7 days in absence (control) or in presence of ELF-EMF (0.1, 0.5, 1.0mT). In fig. 1 a representative proliferation curve of the muscle cell line C2C12 is shown. At every considered intensities the proliferation rate didn't show any significant difference in regard to control cells.

Fig. 1: Proliferation rate in C2C12 cell line exposed 0-7 days at different ELF-EMF intensities (0.1, 0.5 and 1 mT). The data are means \pm SEM, n=8.

In Tab.I we have reported the mean values of cell number/1000 \pm SEM after 4 exposure days in the other tested cell lines. The PC12 cells showed a very slight dose-dependent increase of cell number (529.2 \pm 22.6 in the controls and 579.2 \pm 19.0 in the cell exposed to 1.0 mT), while the SH-SY5Y cell line didn't show any modification and the GL15 cells seemed to suffer a very slight decrease after 4 days at 1.0 mT ELF-EMF.

Proliferating cells (mean of the cell number/1000 \pm SEM after 4 exposure days in growth medium, n=5)				
	Control	0.1 mT	0.5 mT	1.0 mT
PC12	529.2 \pm 22.6	547.2 \pm 25.6	569.0 \pm 27.6	579.2 \pm 19.0
SH-SY5Y	887.0 \pm 49.6	897.0 \pm 39.0	857.5 \pm 33.6	877.0 \pm 40.3
GL15	580.4 \pm 31.6	550.7 \pm 47.8	563.5 \pm 33.8	504.5 \pm 43.8

Tab. I: Cell proliferation of three cell lines (PC12, GL15 and SH-SY5Y) after 4 days exposure to ELF-EMF of different intensities (0.1, 0.5 and 1 mT).

To summarize, under these experimental conditions, the ELF-EMF exposure didn't show a single significant effect on cell proliferation rate.

A possible effect of the exposure to electric and magnetic fields at extremely low frequencies could be an

increase of ROS production and, as one consequence of this, a modification of mitochondrial membrane potential. To check if the exposure to ELF-EMF could induce ROS production, SH-SY5Y and GL15 cells were exposed to ELF-EMF (10-60 min) and ROS production was assayed (fig. 2). The data obtained show that in both cell lines and at each ELF-EMF intensity tested, there is a significant increase of ROS production at 20 min even with a quantitative and qualitative different time-course.

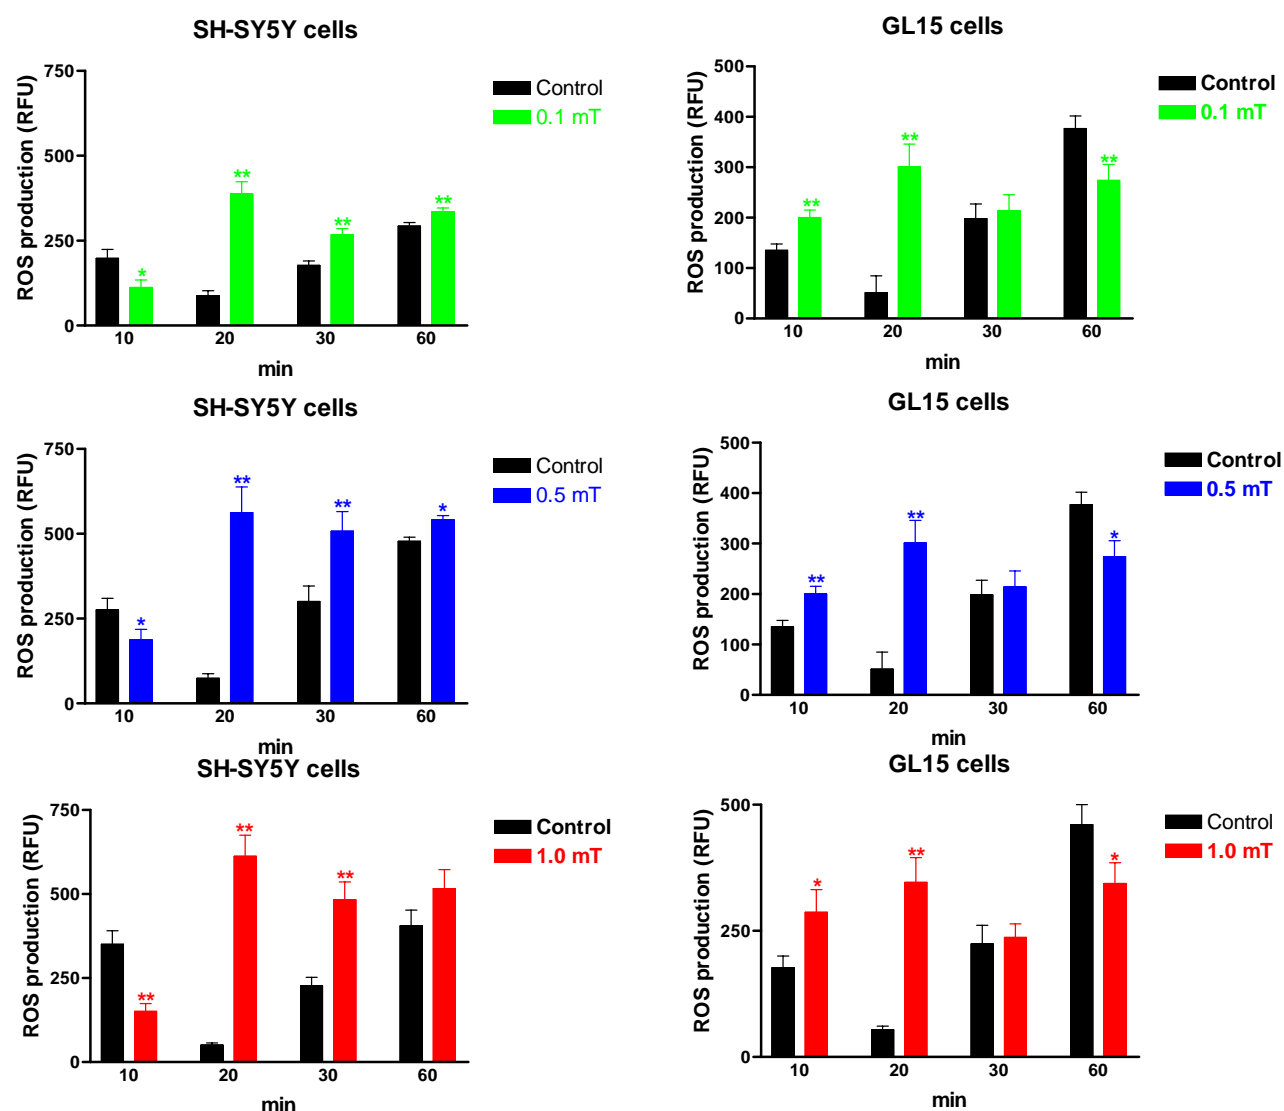

Fig. 2: ROS production analysed on cell populations. The ROS production was measured using DCF fluorescence emission assayed at different exposure times (10', 20', 30', 60') and different ELF-EMF intensities (0,1, 0,5 e 1mT). Data are mean \pm SEM, n=4; *p<0.05, **p<0.01 vs control.

Using a single cell approach and a specific fluorescent dye (JC-1), we monitored mitochondrial membrane potential during ELF-EMF exposures utilizing a confocal microscope equipped by Helmholtz coils. Preliminary data suggested that mitochondrial membrane potential was affected by 1.0mT ELF-EMF on the cell lines tested. The undoubted increase of ROS production could induce, as response, an activation of endogenous antioxidant system. For this reason, in PC12 and GL15, we tested the antioxidant enzymatic activities (superoxide dismutase: SOD, glutathione reductase: GSSG-Rx, catalase: CAT, glutathione transferase: GST, glutathione peroxidase/Se-dependent: GSH-Px/Se⁺, γ -glutamylcysteine synthetase: γ GCS) after 3 days 1.0mT ELF-EMF exposure. As shown in Fig. 3, these activities varied depending on the cellular typology and on the considered enzyme. Each cell line showed a peculiar pattern of enzymatic activities probably depending on their biological activity.

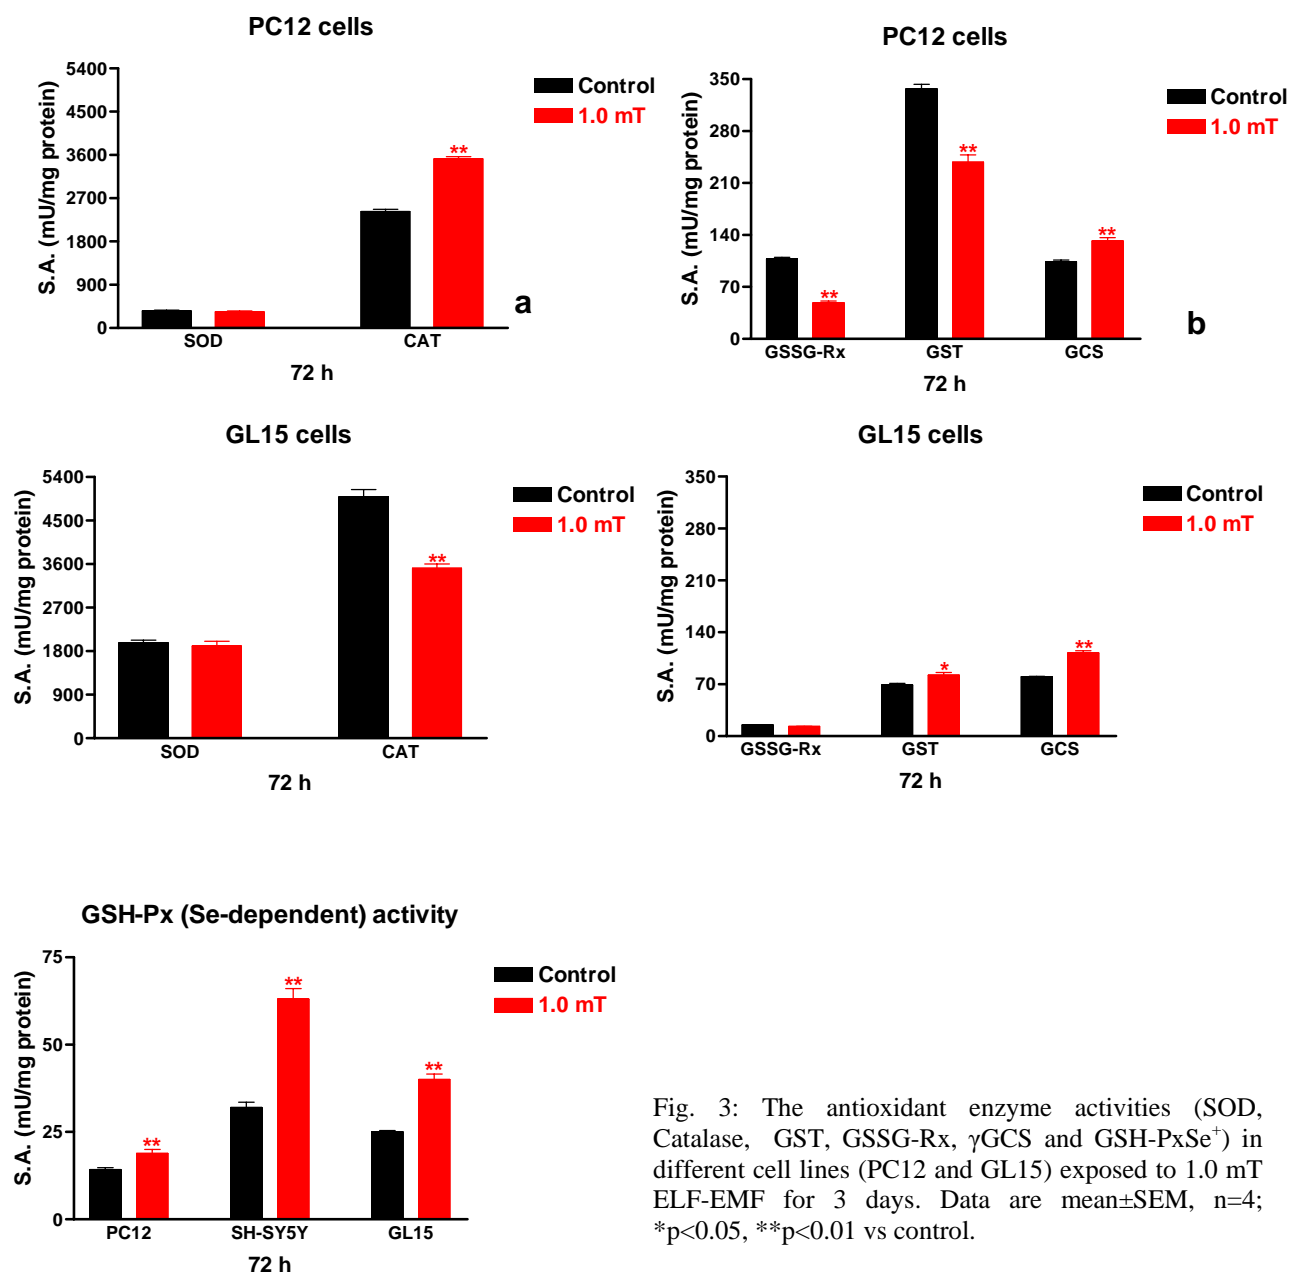

Fig. 3: The antioxidant enzyme activities (SOD, Catalase, GST, GSSG-Rx, γ GCS and GSH-PxSe⁺) in different cell lines (PC12 and GL15) exposed to 1.0 mT ELF-EMF for 3 days. Data are mean \pm SEM, n=4; *p<0.05, **p<0.01 vs control.

To complete the picture of the antioxidant system in GL15 cells, the levels of GSH, an endogenous antioxidant source, were measured. The levels of this molecule increased in GL15 cell line in the presence of ELF-EMF (fig. 4).

Fig. 4: The GSH total levels measured in GL15 cell line. Data are means \pm SEM, n=4; ** p<0,001.

In conclusion, depending on their intensity (mT), ELF-EMF affected the oxidative status, but the cells counteracted the induced increase of ROS production modifying their antioxidant ability.

Discussion. One mechanism through which ELF-EMF could influence neoplastic development is the deregulation of cancer-related genes and, in particular those related to different cyclins and cyclin-dependent kinases which are deputy to control cell cycle progression and cellular proliferation. The results of our experiments show that a slight, but dose-dependent, increase of proliferation rate was observed only in PC12 cells after exposure to ELF-EMF with graduated intensities (0.1-1.0 mT). This result is only apparently contradictory compared to those already published by McFarlane et al (2000) which reported no effect on cell proliferation of PC12 cells exposed to 4.5-15.8 microT ELF-EMF. In addition, during our experiments, if the intensity of ELF-EMF was lower than 0.5 mT, no modification in cell proliferation was noted. In the other cell types no variations (SH-5YSY) nor a significant slight decrease (GL15) after 4 days of exposure to the highest ELF-EMF intensity (1.0 mT) occurred. From these results, an initial consideration comes out: the effect of ELF-EMF on cell proliferation is dependent on the phenotype of cell model rather than on a direct action of ELF-EMF on some steps of cell cycle progression. As previously demonstrated by Ross in the 90's, markedly different effects, ranging from inhibition to stimulation of proliferation, were obtained, depending on the signal parameters (amplitude and frequency of ELF-EMF) as well as the types of utilized cell substrate (Ross SM, 1994). This fact is also supported by somewhat unclear results on the effect of the ELF-EMF on stromal stem cell proliferation (CFU-f); in fact, CFU-f from female mice showed a reduction, while CFU-f from male mice no decrease in cell proliferation (Van Den Heuvel et al., 2001).

More recently Wolf et al (2005) showed that the stimulation of proliferation, as well as the presence of DNA damage, was noted in HL-60 leukemia cells, Rat-1 fibroblasts and WI-38 diploid fibroblasts exposed for 24-72 h to 0.5-1.0-mT ELF-EMF. These effects were prevented by pre-treatment of cells with an antioxidant like alpha-tocopherol, suggesting that redox reactions were involved. Accordingly, the cells after exposure to 1.0 mT ELF-EMF exhibited a significant increase in ROS accumulation which was decreased by addition in the culture medium of an adequate scavenger (Wolf et al., 2005). Also under our experimental condition it was possible to note a significant increase of ROS production in all the tested cell lines even with a different qualitative and quantitative time-course. Moreover, also "in vivo" experiments seem to confirm that the chronic exposure to ELF-EMF is able to generate a stress oxidative status (Regoli et al., 2005; Harakawa et al., 2005; Yokus et al., 2005). In addition, the presence of an increase of ROS production is also indirectly demonstrated by the analysis of the enzymatic pathways involved in the catalytic removal of reactive oxygen species accumulated as an effect of ELF-EMF exposure. The "in vitro" experiments reported here, as well as the results derived from "in vivo" techniques (Lee et al., 2004) in mouse, show that the presence of ELF-EMF can induce a variable and specie-specific alteration of the stress oxidative pathway.

Summary

In vitro experiments performed in excitable cell lines: SY-SY5Y, GL15, PC12 and C2C12, seem to indicate that the biological response (proliferation rate) to ELF-EMF (0.1- 1.0 mT) exposure strictly depends on cell model than on the utilized ELF-EMF intensity or time of exposure. However, in both neuronal-like and glial-like cell lines, a significant increase of ROS production, with a different time-course in each cell line, was detected. This caused the enzymatic detoxification pathway involvement. In conclusion, even if further studies are necessary to identify the kind of ROS produced by the exposure to ELF-EMF, we propose that this biochemical substrate could be the candidate as the cellular "primum movens" of ELF-EMF induced effect on biological systems.

Appendix

Instrumentation. The 50Hz ELF-EMF were generated by two different devices: a solenoid and a pair of

Helmholtz coils. These devices were planned and built to deliver variable, homogeneous, sine-wave alternate current magnetic fields with 50 Hz frequency and intensities ranging between 0.1-1.0 mT \pm 2%. The horizontal cylindrical solenoid (length=340mm, diameter=113mm), on a supporting base, was supplied by a power supply Elgar Electronics (mod. CW-801P). The solenoid was used in an incubator (5% CO₂ and 37°C) for continuous long time cells exposures during which the solenoid's eventual added temperature was negligible. The pair of Helmholtz coils (r=445mm, distance between coils=400mm), producing homogeneous magnetic field over the specified volume-under-test corresponding to the cell chamber, were located in the working zone of a confocal microscope and connected to a power supply Elgar Electronics (mod. CW-1251P).

Cell culture. C2C12 and PC12 (American Culture Collection) and GL15 (functionally characterized in our lab, Mariggiò et al BMC Physiology 1:4, 2001) were cultured as exponentially growing cells in growth medium (GM). The GM for C2C12, SH-SY5Y and GL15 contains Dulbecco's modified Eagle's medium (DMEM), 10-20% foetal calf serum (FCS), 2-4 mM L-glutamine and 100 UI mL⁻¹-100 µg mL⁻¹ Penicillin-Streptomycin. The GM for PC12 cells contains RPMI 1640 with 5% FCS and 10% horse serum, glutamine and antibiotics as mentioned above. Reagents for cellular culture were purchased from Gibco (Paisley, Scotland, UK). The cells were seeded on Petri dishes in GM and sub-cultured every 3 days (C2C12 and GL15) or weekly (SH-SY5Y and PC12) (Mariggiò et al, BMC Physiology 1:4, 2001; Guarnieri et al, Neuroscience 128:697-712, 2004; Pietrangelo et al., J Physiol.572(3):721-733, 2006). We exposed cell cultures to 50Hz ELF-EMF (0-1mT) generated by a solenoid or Helmholtz coils for different times according to the experimental plane.

Cellular proliferation was tested during 7 days in C2C12 and 4 culture days in the other cell lines, using the colorimetric assay of 3-[4,5-dimethylthiazol-2-yl]-2,5 diphenyltetrazolium bromide (MTT) as described by Pietrangelo et al. (J Physiol.572.3:721-733, 2006).

Mitochondrial membrane potential measurements. These were determined using a carbocyanine dye JC-1 (Molecular Probes, Eugene, Oregon, USA) which is taken up by the mitochondria. When the transmembrane potential is high, like in normal cells, JC-1 forms red fluorescence dimers (J-aggregate), while when it is low the red fluorescence disappears and green fluorescence emission appears (monomer). Briefly, the cells on coverslips were incubated in growth medium containing 5 mM of JC-1 for 10 min. After being rinsed three times with PBS, each coverslip was observed and images were recorded with or without the ELF-EMF generated by Helmholtz coils applied to a confocal microscope (excitation was fixed at 488 nm and emission was set to either 522 nm, for green monomer, or 605 nm, for red J-aggregate, using a bandpass filter). To estimate the modification of fluorescence in mitochondria, the change in green and red areas was calculated for the whole image using Scion Image ver. beta 3b (Scion Corporation, Frederick, Maryland, USA). The red/green area ratio, resulting from each single image of the experiment was plotted against time (Castellano et al., Arch. Pharm. Pharm. Med. Chem. 333:373-380; 2000).

ROS production. After different exposure times (10', 20', 30', 60') at different ELF-EMF intensities (0,1, 0,5 e 1mT), the cells, plated on 96 multiwell, were incubated at 37°C with dichlorodihydrofluorescein-diacetate (H₂DCF-DA) for 30'. After incubation the cells were washed and the ROS production was revealed by the fluorescence emission of oxidized 2',7'-dichlorofluorescein (DCF) read on a multiwell fluorimeter (excitation at 485 nm and emission at 530 nm).

Antioxidant enzyme activities. The enzymatic activities were measured on cell extracts using spectrophotometric assays according to Sun and Zigman (Anal. Biochem. 90: 81-89; 1978) for SOD1; Aebi HE (Methods in enzymatic analysis. New York: Academic Press; pp.:673-684; 1974) for CAT; Paglia and Valentine (J. Lab. Clin. Med. 70:158-169; 1967) for GSH-Px Se⁺; Habig and Jacoby (Methods Enzymol. 77:398-405; 1981) for GSSG-Rx; Di Ilio et al. (Bioch. Med. 29:143-148; 1983) for GST; Volohonsky et al. (Chem. Biol. Interact. 140:49-65; 2002) for γ -GCS. The extracts were obtained through homogenization of 1x10⁷ cells and centrifugation at 12,000 rpm for 45 min.

GSH total levels. The total glutathione levels were determined using a kinetic assay in which catalytic amounts of GSH or GSSG derived from the continuous reduction of 5'5'-dithiobis (2-nitrobenzoic acid) (DTNB) by NADPH. The reaction rate is directly related to the concentration of glutathione at values up to about 2 mM. The formation of 5-thio-2-nitrobenzoate (TNB) was measured spectrophotometrically at 405 or 414 nm.

A ROLE OF ERK SIGNALING IN THE PROLIFERATIVE EFFECTS OF 50 Hz MAGNETIC FIELDS ON HUMAN NEUROBLASTOMA CELLS

ABSTRACT

OBJECTIVE. We have reported before that 42 or 63 h intermittent exposure to 50 Hz, 100 μ T magnetic field (MF) can induce cell proliferation in the NB69 line, from a human neuroblastoma (REFLEX Project, Final Report 2004). Evidence exist that mitogen-activated protein kinases can be involved in the MF- induced bioeffects. We have used a MAPK-specific inhibitor (PD98059) to investigate whether the activation of extracellular signal-regulated kinase (ERK1/2) is involved in the proliferative response elicited by MF.

METHODS. The growth response was analyzed through haemocytometer counting after 63 h of exposure to four conditions: control; PD98059 (20 μ M); MF alone and MF + PD98059. In short-term studies, the expression of phosphorylated MAPK/ERK (p-ERK1/2) was analyzed (Immunocytochemistry - Image analysis) at 15, 30, 60 and 120 min of exposure.

RESULTS AND CONCLUSIONS. The results confirm that a 63 h, intermittent exposure to 50 Hz, 100 μ T increases the growth rate of NB69 cells. This effect was blocked by the MAPK-specific inhibitor PD98059. In the short term, the MF induced a transitory significant increase of p-ERK1/2 expression peaking at 30 min (63.4%; $p=0.0010$), such an effect was also negated by the inhibitor. These results indicate that the proliferative effects induced by the MF-exposure in NB69 cells could be mediated by a repeated (intermittent) transitory activation of the MAPK/ERK pathway.

INTRODUCTION

A number of epidemiological data have raised concerns about the relationship between exposure to power frequency magnetic fields (MF) and cancer promotion (Ahlbom *et al.* 2001) and on the potential contribution of the occupational exposure to power frequency fields to the pathogenesis of neurodegenerative diseases such as Alzheimer's or Parkinson's diseases (Feychting *et al.* 2003; Park *et al.* 2005). Cellular studies are needed to reveal the cellular and molecular mechanisms underlying the biological effects and possible health implications of the exposure to power frequency MF.

In previous studies on NB69 human neuroblastoma cell line, we have reported that power frequency fields at 10 or 100 μ T increase proliferation through activation of DNA synthesis (Trillo *et al.* 2003; REFLEX-Project, Final Report 2004). Numerous studies have investigated the influence of power frequency magnetic fields with magnetic flux densities (MFD) in the mT range on cell proliferation (Katsir and Parola 1998; Wei *et al.* 2000; Wolf *et al.* 2005). However, there is limited evidence on the effects of $MFD \leq 100 \mu$ T, which corresponds to the ICNIRP recommended threshold for short-term exposure of the general public to 50-Hz MF. Since it is unlikely that EMF can induce DNA damage directly, most studies have examined EMF effects at the cell membrane level, on general and specific gene expression, and on signal transduction pathways. Among the cellular processes proposed as implicated in the MF growth-promoting activity, signaling and regulatory cycle proteins have been reported altered, though this effect did not result in apparent changes in routine physiological processes such as cell growth or division (Korzh-Sleptsova *et al.* 1995; Richard *et al.* 2002; Lange *et al.* 2004). However, the type, the age and the state of the cell as well as the physical parameters of ELF-MF can affect in a different degree the reported MF bioresponses.

The aim of the present work is to explore the signaling and the regulatory proteins involved in the proliferative action exerted by a 50 Hz, 100 μ T MF on the NB69 human neuroblastoma cell line, investigating whether mitogen-activated protein kinases (MAPK) could be involved in such a proliferative response. MAPK kinase pathways are signaling pathways that enable cells to respond to external stressors and stimuli (Kolch, 2000) and play a key role in a variety of cellular responses including proliferation, differentiation, and death. MAPK have been implicated in the cellular responses to magnetic fields (Jin *et al.* 2000, Nie and Henderson,

2003). The MAPK family includes the extracellular signal-regulated kinases (ERK1/2). This ERK signaling pathway, also called the MEK-ERK cascade, is one of the principal cytoplasmic signal transduction systems that regulate processes of proliferation and survival in eukaryotic cells. Besides, up-regulation of ERK1/2 has been proposed to be implicated in tumor progression and metastasis in different cancer types (de Melo *et al.* 2006; Suthiphongchai *et al.* 2006; Cuevas *et al.* 2006). In the nervous system ERK1/2 has been connected to neuronal responses both, to functional (modulating neuronal survival, neuronal differentiation, and plasticity) and pathologic stimuli (such as Alzheimer or Parkinson disease, Chu *et al.* 2004; Webster *et al.* 2006). The results of the present study indicate that the activation of the extracellular, signal-regulated kinase, ERK1/2, is involved in the proliferative response of NB69 cells to the exposure to 50 Hz 100 μ T MF.

MATERIAL AND METHODS

Cell growth assays. NB69 human neuroblastoma cells were maintained in Dulbecco's Minimum Essential Medium (D-MEM, Biowhittaker) supplemented with 15% heat inactivated fetal bovine serum, 4 mM L-Glutamine and 100 U/ml penicillin and 100U/ml streptomycin (Gibco BRL, Invitrogen, Spain). Cells were cultured at 37 °C in a humidified incubator under an atmosphere of 5% CO₂. Cells were seeded, at a density of 4.5×10^4 cells/ml, into 60 mm Ø plastic Petri dishes (Nunc) or on circular 12 mm Ø coverslips placed into the Petri dishes, and cultured under standard conditions for three days. When needed, media were supplemented with the ERK1/2 kinase inhibitor, PD98059 (2'-amino-3'-methoxyflavone, Biosource). PD98059 was dissolved in dimethyl sulfoxide (DMSO). An equal dose of DMSO was added to the control dishes. The final concentration of DMSO in the medium was 0.1%. The mean value of the number of cells in controls with or without the vehicle, DMSO, was 649.0 ± 114.9 ($\times 10^4$) and 647.2 ± 83.2 ($\times 10^4$), respectively.

Magnetic field exposure. NB69 cells were exposed to a 50 Hz, sinus wave, linearly polarized magnetic field, at 100 μ T. The MF was generated by a wave generator Newtronic Model 200MSTPC connected to a pair of coils set in a Helmholtz configuration. Currents in the coils were monitored using a multimeter (Hewlett Packart, model 974A, Loveland, CO) and measured with fluxgate magnetometers (EFA-3, Model BN 2245/90.20 Wandel and Goltermann S.A, EMDEX II, Enertech Consultants, Campbell CA). Two pairs of coils were placed inside two magnetically shielded chambers (co-netic metal; Amuneal Corp., Philadelphia, PA) kept in identical CO₂ incubators (Forma Scientific) with a 5% CO₂, 37 °C and 100% humidity atmosphere. The background MF inside the shielded chambers was AC: 0.04 ± 0.03 μ T; DC: 0.05 ± 0.04 . In each experiment only one set of coils was energized. The samples in the unenergized set were considered sham-exposed controls. Both incubators were used, in a random sequence, alternatively for MF exposure and sham-exposure.

Study of the growth response at the end of a 63-hour lapse of intermittent exposure in the presence or absence of the MAPK inhibitor PD98059. NB69 cells were cultured under standard conditions for three days. At this time medium was renewed and 20 μ M PD98059 was added to the culture media 60 min prior to the MF exposure. Ten Petri dishes, 5 with and 5 without PD98059 were placed in each exposure set up inside the incubators. The exposed group was treated intermittently, 3h On/3h Off, to 50 Hz MF at a 100 μ T magnetic flux density for 63 h. The cells were subjected to: a) no treatment: controls, b) treatment with PD98059, c) exposure to MF, and d) MF exposure imposed upon PD98059 treatment. At the end of the exposure and or treatment, on day 6 post-plating (pp), the cellular viability and growth were determined through Trypan blue exclusion. All assays and analysis were performed in the blind for experimental condition.

Studies of the phosphorylated ERK1/2 expression in response to short-term MF exposure or PD98059 treatment. NB69 cells were exposed for 15, 30, 60 and 120 min at day 4 pp. The percent of phosphorylated ERK1/2 (p-ERK1/2) positive cells was analyzed by immunocytochemistry. At the end of the magnetic field exposure, the cells were fixed with 4% paraformaldehyde for 20 min at 4 °C and permeabilized with 5% ethanol/acetic acid. The non-reactive sites were blocked (10% goat serum in PBS) for 1 hour at room temperature. Immunostaining was performed by incubating cells overnight at 4 °C with primary antibody antiphospho-specific ERK1/2 (1:100) rabbit polyclonal antibody (44-480G, Biosource) and a secondary, goat antirabbit IgG, antibody (1:500) conjugated with the fluorophore Alexa Fluor 488 (Molecular Probes) for 1 hour at room temperature. Hoechst 33342 (Bisbenzimidazole, Sigma) was included in the mounting medium as a counterstain for nuclei and was visualized and evaluated by photomicroscope. In each experiment 3 coverslips were studied per experimental group (Control; Inhibitor; MF; Inhibitor + MF). In each coverslip 15 random microscope-fields were analyzed and in each microscope-field the total nuclei (Hoechst fluorescent dye) and the percent of p-ERK1/2 positive cells were recorded. A total of about 4500-5000 cells per experimental group was evaluated. The statistical study applied the ANOVA test followed by the Student's T test.

RESULTS

1. Growth response at the end of a 63-hour lapse of intermittent exposure in the presence or absence of the MAPK inhibitor PD98059. The effects of 100 μ T MF on the cell growth in the presence or absence of PD98059 at 20 μ M are represented in Figure 1. The exposure to the MF induced a significant increase in the number of cells (9.1% over controls, $p < 0.01$), which confirms previously reported observations by our group (Trillo *et al.*, 2003; REFLEX-Project, Final Report 2004). In contrast to that, the treatment with PD98059 provoked equivalent, significant decreases in the number of cells of MF-exposed (16.7% below controls, $p < 0.001$) or unexposed samples (16.7 % below controls; $p < 0.001$). The latest indicates that the MAPK inhibitor PD98059 inhibits cell growth in the NB69 line and blocks the MF-induced growing effect on these cells.

Figure 1. Effects of a 63 hours exposure to 100 μ T MF and/or of treatment to 20 μ M PD98059 on the number of cells. Data from 4 experimental replicates normalized with respect to controls (Mean \pm SEM). **: $p < 0.01$; ***: $p < 0.001$ (ANOVA followed by Student's T-test.)

2. Phosphorylated ERK1/2 expression in response to short-term MF exposure or PD98059 treatment.

Figure 2 shows the results of short-term treatment with MF or MAPK inhibitor on day 4 pp. The MF exposure provoked a transitory increase in the percent of cells that express p-ERK1/2, peaking at 30 min of exposure (63.4% over controls $p < 0.01$), the effect being prevented by PD98059. However, at 120 min of exposure a significant decrease in the p-ERK 1/2 expression (19.0% below controls; $p < 0.001$) was obtained. This response was similar to that induced by the inhibitor alone and by the combined treatment (27.6%; $p < 0.05$ and 28.8%, $p < 0.05$ below controls, respectively). As can be observed, the MAPK inhibitor PD98059 only provoked a significant reduction in ERK1/2 activation after 120 min of treatment, although it was able to prevent the MF induced ERK1/2 expression at 30 and 60 min of treatment. Taken together, these results indicate that the MF can induce transitory activation of the MAPK/ERK pathway in NB69 cells and suggest that the proliferative response induced by the exposure to 50 Hz 100 μ T MF could be mediated by this transitory activation of MAPK, ERK1/2 transduction pathway, in each of the 3-hour On periods of the intermittent exposure cycle.

Figure 2. p-ERK 1/2 expression in response to short-term MF exposure or PD98059 treatment. Transitory effect of the MF exposure, peaking at 30 min. The MAPK-specific inhibitor, PD98059, blocks the MF effect. N = 4 independent replicates, data normalized with respect to controls (Mean \pm SEM). *: $p < 0.05$; **: $p < 0.01$; ***: $p < 0.001$, Student's T- test.

DISCUSSION:

The effect of the MAPK-specific inhibitor PD98059 on MF-induced cell growth and on ERK1/2 phosphorylation was examined to determine whether ERK1/2 is involved in the proliferative effects of 50 Hz MF on NB69 human neuroblastoma cells. The ERK1/2 signaling pathway is a major determinant in the control of diverse cellular processes such as proliferation, survival, differentiation and motility. This pathway is often up regulated in human tumors (de Melo *et al.* 2006; Kohno and Pouyssegur 2006), and play an essential role in cell cycle progression, through induction of cell cycle regulatory proteins and transcription factors (Chang *et al.* 2003).

The present data confirm that a 63-hour intermittent exposure to 50 Hz, sinus wave MF at 100 μ T promotes cell growth in the NB69 cell line. This increased growth was prevented when the specific inhibitor of the ERK1/2 activation, PD98059, was present. Besides, the field provoked a transitory increase in the activated, extracellular signal regulated kinase, p-ERK1/2, peaking at 30 min of exposure. The presence of PD98059 blocked this transitory activation of ERK1/2. At 120 min of MF exposure a significant decline in the expression of p-ERK1/2 occurred, both in the presence or in the absence of PD98059. Three other human cell lines (HTB 124, MCF7 and HL60), known to respond to MF with a 2 - 3-fold induction of HSP70 expression (Goodman *et al.* 1998), have also been reported to be responsive to a 30 min MF exposure (60 Hz, 8.0 and 80 μ T) and induce ERK1/2 phosphorylation (Jin *et al.* 2000). The level of MAPK activation in MCF7 and HL60 cells exposed to the MF (60 Hz, 100 μ T) was approximately equivalent to that in cells treated with 0.1 - 0.5 ng/ml of 12-O-tetradecanoylphorbol-13-acetate, TPA, (Nie and Henderson, 2003). Moreover, a cooperative effect on PKC activity has been observed when exposure to TPA and MF (50 Hz, 1 mT) were applied simultaneously on human amniotic cells (Richard *et al.* 2002), which is suggestive of a role for protein kinase C in the process leading to MAPK activation in MF exposed cells. It is currently believed that power frequency fields initiate the activation of the stress response when the signal affect receptors in the plasma membrane and that this subsequently triggers the specific signal transduction pathway that regulates different cell processes. In our study, the question whether the MF-activation of EKR1/2 in NB69 cells is a consequence of the conventional extracellular stress-activated signaling to the nucleus remains unanswered. However, like in the work by Jin *et al.* (2000), in the present study a MF activation of ERK1/2 was obtained, this activation being associated to the MF-induced promotion of proliferation in NB69 cells.

Different authors have reported effects of power frequency MF on cell proliferation in neuroblastoma lines; however, the molecular regulatory mechanisms underlying these MF-induced bioeffects remain unidentified. Namely, proliferation induction was obtained in neuroblastoma cells (LAN-5) after seven days of

continuous exposure to 50 Hz, 1 mT; this effect being associated to transitory increases of the proto-oncogen B-myb (Pirozzoli *et al.* 2003). Also, Tonini *et al.* (2001) reported inhibition of proliferation in NG108-15 cells treated with the differentiating agent BT2cAMP. This chemically-induced inhibition of cell proliferation was relieved by exposure to a 50 Hz MF at 120 or 240 μ T. Our present results suggest that the proliferative response induced by the exposure to 50 Hz 100 μ T magnetic fields could be mediated by a repeated transitory activation of MAPK, ERK1/2 transduction pathway, in each of the 3-hour On periods of the intermittent exposure cycle. Recently Ebisuya *et al.* (2005) have reported that differences in the duration, magnitude and compartmentalization of ERK activity can generate variations in the signaling output that determine the cellular outcome. Furthermore, in the study by Ebisuya and coworkers several molecules have been identified as spatial, temporal or strength-controlling regulators of ERK activity. Consistent with that, a potential induced modulation by the MF exposure of these regulators of ERK activity could represent one of the mechanisms implicated in the MF-induced proliferation observed by us in NB69 cells.

SUMMARY

The purpose of the present work is to determine whether the mitogen-activated protein kinases MAPK, ERK1/2 is potentially involved in previously reported effects of the intermittent exposure to a 50 Hz, 10 or 100 μ T magnetic field on the proliferation of the NB69 human neuroblastoma cell line. The influence of the MAPK-specific inhibitor PD98059 on MF-induced effects on cell growth and on ERK1/2 phosphorylation was examined. The obtained results show that the MF-induced growth response is prevented when the ERK1/2 activation was chemically inhibited. Besides, the MF provoked a time course significant, transitory increase in the p-ERK1/2 expression, peaking at 30 min of exposure. That transitory effect was also prevented by the MAPK specific inhibitor. Taken together, the present data indicate that the increase in cell proliferation induced by a 50 Hz, 100 μ T MF in the NB69 line could be the result of a consecutive, transitory activation of the MAPK, ERK1/2 transduction pathway, during the On periods of intermittent exposure to the field.

Abstract

Human exposure to electromagnetic fields from mobile communications (base-stations and mobile phones) has been widely studied in the last years. Nevertheless, the increasing use of wireless technology for short range data transfer (DECT, Bluetooth and WLAN) in home and office has enhanced the social concern about potential adverse health effects of electromagnetic fields from those technologies. Moreover, epidemiological studies and assessments of electromagnetic environments make necessary to know the influence that the electromagnetic field from a certain new technology source has in the total exposure level of a person.

The aim of this work is to assess, by using the finite-difference time-domain method (FDTD), the human exposure to electromagnetic fields from the antennas of wireless devices such as those of wireless local area networks (WLAN) access points. Several geometrical configurations are considered to simulate the exposure of the head of a person, as a worst case, to the fields from a WiFi antenna operating at 2400 MHz in home or office environments, calculating both, field values to be compared with reference levels and maximum specific absorption rate (SAR) values to be compared with basic restrictions. The situation of short-distance exposure to the bluetooth antenna of a personal digital assistant (PDA) in front of the eye of the user is also studied by calculating the SAR. Results are presented.

Introduction

In the last years, there has been a social concern about the possible harmful effects on the human health derived from people exposure to radiofrequency electromagnetic fields, specially those produced by mobile telephony (base-station antennas and mobile phones). Nevertheless, the rapid introduction in home and office environments of new emerging wireless technologies, such as the wireless local area networks (WLAN of WiFi) and Bluetooth, is motivating the users to worry about possible negative effects on their health caused by these technologies.

The human exposure to radiofrequency electromagnetic fields is regulated by national and international guidelines [1,2] which limit the exposure of general public to those fields, based on the guidelines from the International Commission on Non Ionizing Radiation Protection [3]. In the same way, the European Union has defined a specific directive for the protection of workers from the exposure to those fields [4].

Measurements of the WLAN signals in different environments have been made by several authors considering access points only, with client card enabled, uploading or downloading large files [5], or access points and mobile terminals with a maximum power of 100 mW [6], having found a strong dependence with distance and measured values far below the limits of the international guidelines. Measurements of the electric field near a WiFi 802.11b router so as numerical simulations of the electric field surrounding a wireless laptop computer with two hands over the keyboard have been made in [7], with a theoretical estimation of the channel occupation as a means of knowing the real emitted power of the system and an experimental assessment of compliance with safety limits of several short-range wireless devices used in home and office environments has been made in [8], by means of E-fields measurements in a semi-anechoic chamber and SAR measurements in a body-emulating phantom, concluding that, in the very near future, the background exposure in everyday life situations will exceed exposures from base stations and broadcast stations, so that it is necessary to assess the simultaneous exposure of people to multiple sources in its surrounding environment.

In this work the FDTD technique, which has demonstrated to be very useful for dosimetry studies of human exposure to electromagnetic fields, is used to analyze the field distribution in the vicinity of a person during the use of several radiofrequency devices. Two different situations will be considered, trying to simulate actual operating conditions in exposure to wireless access points antennas (based on the standard IEEE802.11b) in home or office environments and use of a WiFi or bluetooth PDA at several distances in front of the user's eye. In all cases, the SAR in the head of the user will be calculated to be compared with basic restrictions from the guidelines.

Models and Results

A. Exposure to wireless access points antennas.

Several situations of possible exposure to the antenna of a wireless access point in a domestic or office environment have been studied. In the simulations, brick walls and metallic cabinets are included to consider the influence of the environment in the SAR calculated in the head of the exposed person. Figure 1 shows the schematic geometries of four studied configurations: (a) a person working in a table where a desktop antenna is located, near the brick walls of the room, at a distance of 40 cm of the person head; (b) the worst-case of a person with the antenna in front of its eyes at a distance of 20 cm, with a reflecting plate behind the antenna at a distance of 4 cm; (c) a person in front of an antenna which is on the opposite side of a 12 cm thick brick wall, the antenna-eye distance being 20 cm or (d) a person exposed to the radiation of two desktop antennas at 15 and 20 cm from the head, respectively, with metallic cabinets behind the antennas at 15 and 25 cm (fig. 1d).

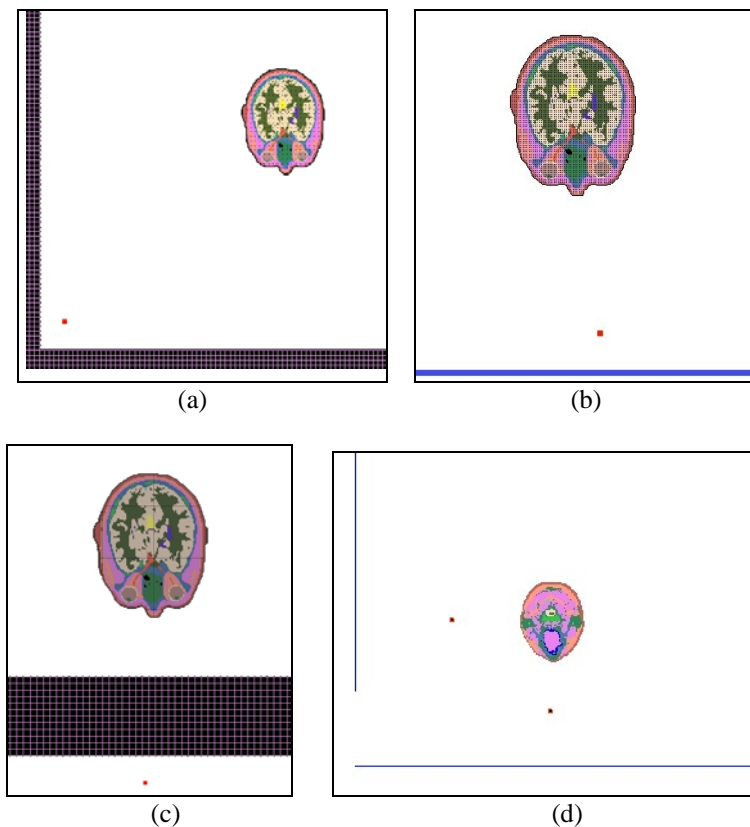

Figure 1. Schematic view of the analyzed exposure situations: (a) Head at 40 cm from the antenna which is at 4 cm of both walls. (b) Head at 20 cm from the antenna and at 24 cm of a metallic wall. (c) Head at 20 cm from the antenna, which is 4 cm on the opposite side of the brick wall. (d) Head in presence of two antennas, surrounded by metallic cabinets.

The antennas have been simulated, in all cases, as half-wavelength dipoles, operating at a frequency of 2400 MHz with a radiated power of 100 mW. To simulate the user, a high-resolution head and shoulders mesh,

GUIDELINES COMPLIANCE IN EXPOSURE TO WLAN DEVICES

developed from nuclear magnetic resonance by REMCOM Inc. and the Hershey Medical Center, Hershey, PA, USA, has been used. The model has $2 \times 2 \times 2,5$ mm cells and includes 17 different biological tissues which corresponding densities and dielectric characteristics at the operating frequency (2400 MHz) are summarized in table 1 [9].

The walls have been modeled by rectangular plates with a width of 12 cm, by using a material which simulates the dielectric characteristics of brick, with a relative permittivity of $\epsilon_r = 5.1$ and a conductivity of $\sigma = 0.028$ S/m, assuming they are similar to those corresponding to 1800 and 2140 MHz [10].

Tissue	ϵ_r (S/m)	σ (S/m)	ρ (kg/m ³)
Skin	37.63	1.29	1125
Tendon	44.03	1.80	1151
Fat, yellow marrow	4.4	0.08	943
Cortical bone	11.67	0.41	1850
Cancellous bone	17.47	0.60	1080
Blood	53.31	2.68	1057
Muscle	55.84	2.32	1059
Grey matter	46.47	2.10	1035.5
White matter	35.80	1.36	1027.4
Cerebro-spinal-fluid	66.87	3.22	1000
Sclera/cornea	51.77	2.11	1151
Vitreous humor	66.80	2.48	1000
Nerve	31.61	1.10	1112
Cartilage	37.18	1.57	1171
Tongue, thyroid	53.14	2.05	1059
Cerebellum	47.31	1.79	1035.5
Esophagus	36.10	1.47	1126

Table 1. Relative permittivities, conductivities and densities of the tissues in the head model for 2400 MHz.

By using the FDTD method, we have calculated the electric field values in the proximity of the antennas when there is no exposed person, to be compared with the limits established in the exposure guidelines (reference levels). Moreover, the SAR values inside the human head model have been calculated to be compared with basic restrictions. Figure 2 shows contour plots of the calculated fields in absence of the head model for, respectively, the four exposure situations described in the first paragraph.

Figure 2. Contour plots of the calculated fields in absence of the head model for the four exposure situations shown in figure 1.

In all the studied configurations, it can be observed that local field values in the position where the person is to be located are below the reference level for this frequency (61 V/m for the electric field). Spatially averaged values are obviously lower. As it is well known, guidelines compliance based on reference levels ensures the fulfilment of guidelines based on basic restrictions. Nevertheless, in exposure situations at short distances from the antennas, it is interesting the assessment of the SAR. The calculated values of SAR averaged over the whole exposed object (SAR_{wb}), so as the maximum local SAR values, averaged over 10 grams of contiguous tissue (SAR_{10g}), are shown in table 2.

	Geometry (a)	Geometry (b)	Geometry (c)	Geometry (d)
SAR_{wb} (W/kg)	0.00044	0.00054	0.00012	0.0006
SAR_{10g} (W/kg)	0.008	0.019	0.008	0.027

Table 2. SAR_{wb} and SAR_{10g} for the four simulated exposure situations.

It can be appreciated that SAR_{wb} and SAR_{10g} values are far below the corresponding basic restrictions for all geometries.

B. Use of a PDA device close to the user's face.

The study of the SAR produced by the use of PDA devices is interesting because, due to the reduced screen size, the distance from the antenna to the eye of the person (which is known to be a critical organ) can be very short. For that reason, we have modeled a 2400 MHz antenna in front of the eye of the head and shoulders model at several distances, from 5 to 30 cm, trying to simulate a worst-case exposure situation. The electrical and geometrical models of the antenna and the person are the same than those used in the previous section. Results for the calculated maximum SAR_{10g} as a function of the antenna-eye distance are presented in figure 3 for different antenna radiated powers.

GUIDELINES COMPLIANCE IN EXPOSURE TO WLAN DEVICES

Figure 3.- Maximum SAR_{10g} as a function of antenna-eye distance for different radiated powers.

It can be seen that SAR values increase strongly as the antenna-eye distance becomes shorter, although the maximum value of 0.18 W/kg, obtained for the lowest (unusual) considered distance, corresponding to a radiated power of 100 mW (the maximum expected with WiFi or Bluetooth standards), clearly fulfills safety guidelines.

Conclusions

In this work, the human exposure to the electromagnetic fields from the antennas of wireless devices such as those of WLAN access points or WiFi or bluetooth personal digital assistants has been analyzed by using the FDTD method. Several exposure situations have been considered, assessing field levels and SAR in the exposure to access point antennas, to be compared with reference levels and basic restrictions, respectively, or max SAR_{10g} in short-distance exposure to a PDA device.

Results show that the exposure levels, even in worst case situations, as can be the case of WiFi access point or bluetooth antennas at a short distance in front of the eye of a person, are lower than those obtained when analyzing the exposure to mobile phones, the SAR_{10g} values being far below the basic restrictions from the guidelines.

Abstract

The aim of this study was to provide an optimization procedure in order to experimentally evaluate RF exposure levels due to wireless devices, other than phones, used in home and office environments. To this end, several measurements were carried out at UMTS and Wi-Fi frequencies and the results were then compared with simulations provided by the ray tracing prediction model ARMONICA. The comparison between measurement and numerical results showed a satisfactory agreement and suggest that, in order to avoid time consuming measurements for monitoring the electromagnetic field levels due to wireless communications in indoor environments, the use of a ray tracing prevision model is a valid support allowing to perform experimental validations only in that points where the simulator has shown some critical aspect.

Introduction

In the last years the enormous growth of mobile telecommunications leads to the necessity of developing effective and accurate techniques to calculate and measure the electromagnetic field (EMF) levels in indoor environments. To determine the EMF levels and to assure population against excessive exposure according to the international standards [1], [2], that have specified the exposure limits, measurements must be done in the place under test, using appropriated procedures for the new types of radio communications signals. However, the use of experimental valuations in order to determine the EM fields levels in indoor settings could give rise to high costs and long times; for this reason an EMF prevision software could represent an advantageous opportunity to reach the purpose. The computation of electromagnetic field propagation in real environments is a complex problem for the difficulty to describe with sufficient precision the antenna system, the geometry, the electromagnetic properties of present objects, the morphology and the ground characteristics.

Besides, the zone interested by the field computation could be extremely extensive compared with the wave lengths of the typical mobile communication frequencies, so that the computation resources could become an excessive load. It is for these reasons, that the classical numerical techniques for the resolution of Maxwell equations such as the finite elements method (FEM) or the finite difference time domain technique (FDTD) are inapplicable. So many studies were carried out about this argument and empiric and semiempiric models were developed to solve the problem [3-6], but in the two last decade the ray tracing techniques [7-9] were applied to the EMF prediction since it is proved the more appropriate, although there are still some unsolved questions.

The aim of this study is to provide a methodology for characterizing realistic electric-field exposures in home, office and occupational settings and suggests an approach for evaluating compliance with guideline limits in such settings. To this end, several measurements were carried out at UMTS and Wi-Fi frequencies and the results were then compared with simulations provided by a ray tracing prediction model.

Materials and methods.

Simulations. The program used for the EMF prevision was ARMONICA; it was developed by DEIS (Dipartimento di Elettronica, Informatica e Sistemistica) at the University of Bologna in a joint work with A.R.P.A. Emilia Romagna (Italy). In particular, we used the “mray” module; it calculates the EM field in the analysis point as the vectorial sum of all contributions corresponding to all main rays that reach the receiving

point after a number of interactions with the possible obstacles. The adopted program implements a three dimensional spatial ray tracing model involving both reflection and refraction contributions but neglecting the diffraction ones. The program requires in input 5 files in order to:

- describe the radiative characteristics of the transmitting antenna;
- describe the geometrical characteristics of environment;
- specify the electromagnetics properties of the materials;
- set up opportune boolean values in order to have an output file with the description of the various rays which contribute to the electromagnetic field value in each analysis point;
- define the irradiated signal frequency, the maximum number of reflected rays, positioning and orientation of the transmitting antenna, power supply, analysis domain and the type of output quantity.

The program provides in output:

- the amplitude of the electric field components: $|E_x|$ [V/m]; $|E_y|$ [V/m]; $|E_z|$ [V/m];
- the amplitude of the electric field $|E|$ [V/m];
- the received power [dB].

Measurements. A large number of measurements were carried out in different environments and configurations. Several analysis domains were considered: the microwave laboratory room (fig. 1), an office room (fig. 2) and a hall way out of the DIET (Department of Electronic and Telecommunication Engineering at the University of Naples Federico II). The WiFi or UMTS signal was transmitted by either a WLAN antenna (Cisco Aironet Yagi 1949) or a ridged horn (Schwarzbeck BBHA 9120D). The measurements were performed using either a spectrum analyzer (R&S FSH3) connected to the receiving antenna (precision conical dipole PCD 8250, Austrian Research Centers, Seibersdorf), or a vector network analyzer (Anritsu 37247C) connected to the receiving (PCD 8250) and transmitting antennas. In the latter, several positions of the transmitting antenna, working at 2.0 GHz frequency, were adopted, while the receiving antenna was mounted on an automated planar scanning system (fig.3). In this way a planar distribution of the electric field was obtained [10] as shown in fig. 4. Then we analyzed the predictive potentiality of the ray tracing technique in indoor environments by comparing the numerical results with those observed in the several measurements carried out in different settings.

Fig. 2. Matlab three-dimensional reconstruction of the office room at DIET, Un.of Naples Federico II.

Fig. 3. Precision conical dipole receiving antenna mounted on planar scanning system.

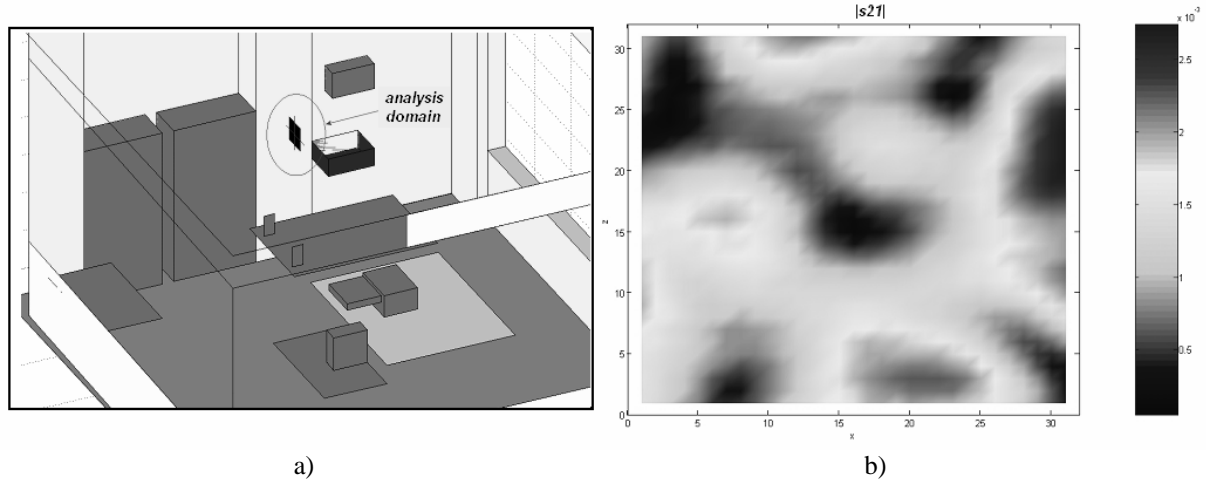

Fig.4.a) Microwave laboratory. Analysis domain; b) planar distribution ($0.3 \times 0.3 \text{ m}^2$) of the measured $|s_{21}|$ values.

Results. The comparison between measurement and numerical results showed a satisfactory agreement (figg. 5, 6). Although, due to the complexity of the analysis domain, some critical aspects were evidentiatiated: a not accurate geometric description of the environment can strongly affect the prevision model results; the addition of diffraction contributes can improve the numerical results; in indoor environments it isn't always simple to guarantee the far field conditions at the wireless working frequencies; a very accurate technical decription of the instrumentation is necessary.

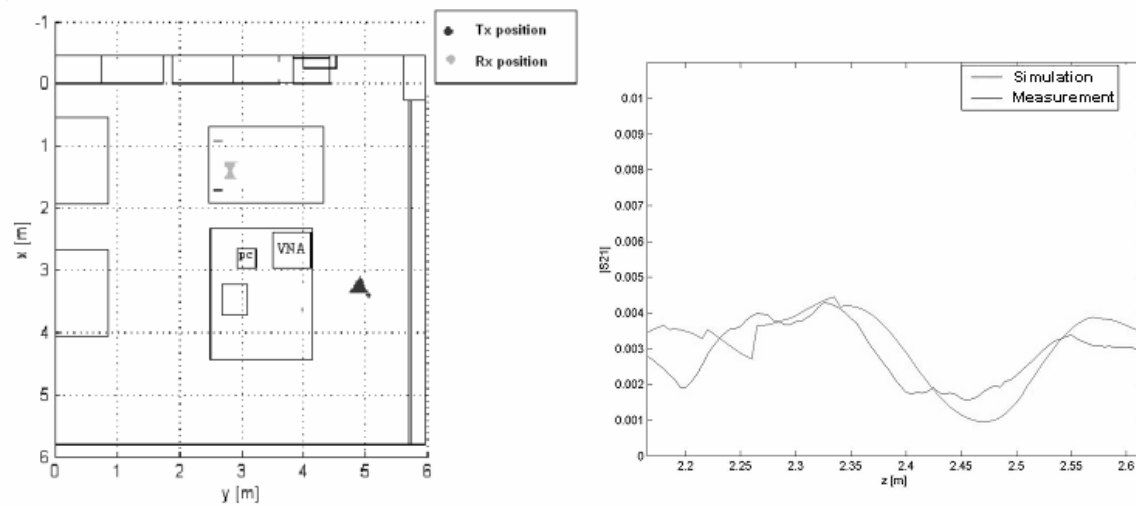

Fig. 5. Measured and calculated $|s_{21}|$ values and the corresponding scenario

Fig. 6. Calculated and measured electric field levels, with estimated uncertainty, and the corresponding scenario.

SUMMARY

The aim of this study was to provide an optimization procedure for evaluating RF exposure levels due to wireless devices other than phones used in home and office environments. To this end several measurements were carried out in different settings; the results were then compared with those calculated by means of a ray tracing prediction model.

A satisfactory agreement between the experimental and calculated results suggest that, in order to avoid time consuming measurements for monitoring the electromagnetic field levels due to wireless communications in indoor environments, the use of a ray tracing prevision model is a valid support allowing to perform experimental validations only in that points where the simulator has shown some critical aspect.

Abstract.

A set of different devices for “*in vitro*” exposures of biological samples (DNA, proteins) to electromagnetic field (300 MHz – 2.45 GHz) and the contemporary control of conformational changes of the exposed biostructure was designed and tested. To this end all the RF applicators were provided of a non perturbative optical apparatus, which allows the continuous monitoring, during the exposure, either the absorption spectra or the absorbance at a given wavelenght in order to observe reversible effects induced by the electromagnetic field.

Introduction

In vitro studies performed on simple but fundamental components of biological systems, i.e., biomolecules, in particular proteins and nucleic acid and artificial or isolated fragments of membranes, can provide important insights into fundamental mechanisms for biological effects due to electromagnetic field action. Proteins possess usually a net charge at pH corresponding to the native condition; moreover a large number of charge aminoacid residues are distributed in their structure. Protein structures are intrinsically flexible structures and can assume multiple conformations (in some cases called “open” and “closed” forms). During the course of their biological function, proteins undergo different types of structural rearrangements ranging from local to large-scale conformational changes. Since protein machines are flexible structures having own electric charges, such motions involved in many basic functions such as catalysis, regulation, transportation, and aggregation could be triggered by their interactions with electromagnetic field.

Since many years our research group is involved in the study of interaction mechanisms between the electromagnetic fields and biomolecules. An irreversible time dependent inactivation was observed in thermophilic enzymes exposed at 10.4 GHz. The percentage of deactivation depended on the temperature (60 – 90°C), SAR (0.8 – 3.1 W/g), and microenvironment (enzyme concentration or influence of salts). Conformational changes detected by fluorescence and circular dichroism techniques suggested that microwaves induced in this cases protein structural rearrangements not related to temperature [1,2,3]. Non thermal effects induced by exposure to 1.95 GHz, a typical frequency used in mobile communication, have been observed on the kinetic of reconstitution of the heme binding site from acidic tuna myoglobin solution [4]. More recently our attention was focussed on the possibility that electromagnetic field can remotely control these nano-biomachines [5,6].

The possibility of evidencing possible reverse effects (effects that fade away when the field is turn off)

is particularly attractive, to this end a family of applicator working in the 300 MHz – 2.45 GHz frequency band was designed and tested in order to expose macromolecules to microwaves and contemporary control the conformational change of the structure during the exposure. In all the devices is possible to insert two fibre optics connected, from one end, to the spectrophotometer Lambda 25 (Perkin Helmer, Wellesley, USA) while the other end was in contact with the quartz cuvette containing the sample.

Device design

At low frequencies (300 MHz – 900 MHz) the applicator was a coil similar to that used in [7]. It consisted of 35 turns with a cross section of $\sim 1 \text{ cm}^2$ and with an open structure in the middle in order to allow the insertion, perpendicularly to the axis coil, of two teflon cylinders that facilitate accurate placement of the fibre optics for absorbance measurements (fig.1). The sample, a DNA solution, was contained in a 3mm x 3mm x 22 mm quartz cuvette axially inserted into the coil. Being the coil an open structure it was possible to follow both the increase of temperature and the temperature distribution on the sample surface by means of an infrared thermocamera (ThermoVision A40M, Flir System, North Billerica, Boston, USA).

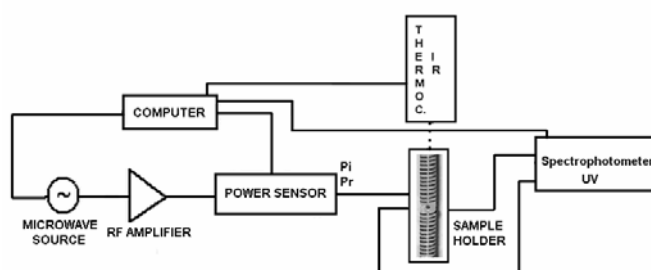

Fig.1 Exposure setup at 300 MHz and 900 MHz

Another applicator was designed in order to expose samples at 1.95 GHz, which is an up-link frequency of universal mobile telecommunication systems (UMTS). It was a rectangular thermostated waveguide (WR 430: 109.2 mm x 54.6 mm). The feeding end of the waveguide was a coax waveguide adapter Maury Microwave R213A2 (VSWR < 1.05) while on the other side a fixed short circuit (SC) termination was adopted. The sample was positioned in a maximum of the unperturbed field and inserted into a teflon support which allowed the fibre optics (fig.2) insertion.

Fig.2 Cuvette inserted into a WR430 waveguide and fibre optics holder

Finally a thermostated rectangular waveguide cavity (72 mm x 33.8 mm x 340 mm), coupled to the coax-adaptor waveguide by means an inductive diaphragm and excited by a 2.47 GHz radiation (fig.3), allowed the exposure of the samples to the only magnetic field. In fact, sample size (35 mm x 10 mm x 1 mm) and position (in contact with the short circuit) ensured a minimum interaction with the electric field and a satisfactory homogeneity of the magnetic field.

Dosimetry

Numerical and experimental dosimetry was carried out in order to assess efficiency and field uniformity into the sample. The efficiency of the system (the ratio between the absorbed power, P_a , and the incident power, P_0 , $\eta = P_a/P_0$) and the absorbed power distribution inside the samples were numerically and experimentally evaluated.

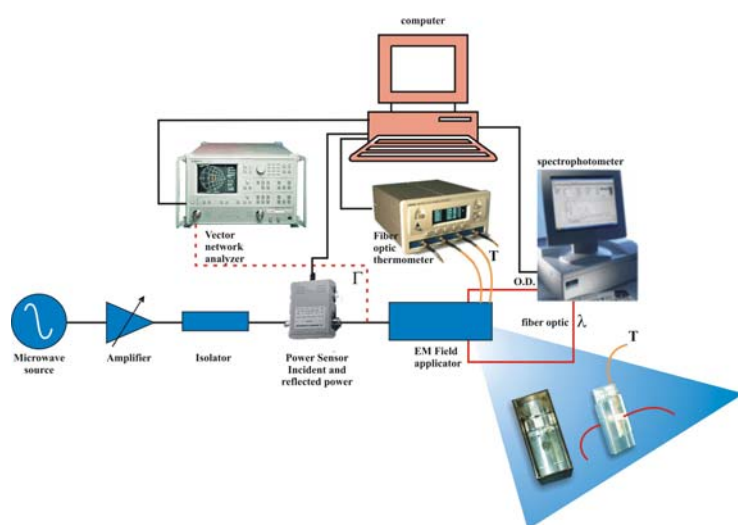

Fig.3 Exposure setup at 2.47 GHz for magnetic field sample exposures.

In particular the following parameters were calculated [8]:

- $|E^1(x,y,z)|$: the local electric field amplitude per unit incident power [(V/m)/W]. This was evaluated at each node of the computing domain.
- $SAR^1(x,y,z) = \sigma |E^1|^2 / 2\rho$: the local absorbed power per unit mass and per unit incident power [(W/kg)/W]. This is also the local specific efficiency, and it is zero outside the sample ($\sigma = 0$).
- AV^1 : the average $SAR^1(x,y,z)$ over the sample [(W/kg)/W].
- SD^1 : the standard deviation of $SAR^1(x,y,z)$ values
- $CV = SD^1/AV^1$: the coefficient of variation [9] is usually taken [10] as the “nonuniformity degree” of the $SAR^1(P_0 = 1\text{ W})$ values. The SAR (any P_0) nonuniformity degree, SD/AV , is the same as $CV = SD^1/AV^1$.

The local SAR values were calculated from the slope of the heating curves [11], $T(t)$, at $t = 0$, as: $SAR = c \, dT/dt|_{t=0}$ (c being the sample specific heat; $t=0$ is the starting time of radiofrequency radiation).

The efficiency, $\eta = P_a/P_0$, was evaluated by measuring the reflection coefficient (s_{11}) [12] of the exposure chamber loaded by the samples by means of a microwave vector network analyzer (Wiltron-Anritsu 37269B, Japan) over the working band, being $\eta = 1 - |s_{11}|^2$. In the case of the cavity the power absorbed by the samples was calculated by means of the measurements of the unloaded and loaded Quality factor [12].

Results

The efficiency simulated was successfully verified through measurements of the scattering parameters; as well as the nonuniformity degree was checked and confirmed by means of local temperature measurements using both the infrared thermocamera and the fibre optic thermometer.

The possibility of following the conformational change of the molecule was obtained. In particular we observed as [7] that a DNA double helix, with a gold nanocrystal covalently attached, was opened up and closed back upon exposition to an oscillating RF signal (~ 1 GHz), i.e., the electromagnetic field denaturated and renaturated the double-helical DNA. The extreme simplicity of assembly and operation of our devices, which resulted to be low cost and with an optical equipment that is commonly used in bio-chemical laboratory, makes them easily available and particularly interesting for studies about interaction mechanisms between biological structures and electromagnetic fields.

Abstract

This study was carried out to evaluate whether or not albumin leakage and degenerated dark neurons were indeed present in rat brains 50 days after a single 2 hour-exposure to 915MHz electromagnetic field (EMF) as reported earlier by Salford et al. Thirty two male F344 rats (12 weeks old) were used in the present study and they were exposed to 915MHz EMF at 0, 0.02, 0.2 and 2.0 W/Kg of whole body averaged SAR in a TEM cell for two hours as protocols described by Salford et al. The rats were killed 50 days later by a trans-cardiac perfusion technique with 4% PFA fixative solution under a deep anesthetic condition. The brains were examined histologically and immunohistochemically. As results, degenerated dark neurons, which were studied by Cresyl violet, HE and Fluoro Jade B stainings were only rarely present in small numbers with no statistically significant difference between exposed and sham exposed animals. In addition, no albumin immunoreactivity was observed anywhere even in any exposed groups. We must conclude thus that the data reported by Salford et al can not be confirmed by the present confirmation study.

Introduction

Since Salford et al. found that albumin leakage sites and increase in appearance of degenerated neurons presented in the rat brain 50 days after a single 2 hours-exposure to radiofrequency electromagnetic field (RF-EMF), many research groups have tried to confirm Salford's results. However, there were few confirmation studies performed using the same exposure system, endpoints, and experimental schedule. Therefore, the aim of present study was to confirm their reported results using a similar experimental design they used.

Thirty two male F344 rats (12 weeks old) were used in the present study. The rat placed in an acrylic box was set only on the upper side of the TEM-cell (Fig. 1) and was exposed to 915MHz EMF at 0, 0.02, 0.2 and 2.0 W/Kg of whole body averaged SAR for two hours as protocols described by Salford et al.. To know the whole body averaged SAR value that actually irradiated to the rat, we measured input, output, and reflected power using a power meter.

The rats were killed 50 days later by a trans-cardiac perfusion technique with 4% PFA fixative solution under a deep anesthetic condition. In the three selected sections of the brain (Fig. 2), albumin leakage sites were examined using immunohistochemistry of albumin. Furthermore, the appearance of degenerated neurons was evaluated using Cresyl violet, HE and Fluoro Jade B staining. We used a cold injury method for making positive control. A piece of dry ice was put on the skull of the rat for 5 min. Brown stained area was observed in positive control.

Degenerated dark neurons, which were studied by Cresyl violet, HE and Fluoro Jade B staining were only

rarely present in small numbers with no statistically significant difference between exposed and sham exposed animals. In addition, no albumin immunoreactivity was observed anywhere even in any exposed groups (Fig. 3).

Summary

We must conclude thus that the data reported by Salford et al can not be confirmed by the present confirmation study.

Acknowledgments

This study was financially supported by Association of Radio Industries and Businesses in Japan. We would like to thank Patrick A. Mason, PhD and Air Force Research Laboratory, Human Effectiveness Directorate, Directed Energy Bioeffects Division, Radio Frequency Radiation Branch, for lending us the TEM-cell.

Fig. 1. Exposure system (A)TEM-cell was used in the present experiment. Input, output, and reflected power were measured by a power meter through RF exposure. Whole body averaged SAR values were calculated these measured powers and rat body weights. (B)Rat placed in an acrylic box was set only on the upper side of the TEM-cell.

Fig. 2. Evaluated brain section. Three regions of the brain were selected for histological evaluation. Section 1, 2, and 3 are typical region including third ventricle, hippocampus, and pineal body, respectively.

Fig. 3. Typical photographs of albumin immunohistochemistry. Albumin leakage sites were examined using anti-albumin antibody in the brain 50 days after RF exposure. Positive control was made by a cold injury method. A piece of dry ice was put on the skull of the rat for 5 min. Brown stained area was observed in Positive control. On the other hand, no stained area was seen in any exposed groups.

ASPECTS REGARDING RADIOFREQUENCY RADIATION EXPOSURE OF POPULATION IN ROMANIA

Abstract

On the background of an accentuated risk perception of Romanian citizens to the radiofrequency (RF) radiation emitted by GSM base station antennas, we present the general situation in our country and results of a little scale measurement campaign we made for RF exposure assessment. The frequency selective method was used, the refinement of the methodology is discussed and results are presented and commented. All measurements showed that urban outdoor and indoor RF exposure is low comparative to the limits given in the ICNIRP guidelines that are applied in our country. We suggest for good quality exposure assessment and the need for a possibility to select between different RF sources radiation contribution in connection to further health impact studies.

Keywords: RF exposure, frequency selective method, measurement methodology, risk assessment

Introduction

Passed years in bioelectromagnetics research show that scientists cannot yet exclude the possibility that electromagnetic fields (EMFs), especially radiofrequency (RF) and microwaves (MW) can cause health problems, even for exposure levels lower than the ones stipulated in present exposure standards. One of the challenges of RF bioelectromagnetics remains the clear demonstration of the existence of athermal or nonthermal effects of RF/MW, since safety standards consider only the thermal biological effects as hazardous, when they give the basic restrictions and the reference levels in conformity [1], [2].

Exposure standards harmonization is not yet accomplished at international level, as with the efforts supported by the International EMF Project of World Health Organization. In the two most known regulations, i.e. ICNIRP guidelines [1] and IEEE standard C95.1-2005 [2], the establishment of the maximum permissible exposure limits is given in different ways: IEEE limits are based on spatial averaging of the incident field over the standing person's projection area, while ICNIRP refers to peak-field limits instead. A sensible aspect is that standard recommendations are based on short-term exposure. Of a special interest in present standardization are the problems concerning mobile and wireless communication systems, due to the rapid and huge spreading of this kind of RF radiation sources in the environment. In Europe there are countries that didn't adopted the ICNIRP reference levels for human exposure, but more stricter ones, as for example Italy and Switzerland, with specific rules for the base station transceivers (BTS) in mobile telephony systems. China and Russia are similar examples, which didn't adopted international guidelines, but due to a different rationale of the limits calculation. A debate is still going on from years, in many countries, on the application of the precautionary principle [3], regarding the sensitive problem of BTS sitting and only some local authorities in Italy, Switzerland and Belgium really apply it. Coming to citizens and media level, the situation is even more complicated, since, for example, neither can people be involved in BTS sitting decision, nor have they the right to be informed of the (expected) EMF exposure.

In Romania, the adopted limits for human exposure are those given in the ICNIRP guidelines [1]. European regulations [4],[5], were applied starting with 2002. That year the Romanian Health Ministry issued the Order no. 1007/13.12.2002 referring to the regulations on admissible exposure limits and the measurement

methodology, order that follows the European Directive no. 199/519/EC. General norms for work safety no. 880/06.12.2002 offer supplementary rules on working places in electromagnetic environment.

In the present, in Romania there are four public mobile communication operators: Vodafone (GSM 900MHz and 3G-UMTS 2GHz), Orange (GSM 900MHz and 3G-EDGE 2GHz), Telemobil - Zapp (CDMA and EV-DO 450 MHz) and Cosmote (DCS 1800MHz). 3G UMTS services were recently launched in Romania by Vodafone – April 2006 and Orange – June 2006. The present number of mobile telephone users in Romania is about 12 million, for a total population of 22 million people (approx. 55% of the population).

Mobile phone BTS antennas debate have become of unprecedented intense public health concern in Romania in the last period, starting with the end of 2005. Numerous journals at central and local level published articles on the issue under the pressure of citizens [6]. Numerous population complaints were received at Local Consumer Protection Agencies, Environmental Agencies and Guards. As a result, some local authorities adopted decisions for national budget financial support of EMF measurements campaigns in 2006 (first one in Cluj county, March 2006 [7]). Most of the newspaper articles and media news were published/broadcasted starting with January 2006 and focused on reported health state impair (even cancer-related cases – one in Oradea city, the second in Sibiu city) and complaints on BTS sitting on the blocks and private gardens (population protests in 2 counties: Sibiu and Zalau). At least 2 titles in newspapers refer to BTS antennas as a second “Tchernobil”, by comparison to the nuclear threat. Two private judicial processes are mentioned in media, won by the complaining persons against mobile telephony operators. One hospital (County Hospital Salaj) cancelled its contract to a mobile phone operator in order to renounce to the antenna mounted on the hospital’s roof. The National Consumers Protection Agency, which received tens of protests and complaints in 2006, decided to demand the Town (Local) Councils in the country to adopt decisions that forbid further BTS sitting on residential buildings. The Agency is preparing a well documented file on the issue. On the other hand, Romanian Government recognised the potential hazard of BTS antenna sitting (even mounted on its own building), by issuing the Ordinance no. 2/12.01.2006, on supplementary financial rights for hazardous workplace conditions (specific RF emissions) of public functionary, in a quote of 10% from the base salary. The authorised institutions for measurements of EMF emissions in Romania are: the Public Health Direction with its local institutions, Ministry of Defence Health Direction and Ministry of Transportation Health Direction. Measurements made till the end of 2005 in our country were done in the majority by using wideband survey meters type EMR-300 and Narda-8718. Relevant information on GSM topic is available to the public via the ACER Bulletin and ACER website (ACER is the Romanian Electromagnetic Compatibility Association - <http://www.acero.ro>), GSM Magazine, mobile telephony company websites and the press (which features related international press reports).

On this background, our study aimed to prepare for a reliable measurement campaign of residential exposure. This is needed from at least two essential perspectives: a) compliance testing of BTS antennas and other RF emission sources and in situ measurements, according to present methodology [5], [8] and standards; b) accurate assessment of frequency-selective RF exposure, that should be considered from the view of the finding that biological effects depend on the carrier frequency, as recently proved in the mobile communication band [9].

We had two principal objectives: a) refinement of the measurement methodology in accordance to the aim of the measurement; b) exposure assessment due to RF sources, especially GSM BTS antennas and comparison between quotients afferent to different sources.

The measurements were made by using the frequency-selective method (spectrum analyser with isotropic antenna) in a number of outdoor and indoor locations, urban and extra-urban places, for different settings of the measurement system.

Materials and methods

As for ICNIRP guidelines requirements, the principal need is that the measurement system be a frequency selective one. The equipment must also be sensitive enough, must allow averaging the values over any 6 minutes in time and averaging in space, considering the volume of the human body respectively the interesting areas of it. It is essential to use procedures that allow measurements with low uncertainty and good reproducibility [10], [11].

The equipment we used for most of the measurements was the TS-EMF system by Rohde & Schwarz, Germany. At some point we also used the Field Nose System by Austrian Research Centre in Seibersdorf, which

also helped in comparison of the same measurement results during one session. The TS-EMF system is composed by the R&S FSH3 spectrum analyser, an isotropic sensor (30MHz to 3GHz) and the computer software R&S RFEX for data acquisition and settings management. The tri-axis sensor has got an isotropic characteristic so the measurement is done independent from direction or polarization of the emitter. This makes measurements easier. In contrast to directional antennas, it is no longer necessary to move the antenna for covering all directions and polarization. The Field Nose System uses the proven Add3D technique to conduct precise measurements and is composed by an Anritsu M2711D spectrum analyzer with a broadband omnidirectional precision conical dipole PCD8250 as measurement antenna (80MHz to 2.5GHz), driven by Nose Basic software. The antenna is consecutively positioned in three orthogonal directions during the measurement, by a software-driven rotor. A picture of the two measurement systems is presented in fig.1.

Figure 1 –TS-EMF system by Rohde&Schwarz (left, “spherical antenna”) and Field Nose System by ARCS Seibersdorf, (right, “biconical dipole”).

Reproducible time averaging method with well known uncertainty estimation can be performed on one single point in the area of interest. Different measurement modes were possible and applied: a) single measurement; b) average and peak (e.g. 6 minutes average); c) long term (e.g. determination of time variations of the signals). The most used was the average & peak measurements. To increase the sensitivity of the TS-EMF system, the function Threshold-Calibration can be introduced, and in all measurements this was applied.

The measurement protocol took into account the objectives of the research which was either compliance verification, or in situ measurements [10]-[12]. We followed the measurement methods described in [5] and [8]. No a-priori knowledge was available regarding sources emissions or the environment. The general scheme for compliance verification was not completely followed, since no simulation was made prior to measurements and no measurement with broadband field probe was prior made. The measurements were executed by means of the frequency-selective system, in urban and extra-urban locations, either outdoor or indoor. The choice of measurement points (location and number of points) was in accordance with the general considerations in [5]. Refinement of the measurements by settings modification was made in most locations, in order to consider the “worst case” exposure. Processing of measured data and final report followed each measurement.

For the major services, the TS-EMF system offers pre-defined measurement packets. This should insure optimum settings for evaluation according to single frequencies, complete services and total emission. However, at least in the case of GSM measurements, personally defined packets/settings were also prepared, since we need to refine the measurements. Comparison between results obtained with different settings will be presented and discussed. Data presentation of the measured emissions (field strength, power density or exposure ratio - ‰ of

ICNIRP limit) was possible as a sum value and can be split into frequency bands if necessary. Detected signal spectrum and histograms may be represented.

All measurements were made fully-automatic using the R&S software RFEX and they were performed inside macrocells and mostly outdoor. The ten locations chosen for measurements were situated in intra-urban highly populated areas, and only in two cases it was situated remote from the city. All were positioned in the vicinity of the transmitter sites, the distance between the measurement system and the base stations being from 40 to 500m.

Results and Discussion

A. Refinement of the measurement methodology:

Residential exposure assessment, if highly accurate, is a complex task. It should take into account:

- position of the spot measurement;
- signal characteristics and variations in time and space;
- environment impact thru physical influences (fast fading, etc.)

However, since in the great majority the population partial exposure quotients due to various RF signals proved to be much lower than that stipulated in standards (for example, for BTS antennas generally the measured power density levels are $\ll 10\%$ from the reference levels, [13]), the question of optimum settings of a measurement system may be not so important. But if one is more sceptical regarding fundaments that conducted to present “safe” reference levels in standards, than he might always keep in mind that:

- not only RF/MW heating may be responsible for health hazards, but also athermal/nonthermal mechanisms of interaction could trigger a biological response;
- long term exposure was not the basis of standard value considerations;
- “frequency windows” were proved to exist in connection to specific biological responses,

and then the optimum settings of a system may crucially influence the results of the exposure assessments and further epidemiological findings.

In this respect, it is of big importance to correctly set the resolution bandwidth (RBW), sweep rate (SR) and detector type (DT) [14], in function of the measured signal. Secondary, in the case of GSM signal for example, the resolution of adjacent channels and the effect of number of active time slots should be attentively considered. We made measurements to compare results, while modifying different setting parameters. As an example, we show here the consequences of modification of “Trace mode” (TM) and “Detector type” (DT) on the results obtained in the case of a GSM 900MHz signal measured in one indoor location, with conserving all the interior environmental conditions the same, and all other system settings. The results are showed in table I and were obtained for a series of 10 consecutively measurements for each setting. For these measurements, the commune settings of TS-EMF system were: RBW=200kHz; Span=30MHz; Reference level=91 dB μ V; Dwell time=5s.

Table I : Influence of trace mode (TM) and detector type (DT) of the measurement settings on the results

	TM = Clear/Write DT = RMS		TM = Max hold DT = Positive peak		TM = Max hold DT = RMS	
	<i>Average</i>	<i>Peak</i>	<i>Average</i>	<i>Peak</i>	<i>Average</i>	<i>Peak</i>
Total field strength, RMS, (V/m)	0.141 \pm 0.005	0.190 \pm 0.004	0.510 \pm 0.004	0.720 \pm 0.003	0.091 \pm 0.003	0.110 \pm 0.006
Max single value (V/m)	0.050 \pm 0.003	0.050 \pm 0.002	0.082 \pm 0.002	0.111 \pm 0.003	0.051 \pm 0.002	0.050 \pm 0.004

“Max hold” setting is generally used for worst case when time variations of the signal are present. “Positive peak detector” represents also a worst case, but it may give over-rated values. “RMS” detector is usually used for non-sinusoidal signals to correctly derive the average signal power (it is especially used for UMTS mobile signals). As one can observe in the table above, the combination “Max hold” + “Positive peak detector” will give the worst case assessment possible. The values in this case are approximately 5 times larger in the case of total field strength than the ones obtained with the setting “Max hold” + “RMS detector” and about 3.5 times higher than the ones with the setting “Clear/Write” + “RMS detector”. However, these values may be overestimated. The results repeated as well for measurements on GSM 1800 signals. We could then conclude about the “worst case” settings. Due to these observations, most of the compliance testing or in situ measurements made by us for GSM900 and GSM1800 signals were done by using the intermediary setting, “Clear/Write” + “RMS detector”.

Moreover, we were able to observe that a lower RBW, for example one of 30kHz, is a better choice for “worst case” measurement. This setting should be completed by a sufficiently low sweep rate (long dwell time, thousands of milliseconds), or even better, multiple sweeps, so that the independence of the result upon the instantaneous traffic on a GSM signal to be assured.

As a result of lots of GSM measurement sessions, we were able to conclude that it is practically impossible to predict positions in space where hot spots of field distribution will appear, either outdoor or indoor. Time evolution of the field level is only predictable on the basis of traffic diminution in the late time hours, but otherwise is low-predictable also. Special aspects for further refinement of measurement methodology should focus on frequency hopping and power control of BTS.

B. Compliance testing and in situ measurement results:

Peak values measured in some outdoor locations for GSM900 signals are given bellow. Locations 1 and 2 are urban locations, while location 3 is extra-urban. In figure 2 – a,b,c one can visualise these locations. The settings of the TS-EMF system were: Trace Mode:Clear/Write; Detector: RMS; RBW=200kHz, span=30 MHz, Dwell time=5000ms. Power density (S) peak values measured in the 3 locations exemplified in fig. 2 are:

$$S_1^{\text{peak}} = (9.66 \pm 2.73) \times 10^{-5} \text{ W/m}^2$$

$$S_2^{\text{peak}} = (23.00 \pm 5.51) \times 10^{-5} \text{ W/m}^2$$

$$S_3^{\text{peak}} = (62.00 \pm 13.54) \times 10^{-5} \text{ W/m}^2$$

a – Loc. 1

b – Loc. 2

c – Loc. 3

Figure 2 – Locations of outdoor measurements for GSM900 signals

The maximum peak value measured outdoor during the campaign either for GSM 900 or for GSM 1800, was $S_{\text{max}}^{\text{peak}} = 100 \times 10^{-5} \text{ W/m}^2$, which is also far beyond ICNIRP reference levels. The reference levels are: for

GSM900, $S_{ref}=4.5 \text{ W/m}^2$ and for GSM1800, $S_{ref}=9 \text{ W/m}^2$. They are equivalent, for the E-field RMS value, to $E_{ref}=42 \text{ V/m}$ for GSM900 and $E_{ref}=58 \text{ V/m}$ for GSM1800.

Average values for GSM packets measured in location 2 (fig.1), at a later date, are given in table II. The location of the measurement is very central in the city. In table II, ER is the exposure ratio ($=E^2/L^2$ where L is the E-field limit given in standard). The values were obtained by “peak/average” menu of RFEX software, the averaging being made on 6 minutes of continuous scan. The scans alternatively changed from packet GSM900 to packet GSM1800. One can see from table II that the field levels are very low comparative to the reference levels. In figure 3 – a,b, a sample of the spectrum of measured GSM signals is given. Figure 4a shows a comparison of the prevalence of the two RF signals measured in location no. 2 as average exposure quotients (% of ICNIRP limits). In figure 4b, exposure quotients are represented for all significant RF signals present in the environment at the position of location no. 2. We used the prefigured packets with afferent settings offered by RFEX software itself for the measured bands. From fig. 4 one can outline that GSM 900 contribution is not much higher than “UKW” band or than “All 200M” band. In fact “UKW band” and “All 200M” band are the same, but have different analysis settings. “UKW band” covers frequencies between 87.6 – 106.3 MHz, with the following settings: Trace Mode / Detector: Max Hold / RMS, RBW=100kHz, Span=7.5 MHz, Dwell time=1000ms, while “All 200M” band covers emissions in the 88-106 MHz band, with the following settings: Trace Mode / Detector: Max Hold / RMS, RBW=300kHz, Span=45MHz, Dwell time=250ms. From histograms corresponding to the two similar packets, it is obvious how important the settings are, concerning field level assessment.

Table II: Values of average E-field RMS values for GSM signals in location no.2 from fig.1 and afferent exposure ratios:

Packet	Total Field (RMS) [V/m]	Total ER * 1000 [%]
FSH3 GSM1800 bis	0,1224	0,0044
FSH3 GSM900	0,2815	0,0443
Sum	0,3070	0,0486

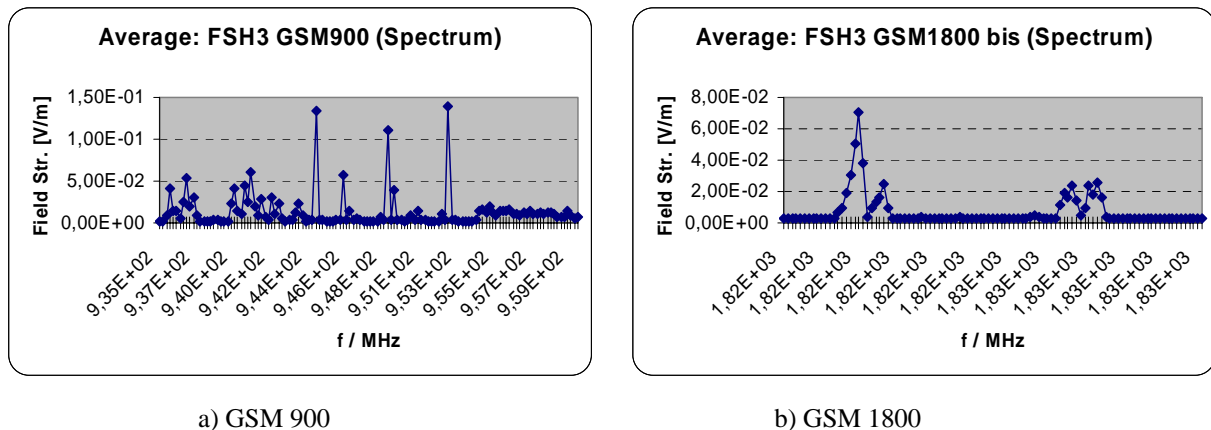

Figure 3 – Spectrum of averaged values of GSM signals measured in location no. 2

Average values of total field and total exposure ratios for measured packets from above are given in table III. Here one observes a significant difference of the values corresponding to first and last line of the table respectively, which is solely due to system settings, and once more outlines the findings presented in part A of current section of the paper.

Generally, the existence of a large number of scatterers and absorbing objects around leads to a highly non-uniform field distribution in the environment of BTS antennas, due to shadowing and fast fading effects. Houses, trees, cars and other objects lead to field variations that can only be determined by very large measurement campaigns. The buildings cause a strong shadowing effect so the field distribution is very heterogeneous [15] – [17].

a) GSM bands comparison

b) all RF signals comparison

Figure 4 – Histogram with exposure quotients (% of ICNIRP limits) corresponding to different RF signals measured in location no. 2

Table III: Values of average E-field RMS values for various RF signals measured in location no.2 and afferent exposure ratios:

Packet	Total Field (RMS) [V/m]	Total ER * 1000 [%]
FSH3 AIL_200M	0,1568	0,0325
FSH3 GSM1800 bis	0,1309	0,0050
FSH3 GSM900	0,2941	0,0483
FSH3 TV UHF	0,0615	0,0028
FSH3 TV VHF III	0,0000	0,0000
FSH3 UKW	0,1876	0,0466
Sum	0,4089	0,1351

Time evolution of radiated GSM signals was also studied (long term measurements). Two examples are illustrated in figure 5 a,b, where traffic variations and trend in daytime, as a function of hour, can be seen for two indoor sites, situated between 300-500m distance from BTS antennas. For fig. 4a, the measuring location was location no. 2 from fig. 1. The field values are again far beyond ICNIRP references.

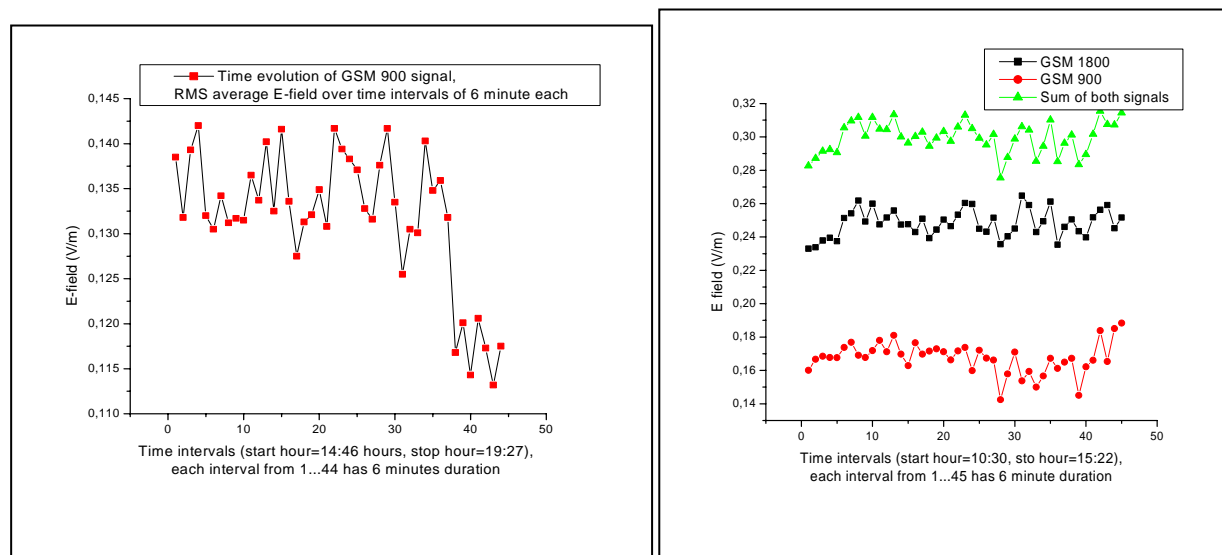

Figure 5 – Time evolution of GSM signals: a) GSM900, measured between hours 14:46 and 19:27 in one indoor location; b) GSM900, GSM1800 and sum of them, measured between hours 10:30-15:22, in a second indoor location

Other indoor measurements were made in some sensitive sites, for both GSM signals and also for other RF signals in the environment. In indoor conditions (inside buildings), the field distribution is even more complicated. It may happen that inside a room volume, the E-field strength of a GSM broadcast channel (BCCH) alone, which operates permanently and on the same power, to vary from point to point inside the room as much as +8 to -10 dB from the average value. So a single measurement is completely non-representative for the exposure scenario. Field variations versus time caused by changes of the power of traffic channels, the stability of BCCH's or moving scatterers have to be taken into account in order to determine their contribution to the uncertainty of exposure assessment [18]. The search for maximum field level is a very crucial point, because of the need of comparison to the limits given in exposure standards. The reproducibility of identified maxima is one of the largest problems, due to field variations in time and space. In this context it is important to say that the selection of the location for performing measurements is very important.

A challenging vista with regard to human exposure is nowadays the wireless devices technologies used in homes and offices. Several new wireless connectivity standards and technologies, e.g., DECT, Bluetooth, IEEE 802.11, may be interesting to be evaluated from human safety point of view. In present paper we assessed a DWL-2100AP 2.4GHz (802.11g) Wireless Access Point connected to the ANT24-1201 Outdoor antenna (figure 6). The antenna is mounted on the window frame of an educational institution, as seen in figure 6 and has a peak output power of 100mW. We measured the field level in the far field of the antenna, indoor, starting at a distance of 2 m of it. As in other cases, a non-predictable distribution of the E-field was achieved inside the classroom, all the values complying with the ICNIRP reference levels. At distance $d=2\text{m}$ from antenna, average field value over 12 minutes was $E=0.21\text{V/m}$, representing an $ER=0.01\%$. A measurement sample spectrum for the antenna is presented in figure 7, in a position at a distance $d=3\text{m}$. The settings for these measurements were: Trace Mode / Detector: Max Hold / Max peak, RBW=1000kHz, Span=150 MHz, Dwell time=1000ms. Total field strength for the single measurement in fig. 7 was 0.29V/m , and $ER=0.02\%$.

Access Point

Figure 6 – Measurement of indoor field emitted by a 8011.g technology wireless access point antenna type ANT 24-1201.

A local radio broadcasting antenna radiation, placed in a residential zone, was measured in the neighbourhood zone, as seen in figure 8a. The Field Nose system was used this time. FM broadcasting antenna was placed on a tower at about 30m above the ground. The emitted frequency was $f=103.2\text{ MHz}$. The system settings were: frequency band=80 to 120 MHz; max peak detector; RBW = 100KHz; sweep rate= 40MHz/s; reference level=-20 dBm. Measurements were made at 2 different heights above the ground, at 1.7 and 1.2 m respectively, at a distance of about 50m from broadcasting antenna. E-field strength value for the two positions were: $E_1=2.2\text{ V/m}$ and $E_2=2.6\text{ V/m}$ respectively. Spectrum of the total field at 1.7 m height is represented in fig. 8b. The reference

level in ICNIRP guideline for this frequency is $E=28\text{V/m}$. In these conditions $ER \approx 10\%$ and we can conclude that this case represents one of the highest exposures measured during present session. Cumulating with other RF sources emissions could conduct to non-negligible exposure but still considerably under ICNIRP limits.

Figure 7 – Spectrum and histogram of E-field strength for wireless point outdoor antenna

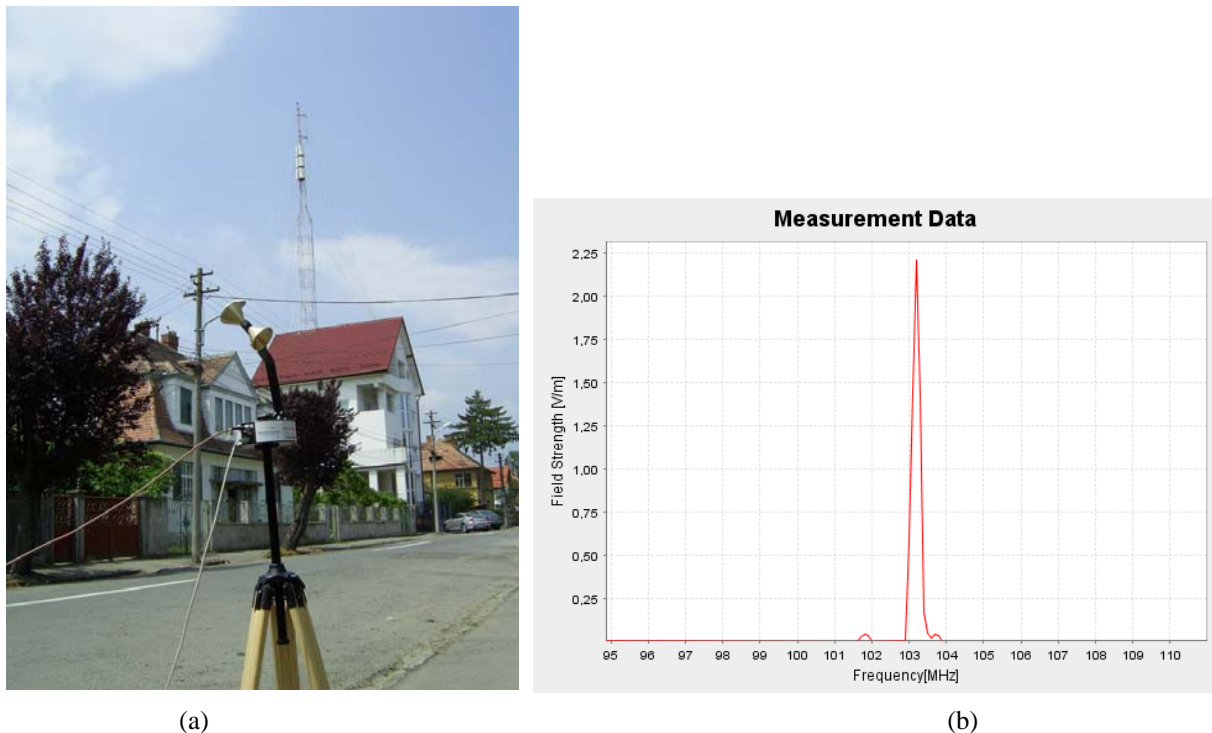

Figure 8 – RF broadcasting antenna measured by Field nose system: a) position in respect to emissive antenna; b) total E-field spectrum in a position at approx. $d=50\text{m}$, and at 1.7 m above the ground.

Conclusion

Risk perception accentuated in the last period in Romania in connection to RF sources emissions, and especially to BTS antennas. We consider that perceived risk differs from the assessed risk, in that it may more readily be manipulated. On this basis, at the level of accredited institutions it became obvious the need for measurement campaigns. Systematic studies to evaluate individual exposure of different parts of the population are needed. In this regard, at the level of each county, specific measures were taken, starting with financial support of measurement campaigns and ending to risk communication. However, fears exist that precautionary measures may undermine the scientific basis for the established exposure limits. In this view, precautionary measures for EMFs should be adopted only with great care. The national Agency for Consumer's Protection demanded all Local Town Councils to refuse further sitting of BTS antennas on blocks or residential roofs. The same agency prepares a well documented file on the issue and the Public Health Direction and Institutes were designated to apply specific measures for exposure assessment and reduction.

Results of present study showed the importance of a refined measurement methodology from the perspective that frequency and/or signal specific exposure recently turned out to be relevant, so exposure due to base stations might be important. Biological relevant exposure circumstances are of great interest in our opinion. Contributions from other RF sources have also to be taken into account. The reduce-scale campaign we developed in and around one single town in Romania, showed that RF exposure of citizens is reduced reported to regulations limits. A key concern across the epidemiological or health-related studies should be the quality of assessment of RF exposure. Despite the ubiquity of new technologies using RF, little is known about population exposure from RF sources and even less about the relative importance of different sources.

Abstract

In this study young plantlets, obtained from the control and microwave irradiated seeds, were studied in laboratory experiments. The electromagnetic radiation with the frequency of 10.8GHz was generated by a microwave generator, based on a rectangular waveguide. The effective incident power was measured to be of 5.2mW. The *maize* seeds with uniform genophond were irradiated one at a time inside the irradiation waveguide, by means a Teflon cuvette, with different exposure times. After germination the young plantlets growing was conducted in the same controlled laboratory conditions and the culture medium of young plantlets was daily the same amount of deionized water. The length of the 12 days plantlets was measured as well and statistical analysis was performed on the data. Assimilatory pigments and average nucleic acid level were assayed of 12 days old plantlets, by spectrophotometric methods and using a Perkin - Elmer UV-VIS spectrophotometer. The data provided by the chlorophylls ratio (chlorophyll **a** / chlorophyll **b**) measurement offered the main insight into the photosynthesis complex processes since they revealed the response of the LHC II system (Light Harvesting Complex II), associated to the photosynthetic system II from the tylakoidal membranes, to the external stress. For chlorophylls ratio a slight stimulatory effect was noticed for shorter time exposures, suggesting putative stimulation of photosynthesis process. The same effect was registered to average nucleic acid level.

Keywords: low power microwave, *maize*, plants growth, photoassimilatory pigments, nucleic acids.

Introduction

The effect of electromagnetic microwave irradiation on agricultural crops has scarcely been studied yet. For decades a great variety of living beings have been used by researchers in order to detect possible changes in ecosystems. Thirty years ago two Canadian researchers observed a deterioration that was unpredictable on the plants subjected to microwaves (Tanner and Romero-Sierra) [1].

Some studies on the effect of microwave irradiation (2.45 GHz) on seeds were conducted and detected an enhanced rate of germination [2-4]. Bhaskara Reddy *et al.* [3-4] used the microwave range (2.45 GHz) on seeds of charlock, wheat, soybeans, peas and rice with the aim of pre-storage destroying. Yoshida *et al.* [5-7] used microwave radiations (2.45 GHz) on soybean, peanut and sunflower seeds for improving the triglycerides distribution in the seed. Studies on the effect of electromagnetic irradiation of the microwave range on seeds have also been conducted by Aladjadjian *et.al.* [8] and Kalinin *et.al.* [9].

Recent experiments have shown that exposure to radiation emitted from a global system for mobile communication (GSM) telephone followed by calcium deprivation, leads to meristem production in flax seedlings [10]. To investigate the possibility that plants may be affected by exposure to a frequency in this range some investigators used radiation with 105 GHz frequency at non-thermal levels by a Gunn oscillator [11].

As well known, photosynthesis is a very complex phenomenon resulting in the transformation of solar electromagnetic energy into chemical energy, stored in organic compounds, synthesized from inorganic carbon and water. The study of assimilatory pigments from plant green tissue is able to provide information upon the capacity of solar energy conversion at the level of chloroplast membranes, during photosynthesis.

In this paper the authors present some quantitative observations of microwave radiations exposure influence of seeds on the growth of *Zea mays* (maize) agrotechnical plants.

Materials and methods

Young plants, obtained from the control and microwave irradiated seeds, were studied in laboratory experiments. The electromagnetic radiation was generated by a microwave generator, based on a rectangular short-ended waveguide. The microwaves were generated as 10.8 GHz continuous waves modulated by rectangular pulses with a duty factor of $\frac{1}{2}$ at a repetition frequency of 1.75 kHz. The effective incident power was measured to be of 5.2 mW. The absorbed microwave power inside the cuvette was estimated at 0.20 mW, corresponding to an average specific absorption rate of 1.33 W/kg. The *maize* seeds (plant species with major role in people life) with uniform genophond were irradiated one at a time inside the irradiation waveguide, by means a Teflon cuvette, with different exposure times. Batches of 30 seeds were irradiated for 5, 10, 15, 20, 40, 60 and 120 minutes. The irradiated seeds germinated in deionized water on porous paper support, in darkness and closed Petri dishes. After germination the young plantlets growing was conducted in the same controlled laboratory conditions (temperature (24°C), illumination (10 h: 14 h light/dark cycle) and 90% humidity) and the culture medium of all young plantlets groups was daily the same amount (10ml) of deionized water.

The length of the 12 days plantlets was measured with 0.1 cm precision as well and statistical analysis was performed on the data.

After 12 days of plantlets growth, spectrophotometric assays were accomplished: the content of chlorophyll a and chlorophyll b and total carotenoid pigments (Meyer-Berthenrath's method modified by Știrban [12]) and the average content of nucleic acids (Spirin's method [13]). The spectral device was a Perkin-Elmer spectrophotometer UV-VIS provided with quartz cells.

Green tissue harvested, from each exposed and control sample (mixture of green tissue picked up from all the 30 plantlets), was weighted, crushed and mixed with the same volumes, of 85% acetone in deionized water for the assimilatory pigments extraction [12] and 6% perchloric acid for nucleic acid extraction [13], being further quantitatively transferred into quoted glass tubes.

The levels of chlorophyll a, chlorophyll b and total carotenoid pigments may be calculated with the next formulae according to [12]:

$$\begin{aligned} \text{chla} &= \frac{12,3 \cdot A(663) - 0,86 \cdot A(645)}{1000 \cdot d \cdot w} \cdot V, \\ \text{chlb} &= \frac{19,3 \cdot A(645) - 3,6 \cdot A(663)}{1000 \cdot d \cdot w} \cdot V, \\ \text{t.c.} &= \frac{10 \cdot A(472)}{2485 \cdot d \cdot w} \cdot V, \end{aligned}$$

while the average content of DNA and RNA is given by the relation [13]:

$$[\text{AN}] = \frac{E(270) - E(290)}{0.19} \frac{V}{w}$$

where: w-the fresh vegetal sample mass, V-the extract volume; $A(\lambda)$ -the light absorption to the wavelength λ ; d-the quartz cell width.

Three repetitions of each spectrophotometric assay have been accomplished. Statistic analysis was accomplished by means of average values, standard deviations and *t*-test (two tails, pair type) considering the significance criterion of 0.05.

Results and discussions

The average lengths and the standard deviations were calculated for each batch of test seeds. The confidence interval was calculated for every batch of plantlets using the Student test, for the confidence level $P = 90\%$. In Fig. 1 average plantlets length for control and microwave exposure samples is presented.

The average values of plants length are enhanced proportionally to the microwave exposure time – a linear regression curve with correlation coefficients R^2 about 0.9561 was found.

Fig.1. The average length versus microwave exposure time

The contents of photosynthesis pigments (**a** and **b** chlorophylls and total carotenoids) in the green tissue of young maize plantlets (aged of 12 days) for experimental samples in Fig.2 are presented. For all exposure times all three pigments present averaged values ranging around control values, i.e. small enhancements or small diminutions, with statistical significance for short exposure times (5; 10 and 15 minutes) while for longer exposure times (15; 20; 40; 60 and 120 minutes) the statistical analysis no revealed statistic significance. Similar response at microwave irradiation of seeds was get for the all three assimilatory pigments analyzed.

Fig.2. Assimilatory pigments level in *maize* plantlets versus microwave exposure time (chl a –the content of chlorophyll a, chl b-the content of chlorophyll b, t.c.-the content of total carotenoid pigments)

The total assimilatory pigments contents have the same variation to the increase of the microwave exposure time that was observed for chlorophyll **a** level. Very good linear correlations were revealed between pairs of pigments level (Fig.3). These results can be taken as an indication upon the correlated influences of microwave radiation in the all: chlorophyll **a**, chlorophyll **b** and the secondary carotenoids like pigments. As known chlorophyll **a** molecules represent the main photosynthesis pigment, able to control directly the solar energy conversion into chemical form while carotenoids are playing very important role in the sustaining of photosynthesis efficiency, by indirect energetic transfer of the absorbed energy to chlorophyll **a** molecules. Concluding on these results, all analyzed assimilatory pigments had similar variations versus microwave irradiation times.

Fig.3. Linear correlation between chlorophyll a, chlorophyll b and total carotenoid pigments levels
(chl a –the content of chlorophyll a, chl b-the content of chlorophyll b,
t.c.-the content of total carotenoid pigments)

The best indicator upon the photosynthesis process efficiency is considered the chlorophylls ratio (chlorophyll a / chlorophyll b) [14] which provides indirect information on the enzymatic aggregates of the **Light Harvesting Complex II (LHC II)** from the photosynthetic system II located in the chloroplasts membranes. In Fig.4 a slight stimulatory effect can be seen for shorter microwave exposure time to photosynthesis process, as suggested by chlorophyll a and b ratio; inhibitory effect is obvious for the highest microwave exposure time. The ratio chlorophyll a / chlorophyll b was enhanced with 6% for shorter microwave exposure time sample and diminished with 15% for higher microwave exposure time.

Fig.4. The effects of microwave exposure of seeds on chlorophylls ratio in 12 days old plantlets

The average content of nucleic acids (DNA and RNA) in young *maize* plantlets provided by microwave irradiated seeds, after 12 days of grown is presented in Fig.5. A stimulatory influence of microwave exposure on the biosynthesis of nucleic acids was revealed for low exposure times (to 14% for 20 minutes microwave exposure sample) while for the higher microwave exposure time an inhibitory effect (35%) than control was observed. Applying the *t*-test to compare control and test sample, data for the average nucleic acid level have revealed statistic significance ($p < 0.05$) for all exposed samples.

Thermal as well as non-thermal effects of microwaves interaction with seeds are supposed to underlay these modifications.

Fig.5. The average nucleic acid levels in *maize* plantlets provided by irradiated seeds

The electromagnetic energy of the microwave absorbed photon is six orders of magnitude lower than that of chemical or even hydrogen bonds needed to break down. So, the absorption of a microwave photon cannot break these bonds [15]. But, more complex indirect phenomena, possible within cellular complex structures may occur, that finally can lead to the plants growth disturbing. Maybe the accumulation of oxygen radicals is the primary cause, as they are suspected for dissociating the covalent bonds of DNA [16] when water molecules are adsorbed on the surface of large bio-molecules within cellular medium.

Summary

In summary, in this experimental study regarding microwave radiation with 10.8 GHz frequency influences upon maize seeds, observed on the 12 days old plantlets derived by irradiated seeds, a very slight stimulation of the photosynthesis process was revealed by means of chlorophylls ratio (to 6% increasing) in the case of shorter microwave exposure time. For the higher microwave exposure time the chlorophylls ratio was diminished with 15% than control. Also, a stimulatory influence of microwave exposure on the biosynthesis of nucleic acids was revealed for low exposure times (to 14%) while for the higher microwave exposure time an inhibitory effect (to 35%) than control was evidenced. The low power microwave treatment of seeds has revealed that *maize* young plantlets development may be slightly affected during their first twelve days of growth.

In fact the complexity of plant growth phenomena can not be evaluated only by means of the chlorophylls and carotenoids or nucleic acids behavior but also by considering the enzymes activity, the capacity of water accumulation and so on. It is designed that our further experimental projects to be focused on the diversification of the investigation methods able to provide data regarding the plant electromagnetic sensitivity in the range of microwave exposure parameters tested inhere.

Based on the fact that such microwave exposure can often occur in natural plant populations but no phenotypic changes are reported regarding the perturbation of the main biological patterns, the presumption that the recover mechanisms are also activated following the microwave exposure is a challenging issue.

Abstract

A total of 200 female Donryu rats at 11 weeks of age were randomly divided into 10 groups of 20 rats. Animals in 8 groups were given 0 (olive oil: vehicle only), 10, 20, 30, 40, 50, 60 or 70 mg/kg body weight of 1-propyl-1-nitrosourea (PNU) by oral administration, 5 days a week for 5 weeks. Animals in other 2 groups were given 300 or 350 mg/kg body weight of PNU, once a week for 5 weeks. They were observed for 30 weeks after PNU administration. Except for dead animals due to acute PNU toxicity during PNU injection period and the first 2 weeks of observation period, the cumulative proportions of dead animals and animals with leukemia in 0, 10, 20, 30, 40, 50, 60, 70, 300 or 350 mg/kg of PNU-injected groups were 0.0, 0.0, 0.0, 10.5, 40.0, 47.4, 73.7, 80.0, 22.2, 27.8% and 0.0, 0.0, 5.0, 10.5, 10.0, 21.1, 63.2, 80.0, 27.8, 27.8%, respectively. Main cause of death was erythrocytic leukemia. The incidence of myelocytic leukemia, which we intended to induce mainly, was low and 5.0, 16.7, 22.2% in 20, 300 and 350 mg/kg of PNU-injected groups, respectively. Body weight gain during observation period showed that PNU toxicity was lower in 300 mg/kg group than 350 mg/kg group. Based on these results, administration of 300 mg/kg body weight of PNU, once a week for 5 weeks was selected for initiation method. 50Hz magnetic field exposure study of up to 350 μ T_{rms} is now in progress.

INFLUENCE OF LOW-FREQUENCY MAGNETIC FIELD ON ENZYME ACTIVITIES OF STREPTOZOTOCIN- INDUCED DIABETIC RATS

The effects of magnetic fields seem to depend on their respective codes (frequency, intensity, and waveform). The aim of the present study is to examine the effects of magnetic field on changes of glucose, lipid levels and activations of alpha-amylase and lipase enzymes in diabetic rats that were different exposed durations to magnetic field. The rats were first divided into two groups. The first group (30 rats) was made up diabetic control group (D_I, D_{VII} and D_{XIV}), the second group was comprised of rats described as diabetic-exposed to magnetic field groups (DMF_I, DMF_{VII} and DMF_{XIV}). Diabetic (D) and diabetic-exposed to magnetic field (DMF) groups were made up adult male Wistar Albino rats (60 rats). DMF groups (30 rats) were exposed to magnetic field for thirty minutes per one, seven and fourteen days. The combinations: of alternating modulated magnetic fields were set up 5 mT intensity, 50 Hz frequency and oriented north-south direction. Also, diabetic groups of adult male Wistar Albino rats (30 rats) were treated in identical fashion to the exposed rats, except that the magnetic field was switched off.

The end of first, seventh and fourteen days, blood of rats in diabetic-exposed to magnetic field and diabetic groups was collected under ether anesthesia for biochemical parameters, activations of enzymes and ion concentrations. The end of 1 st day that in diabetic-exposed to alternative magnetic field groups, while serum glucose and lipid levels were changed, changes of ion concentrations were changed end of seventh and fourteen day; increased serum K⁺ and decreased serum Ca²⁺ concentrations.. In addition, activations of enzymes were no changed in diabetic rats exposed to 14 days magnetic field. Data are significantly (p<0.05). The effects of magnetic field in diabetic rats depend on exposed-duration to magnetic field. The changes of activations of enzymes of ion concentrations were depended on combinations of magnetic fields as exposure duration, intensity and directions. We observed different affected activations of enzymes and ion concentrations in diabetic-exposed to magnetic field according to exposed duration of magnetic field. The results indicate that an alternative magnetic field may positively affect diabetic rats in respect of blood serum parameters, depending on exposed duration of magnetic field

Key Words: Diabetic rats, alpha-amylase enzyme, Magnetic field, exposure duration to magnetic field.

Introduction

Numerous experimental findings suggest that exposure to extremely low-frequency (ELF) magnetic fields (MFs) affects various cell functions via actions exerted on intracellular and membrane proteins; including ion channels, membrane receptors and enzymes (1,2).

Diabetes has profound effects on the metabolism of various tissues, including vascular smooth muscle. Both glycolysis and glucose oxidation are decreased in diabetic animals and there is an overall decrease in ATP production (3). One mechanism that may contribute to this disturbance in tissue metabolism is the elevation of long-chain fatty acid levels (4,5). Recent investigations revealing that after exposure to magnetic fields, insulin release and glycogen levels are increased in diabetic rats and the blood glucose level is decreased provided the stimulus for the current studies. (6,7). Similar results were recorded in other studies (8-10). Goodman et al has been suggested that an electromagnetic field affects the movement of Ca²⁺ ions across membranes and has

effects at the gene level, but the mechanism of the MF effect is not yet clear (11,12). A recent study revealed ultrastructural changes in β cells, with indications of extension of the rough endoplasmic reticulum and significant expansion of the Golgi apparatus, in a group of rats exposed to a magnetic field (13). The rats used in this research had body weights of 284.4 ± 12.6 g: 35 were put into a sinusoidal magnetic field with frequency 10 Hz and intensity 1.8-3.8 mT; 35 were put into a sinusoidal magnetic field with frequency 40 Hz and intensity 1.3-2.7 mT for 30 minutes per day for 1, 3, 6, 9 and 14 days. It was thought that the expansion of the Golgi apparatus might relate to storage of increased amount of proinsulin in the form of small vesicles (14). The special granules around the site might indicate insulin storage by the β cells; they are affected by the magnetic field. On the other hand, electron-transparent vesicles in the β cells may indicate an intensification of hormone secretion after the oscillation of the insulin granules (13, 14). Finally, the reversible structural changes in β cells that occur depending on the magnetic parameters may increase insulin oscillation and synthesis.

A low intensity magnetic field has been used to treat late complications of diabetes such as diabetic retinopathy, diabetic angioplasty and peripheral neuropathy (15). In almost all the patients receiving this treatment, complaints of intestinal motor activities and pain disappeared and laboratory markers were normalized; magnetic therapy was further suggested for the treatment of juvenile diabetes (16,17). These studies on the effects of electromagnetic fields on living systems led us to investigate whether such fields may be used for treatment. For these reasons, we undertook this study to determine the effects of exposure to alternating modulated magnetic fields on blood parameters and activation of enzymes in diabetic rats.

Material and Method

Experiments were conducted on 60 male Wistar albino rats aged 5 months, weighing 245-300g. The experimental protocol was approved by the Animal Ethics Committee at Cukurova University. Firstly, animals were divided into two groups: control diabetic (D_I , D_{VII} and D_{XIV}) and diabetic-exposed to magnetic field groups ($D-MF_I$, $D-MF_{VII}$ and $D-MF_{XIV}$). We injected 45 mg/kg streptozotocin (STZ) in citrate buffer (CB) (pH 4.5) into the tail veins to induce diabetes (D group). A similar volume of CB solution without STZ was injected into control rats (S group). Then, animals were exposed to magnetic field between 09:00 and 09:30 or 13:00 and 13:30 h for one, seven and fourteen days to control for possible circadian variations in response. Rats in the D-MF groups were exposed for thirty minutes per day to alternating modulated magnetic fields of frequency 50 Hz, intensity 5 mT

Rats in the control or sham diabetic groups were treated in exactly the same fashion as the exposed rats, except that the magnetic field was switched off. The rats in each group were allowed to roam freely in the cage irrespective of exposure to the MF. They were fed a standard rat chow and tap water *ad libitum* and kept in an environmentally controlled room at 21-23°C, relative humidity 40-60%, with a light/dark cycle of 12/12 h.

The end of exposure period of one, seven and fourteen days, serum glucose and lipid levels were determined to indicate any relationship with diabetes mellitus. The serum was used to determine levels of glucose and lipids K^+ and Ca^{2+} concentrations, activations of α -amylase and lipase enzymes.

All values were expressed as means \pm SEM. Levels of glucose, K^+ and Ca^{2+} ion concentrations and activations of enzymes were compared between diabetic and diabetic-exposed to magnetic field groups by 2-way ANOVA. Statistical significance was assumed at $p < 0.05$.

Results

The mean values of serum glucose and lipid levels of rats in three groups were significantly decreased after diabetic rats were exposed to magnetic field during one, seven and fourteen days, compared to those of the rats (glucose: D_I 259.8 \pm 5.1 mg/dl, DMF_I 257.2 \pm 7.1 mg/dl, D_{VII} 240.6 \pm 10.1, DMF_{VII} 190.2 \pm 2.7 mg/dl, D_{XIV} 239.4 \pm 3.8 mg/dl; DMF_{XIV} 176.6 \pm 1.2 mg/dl) The mean values \pm SEM of the other lipid levels were shown in Table1. When K^+ and Ca^{2+} ion concentration in serum of rats in diabetic-exposed to magnetic field groups were compared to control diabetic rats, we were measured decreased Ca^{2+} ion concentration in end of the fourteen days and increased K^+ ion concentration in end of the seven days according to intensity or density of diabetic (Table 2, Fig1,2).

There were no significant difference activations of α -amylase or lipase enzymes of rats between diabetic and diabetic-exposed to the magnetic field groups. (Table 2, Fig3,4).

Table 1. Serum parameters (glucose, cholesterol, triglyceride, HDL and LDL (mg/dl)) of rats were measured by enzymatic techniques in diabetic and diabetic-exposed to magnetic field groups (mean \pm SEM).

Serum Parameters	Groups					
	D _I	D-MF _I	D _{VII}	D-MF _{VII}	D _{XIV}	D-MF _{XIV}

Discussion

Data from this study show that exposure duration of magnetic field can interact. In diabetic-exposed magnetic field one day, no significant change in blood parameters was observed in glucose, lipid and enzymes activities. The plasma glucose, lipid and cholesterol levels were slightly decreased in the D-MF group compared with the D group. These results might indicate a transiently healthy response by rats to the alternating modulated magnetic field. The decrease in plasma glucose was statistically significant ($p < 0.05$). The MF may cause an increased synthesis and oscillation of insulin. Therefore, MF is expected to decrease the glucose level and increase the glycogen level (7,18-21) Oroza et al. 1987 found similar results. They suggested that the magnetic field slowed down the fat metabolism of the rats and so decreased the levels of glucose and lipid. If the magnetic field increases the synthesis and oscillation of insulin, as Laiti-Kobierska et al. 2002 suggested, then there may be a decrease in the blood glucose level in the diabetic rats. Epidemiological studies have indicated that MFs can also induce adverse health effects. Other studies have yielded important clues to the interaction between MF and cellular systems, particularly at the molecular level. Laiti-Kobierska et al. 2002 identified granules in the β cells of rats exposed or not exposed to a magnetic field; these granules were called special granules. On the other hand, there were inflated mitochondria and expanded endoplasmic tubules in the pancreatic acinar cells. These authors suggested that the observed changes occurred because of the magnetic field and were related to increased

synthesis and oscillation of insulin (13). If the special granules stimulate insulin synthesis, then decreased lipid and glucose levels are to be expected.

Chernysheva suggested that if the rats were exposed to an alternating magnetic field for 5 hours a day, the concentrations of cholesterol esters, triglycerides and free fatty acids decreased, so there was an increase in lipid catabolism and energy production (10). In addition, they observed that magnetic fields change the velocity, flow and direction of particles in biological systems, with impacts on the transport/charge system depending on shape, frequency, intensity and exposed duration (10). The decrease in plasma glucose, total cholesterol and triglyceride levels may be attributed to the retardation of lipid metabolism as suggested by Hefco et al, or to the increased synthesis and oscillation of insulin in the β cells as Laiti-Kobierska et al. 2002 suggested (13,22). Byus et al. and Blank et al. realized that there was an increase in the concentration of Na^+ - K^+ ATPase, effected through changes in intracellular Ca^{2+} . One of the most obvious candidates is the calcium ion. Changes in calcium concentration may influence the interaction with calmodulin, activate the protein kinase C, or act directly on the activity of intracellular enzymes. Other signal transductive candidates may membrane receptors whose interactions with G-proteins are modified by MF stimulation or ligand-gated channels that are acted upon by the fields. These findings might be attributed to complicated mechanisms. Further studies are required to show the effect of MF on intracellular Ca^{2+} ions and their movements, and on enzyme levels. Diabetes affects many mechanisms causing different complications at different stages of the disease. The apparently healthy response of the exposed rats might be consequent on a temporary recovery in hormonal regulation caused by the magnetic field, which may be a stress-generating factor. Therefore, we need to identify the mechanisms affected by the diabetes and the magnetic field and further studies are needed for this purpose. The mechanism of action of alternating magnetic fields on biological systems at the cellular level is under investigation.

Abstract

Endothelium-dependent and independent derived responses are diminish in some diseases, including hypertension, preclampsia and some models of diabetes. A study of the effects of weak, modulated sinusoidal low frequency electromagnetic field stimulation in changes in membrane potentials of the rat aorta in diabetes was carried out. Forty rats (n=40, Wistar albino spp) weighing between 220-300g were used in this study. The rats were first divided into four groups. The first group was made up of the citrated rats or sham (S, n=10), the second group was comprised of rats described as sham or citrated+magnetic field group (S-MF, n=10), third group contained experimental diabetic rats (D, n=10), and the fourth group was comprised of both experimental diabetic+magnetic field group (D-MF, n=10). Magnetic fields of 5 mT intensity and 50 Hz frequency oriented in the north-south direction was applied to the S-MF and D-MF groups for 2 hours and 45 minutes at each day during one month.

After one month, Rats were killed by decapitation. After the thoracic aorta preparation isolated, excess fats and/or connective tissues were removed. For measurement of smooth muscle membrane potential, arter was cut open longitudinally and pinned to the bottom, endothelial surface uppermost. Tissues were maintained at 37 °C and constantly perfused with Krebs buffer at a rate of 2 ml min⁻¹. Measurements of membrane potential were made sharp glass microelectrodes, back-filled with 3 M KCl and with resistances of 60-100 M Ω. All data were recorded through a Nihon Kohden instruments.

The negative of membrane potential of aorta in diabetes was significantly increased compared to control animals. One of the most obvious candidates is the calcium ion. Changes in calcium concentration may influence the interaction with calmodulin, activate the protein kinase C, or act directly on the activity of intracellular enzymes. Other signal transductive candidates are membrane receptors whose interactions with G-proteins are modified by EMF stimulation or ligand-gated channels that are acted upon by the fields. This knowledge could provide the basis of novel therapeutic inventions in the amelioration or prevention of vascular complications of these diseases.

Key words: Magnetic field, diabetes rat, rat aorta, resting membrane potential

Introduction

Macro and microvascular disease are currently the principal causes of morbidity and mortality in patients with type I and type II diabetes mellitus. Loss of the modulatory role of the endothelium may be a critical and initiating factor in the development of diabetic vascular disease. Microvascular disease is the main cause of morbidity and mortality in patients with diabetes Mellitus (DM). Endothelial dysfunction may be a critical and initiating factor to develop diabetic vascular disease (1). Mechanisms that participate in the reduced vasodilatory

responses in endothelial dysfunction include reduced nitric oxide generation, oxidative excess, and reduced production of hyperpolarizing factor.

Vascular smooth muscle relaxation in response to a signal initiated by stimulation of overlying endothelium is known as endothelium-dependent relaxation and involves the release of at least endothelium-derived relaxing factor (EDRF). There appear to be several important EDRFs the most well understood of these being NO and prostacyclin. It is now well established that endothelium-dependent vascular relaxation is often accompanied by K^+ channel-mediated hyperpolarization of the vascular smooth muscle. Because both NO and prostacyclin are known to be able to elicit vascular relaxation, at least in part, through activation of K^+ channels, endothelium-dependent hyperpolarization may often simply reflect part of the mechanism of relaxation produced by NO and prostacyclin.

An important function of all cells is their ability to regulate the movement of ions and macromolecules between the cell interior and its environment using membrane bound protein channels. If (K^+) channel opens in the vascular smooth muscle cell membrane, K^+ efflux increases, causing membrane potential hyperpolarization, closure of voltage-activated calcium (Ca^{2+}) channels, decreased Ca^{2+} entry, and vasodilatation. Biological effects of magnetic fields can be mobility or movement or induce variety of ions of effects in cells and tissues. These biological effects include nerve regeneration, influences on cell calcium levels and bone healing.

The release of endothelium-derived NO by agonists, such as acetylcholine (ACh), is dependent on a rise in intracellular calcium levels ($[Ca^{2+}]_i$) within endothelial cells and activation of NO synthase (NOS). The entry of Ca^{2+} from the extracellular space is required to maintain production of NO (2,3) and several lines of evidence indicate that endothelial cell membrane potential plays a critical role in the regulation of Ca^{2+} entry (4). Ca^{2+} entry is not dependent on voltage-gated Ca^{2+} channel activity, rather it occurs via a nonselective cation pathway and is dependent on membrane hyperpolarization to provide an inwardly directed electrochemical driving force for Ca^{2+} movement (4-7) Ocal et al magnetic field was supported to cause the changing movement of Ca^{2+} ions and direction in aorta rings of diabetic rats (8).

In the present study, we attempted to combine the beneficial properties of MF, which have been proved to be ion flows according to measure resting and 10^{-7} M phenylephrine (PE), 10^{-6} M acetylcholine (ACh) and 10^{-6} M sodiumnitroprusside (SNP)-induced membrane potentials.

Material and Methods

Approval for this study was obtained from local Institution's Animal Care and Ethics Committee. Forty adult white Wistar rats weighing 220 to 300 g were used in this study. The rats were first divided into four groups. The first group was made up of the citrated or sham rats (S, n=10), the second group was comprised of rats described as sham or citrated+magnetic field group (S-MF, n=10), third group contained experimental diabetic rats (D, n=10), and the fourth group was comprised of both experimental diabetic + magnetic field group (D-MF, n=10). We injected 45 mg/kg streptozotocin (STZ) in citrate buffer (CB) (pH 4.5) into the tail veins to induce diabetes (D group). A similar volume of CB solution without STZ was injected into control rats (S group). Then, magnetic fields of 5 mT intensity and 50 Hz frequency oriented in the north-south direction was applied to the S-MF and D-MF groups for 2 hours and 45 minutes at each day during one month.

After the one-month study period, the rats under ether anesthesia before rats were killed by decapitation. After the thoracic aorta preparation isolated, excess fats and/or connective tissues were removed. For measurement of smooth muscle membrane potential, arter was cut open longitudinally and pinned to the bottom, endothelial surface uppermost. Tissues were maintained at 37°C and constantly perfused with Krebs buffer at a rate of 2 ml min^{-1} . Measurements of membrane potential were made sharp glass microelectrodes, back-filled with 3 M KCl and with resistances of 60-100 M Ω . A vessel sample was pinned to the bottom of the recording chamber. Modified Krebs solution had the following composition (mM): 119, NaCl, 4.6 KCl, 1.5 $CaCl_2$, 1.2 $MgCl_2$ 15 $NaHCO_3$, 1.2 $NaHPO_4$ and 11 Glucose. All data were recorded through a Nihon Kohden instruments.

After the resting membrane potentials of rat aorta in each group were measured, ACh, PE and SNP-induced membrane potentials of aorta preparations were measured. ACh, PE and SNP-induced membrane potentials were recorded through a Nihon Kohden instruments.

The negative of membrane potential of aorta in D group was significantly decreased compared to S group. While 10^{-7} M PE-induced negative of membrane potential were decreased in each group, 10^{-6} M-induced membrane potential in D-MF group was enclosed resting membrane potential of D group. Results were significantly ($p<0.05$).

Ultrastructure of thoracic aorta preparation

For histopathology of thoracic aorta preparations of rats, of citrated or sham, sham-exposed to magnetic field, diabetic and diabetic-exposed to magnetic field groups were examined. After opening the abdominal cavity,

Changes in Membrane Potentials of Aorta in Streptozotocin-induced Rats

samples of the thoracic aorta were taken, and after appropriate fixation and preparation were examined ultrastructurally in an electron microscope.

Solutions and chemicals

All drugs were obtained from Sigma Chemical Co. (St. Louis, MO,USA). Stock solutions of phenylephrine hydrochloride (PE), acetylcholine bromide (ACh) and sodium nitroprusside (SNP) were dissolved in distilled water. Streptozotocin was freshly dissolved in 0.1 M citrate buffer (pH 4.5) immediately before use at a concentration of 45 mg/kg; all drugs were obtained from Sigma Chemical Co.

Statistics

All data were expressed as means \pm S.E.M. The statistical significance of all differences between mean values was calculated using Student's paired *t* test or repeated measures ANOVA followed by Tukeys *post hoc* test. A level of $P < 0.05$ was considered to be statistically significant.

Results

Table 1. The mean \pm SEM of 10^{-7} M phenylephrine (PE), 10^{-6} M acetylcholine (ACh) and 10^{-6} M sodium nitroprusside (SNP)-induced membrane potentials.

Experimental Groups	Membrane Potential (mV)			
	Resting	10^{-7} M PE	10^{-6} M ACh	10^{-6} M SNP
S	$-56,2 \pm 1,0$	$-51,1 \pm 0,9$	$-59,2 \pm 0,9$	$-56,1 \pm 1,2$
S-MF	$-53,6 \pm 0,6$	$-48 \pm 0,6^*$	$-57,8 \pm 0,9$	$-51,8 \pm 0,6$
D	$-47,5 \pm 0,6^*$	$-42,8 \pm 0,8^*$	$-43,1 \pm 1,7$	$-46,7 \pm 0,8$
D-MF)	$-43,4 \pm 0,7$	$-36 \pm 0,3^*$	$-43,7 \pm 0,7$	$-44,4 \pm 0,4$

The mean values of negative of resting membrane potential of aorta preparations were significantly decreased in both groups of rats after sham-exposed and diabetic-exposed to the alternating modulated magnetic field groups for four weeks, compared to those of sham and diabetic groups (Table 1, Fig 1). The negative of 10^{-7} M PE-induced membrane potential of aorta in S, S-MF, D and D-MF groups were decreased (Table 1, Fig 2), while negative of the 10^{-6} M ACh-induced membrane potential in S, S-MF, D and D-MF groups were increased (Fig 3). Data were significant ($p < 0.05$).

There was no significant difference between the membrane potentials of aorta preparation of rats in D or S and in SMF or DMF groups that the aorta induced by 10^{-6} M sodium nitroprusside (Fig 4).

Electron micrographs of the thoracic aorta preparations from the S-MF group showed only minimal ultrastructural changes (Fig 5,6). In the D-MF group, however, a decreased density of elastic tissues compared to the D group was apparent after 30 days (Fig 7,8).

Discussion

Changes in EDRF in diabetes have been studied in most detail in streptozotocin (STZ)-induced diabetes in rats. In the rat aorta vessel, negative of resting membrane potentials were significantly diminished compared with membrane potentials of aorta preparations of rats in S group. The mechanisms underlying disease-associated impairment of EDHF-attributed hyper polarization and relaxation are far from clear and require further studies to determine whether the dysfunction arises in the smooth muscle cells and/or the endothelial cells and/or myoendothelial communication. This knowledge could provide the basis of novel therapeutic inventions in the amelioration or prevention of vascular complications of these diseases.

In the resting membrane potential of the rat aorta, negative of resting membrane potential in S group was decreased from -56.2 ± 1.0 mV to -53.6 ± 0.6 mV compared with resting membrane potential of S-MF group. But there was no significant difference between the S and S-MF groups. When the resting membrane potentials of rat aorta in S group (-56.2 ± 1.0 mV) were compared with D groups (-47.5 ± 0.6 mV), negative of resting membrane potentials were increased (Table 1). Data were significantly. Also, negative of resting membrane potentials in D-MF groups were decreased from -47.5 ± 0.6 mV to 43.4 ± 0.7 mV too. Ocal et al were observed the positive effects of low frequency magnetic field on mechanical activities in diabetic rats (8). Magnetic fields may affect movement ions and directions in biological tissues. K^+ channels are critical in maintaining the normal resting membrane potential in a variety of excitable cells. But mechanism of relaxation is no only affected K^+ ion or K^+ ion movements.

In this study, we observed only minimal ultrastructural changes in electron micrographs of thoracic aorta preparations from rats in the S-MF group (Fig 5, 6). However, by the end of the 30th day, ultrastructural changes related to decreased elastic tissue density were seen in the D-MF group compared to the D group (Fig 7,8). Laiti-Kobierska et al. 2002 identified granules in the β cells of rats exposed or not exposed to a magnetic field; these granules were called special granules. On the other hand, there were inflated mitochondria and expanded endoplasmic tubules in the pancreatic acinar cells. These authors suggested that the observed changes occurred because of the magnetic field and were related to increased synthesis and oscillation of insulin (Laiti-Kobierska et al. 2002). Numerous experimental findings suggest that exposure to extremely low-frequency (ELF) magnetic fields (MFs) affects various cell functions via actions exerted on intracellular and membrane proteins, including ion channels, membrane receptors and enzymes (9,10). For these reason, enzymes activities and membrane receptors and as Ca^{2+} the other ions have to examine. One of the most obvious candidates is the calcium ion. Changes in calcium concentration may influence the interaction with calmodulin, activate the protein kinase C, or act directly on the activity of intracellular enzymes. Other signal transductive candidates may membrane receptors whose interactions with G-proteins are modified by MF stimulation or ligand-gated channels that are acted upon by the fields.

Abstract

In this study, temperature rise and Specific Absorption Rate (SAR) induced by 1800MHz microwave (MW) frequency non-ionizing radiation in human brain tissue has been investigated by using brain equivalent liquid. Brain equivalent tissue was exposed to MW radiation of 1800MHz for various time duration within a system allowed positions. As a radiation source, 1800MHz MW generator was used. The brain tissue phantom model was placed in a near field of half wave dipole antenna. A temperature rise in a brain tissue which's equivalent model was exposed to 1800 MHz was measured for investigating a SAR absorbed in brain tissue of human head.

Keywords: MW, Cellular Phone, Brain-equivalent phantom, Temperature Rise, SAR.

INTRODUCTION

During the last years, wireless data and phone networks have become widely used. And especially, adverse health effects of cellular phones and base stations have been discussed. Many international organizations have defined safety limits for exposure to these type communication devices. Adverse health effects of the cellular phones used close to the human body have been especially interested, because of complexity of interaction of RF (Radio Frequency) radiation and human body, and EM (Electromagnetic) fields induced in human head difficulty determinations. Recently, it is possible to find a lot of investigations on this subject in the literature. Whole body SAR (Specific Absorption Rate) limit of 4 W/kg is recommended by international organizations [1]. After applying the safety standards, maximum SAR limits are 0.4 W/kg and 0.08 W/kg for controlled and uncontrolled environment, respectively. European standard of ENV50166-2 is determined SAR limit of 2 W/kg for 10g tissue and 6 minute period in a controlled environment [2]. Heat transfer mechanisms of human body are limited temperature rise for the SAR limit. For general public in Turkey, power density limits of $f/200$ W/m², 10 W/m² and $6.67 \times 10^{-5}f$ are approved in the frequency ranges 0.4-2 GHz, 2-150 GHz and 150-300 GHz, respectively [3].

While theories on the biological effects of EM fields have not been exactly established, there are still insufficient treatments have not been exactly understood, yet. The interdisciplinary investigations have been continued. One of the known basic experimental method was used to investigate thermal effects of EM radiation in tissue equivalent liquids[4]. In this study, the temperature rise in human brain and SAR are investigated by using an equivalent model.

SPECIFIC ABSORPTION RATE (SAR)

SAR is an important quantity in dosimetry which indicates the temperature rise and the absorbed energy by tissue, and other biological events that occur in the tissue depended on internal fields. SAR varies depending on frequency and tissue properties. The effects in the biological tissues depend on the penetrated fields not to the external fields. To determine the SAR in human body and laboratory animals is so important to explain biological effects. There are two basic methods are used to evaluate SAR. They are calculation and measurement of absorbed energy in phantom models. Experimentally, SAR is determined measuring electric field $|\vec{E}|$ induced in tissue or temperature rise $\partial T / \partial t$.

$$SAR = \frac{\sigma}{2\rho} |\vec{E}|^2 = C \frac{\partial T}{\partial t} \quad (1)$$

Where; σ (S/m) is tissue conductivity, ρ (kg/m³) is tissue density, C (J/kg°C) is the heat capacity of tissue (or phantom material) and E (V/m) is the rms value of intensity of the electric field induced in tissue. If the heating time is sufficiently short so that the effect of thermal conduction in the phantom can be neglected, the SAR can be derived from the measured temperature rise as follows[5]. If the temperature rise in tissue is measured, (1) can be arranged as

$$SAR = C \frac{\Delta T}{\Delta t} \quad [\text{W/kg}] \quad (2)$$

Where; ΔT is the temperature rise in °C for Δt second period and C (J/kg°C) is the heat capacity of tissue (or phantom material). From the above, it is found that a temperature rise sufficient for SAR observation can be obtained by low power illumination for a short time if the specific heat of the phantom is small to a certain degree to an advantage in the measurement[6].

MEASUREMENTS

In this study, the brain equivalent tissue suggested by [7, 8] has been prepared and used. The human brain tissue equivalent mixture contains water of 54.90%, salt of 0.18% and Glycol (Diethylene Glycol Butyl Ether) of 44.92%. Electrical parameters of the equivalent tissue have been measured as $\epsilon_r=40.3$ and $\sigma=1.35$ (S/m) using HP4194A Impedance/Gain-Phase Analyzer. The measurement set-up of the temperature rise is shown in Figure 1. Prepared brain tissue equivalent liquid has been put into a spherical pyrex glass bowl that has an outer diameter of 224 ± 0.5 mm and glass thickness 5 ± 0.5 mm. Glycol provides a big easiness to prepare brain equivalent tissue. Evaporation of phantom liquid has been prevented from taking precautions in the measurement period and the measurements have been completed in one week.

The expected temperature rises in the liquid have been measured depending on the parameters of antenna-tissue distance, deepness, exposure time and signal generator output power and logged on a computer. PT-104 Platinum Resistance Thermometer Data Logger measurement system has been used. The system has sensitivity of 0.001°C and accuracy of 0.01°C . RF signal generator has adjustable output power level in the range of 0-2W and frequency in the range of 1800-1900MHz. 1800MHz half-wave dipole antennas has been used in the measurements. The liquid level was equal to 160 mm during all measurement.

Figure 1. The measurement set-up of the temperature rise in the brain equivalent tissue

Measurements have been realized in the isolated box where the change in temperature approaches to zero. The temperature variation in the box has been continuously measured, and it has been logged when its value is approximately $22^\circ\text{C} \pm 0.2^\circ\text{C}$. Considering the radiation characteristics of the half wave dipole antenna, maximum field intensity is expected on the feed point direction. Because of this, temperature rise in the tissue that is on the feed point direction has been measured considering various exposure probabilities.

Temperature Increase in a Phantom Model of the Human Head

Figure 2. Varying in the temperature rise ($^{\circ}\text{C}$) in the brain equivalent liquid at 1800MHz depending on the exposure time period and deepness ($d=13\text{mm}$ and $p=1.5\text{w}$)

The distance to the tissue surface has been adjusted to $d=13\text{mm}$ and the temperature rise generated in the tissue at the distances of $y=3\text{mm}$ and $y=6\text{mm}$ has been measured depending on the exposure time period, as shown in Figure 2. The temperature rise decreases depending on the deepness.

Figure 3. Changing in SAR depending on the distance between the antenna and the tissue at 1800 MHz ($y=1\text{mm}$, $p=1.5\text{w}$, $\Delta t=120\text{sn}$)

Absorbed SAR has been calculated by Equation 2. with the measured temperature rises in the brain equivalent tissue. The SAR calculated at the deepness of $y=1\text{mm}$ at 1800MHz versus the distance between the dipole and the tissue is shown in Figure 3. The specific heat capacity has been chosen as $C=4000$ ($\text{W sec/kg } ^{\circ}\text{C}$) for the SAR calculation. As shown in Figure 3, the SAR absorbed by tissue decreases depending on the distance between the dipole and the tissue like the change of the temperature rise. The temperature rises depending on the various distances, d and exposure time at 1800MHz is shown in Figure 4.

Figure 4. Shows the temperature rises depending on the various distances, d and exposure time at 1800MHz ($y=1\text{mm}$ and $p=2w$)

CONCLUSIONS

The temperature rise generated in the brain tissue does not exceed $0.1\text{ }^{\circ}\text{C}$ at 1800 MHz cellular phone frequency. The cellular phones operated at 1800 MHz cause the temperature rise less than the lower limit value 1°C . The temperature rise curves formed using measurement data are exponential function of the exposure time period. The SAR estimation has also been done depending on the temperature rise in the equivalent tissue using the model in this study. The cellular phones used in close body situation especially the head close usage causes absorbing the high level SAR. An investigations with laboratory animals present an indirect data for human being, and it is clear that the experimental investigations realized using biologic tissue equivalent phantom models provide big easiness. Further investigations on the other biological effects of the cellular phones are required considering thermal effects. Since the knowledge of biological structure and dielectric properties of children have not been exactly revealed, further investigations need to be focused on children.

Abstract

RF radiation values generated Nokia 3210 mobile phone operating 1800 MHz frequency band measured by Electromagnetic (EM) radiation meter during experiment. Male Guinea pigs were exposed to operating mobile phone for 10 minute-periods in 7 days of a week. Average external Electric (E) field measured during exposure was 11.2 V/m. Effects of whole body exposure of 11.2 V/m to collagen synthesis in liver tissue were determined by using three different hydroxyproline level designation methods named H. Stegemann-K. Stalder, I.S. Jamall, V.N. Finell and ISO 3496.

It was observed that the increment found hydroxyproline level due to mobile phone radiation in liver was statistically insignificant. It was detected statistically that the hydroxyproline level designation methods of ISO 3496 is the most accurate way of measuring hydroxyproline level in between the methods used in this research.

Introduction

Since time began until about hundred years ago living beings had to deal with naturally occurring radiation, which somehow was balanced or life was shielded from detrimental parts of that radiation such as certain cosmic radiation. When people began to harness electricity, generate and transport it over long distances a different kind of energy was introduced to our life: AC (Alternating Current) electric, AC magnetic fields and radiofrequency radiation. The superimposition of electromagnetic fields caused by all kinds of electromagnetic radiation that arise in the human environment is known as electromagnetic pollution. Not only is electromagnetic pollution responsible for interference between electrical devices, but it is also affects the human body. The organism reacts to the electrical, magnetic and electromagnetic fields around it. The biological effects depend on the type, frequency and strength of these fields. The boom in the use of the cellular phone has led to a very evident increase in this kind of stress.

Many in vivo and in vitro studies have been performed to investigate the biological consequences and to assess health risks of RFR (Radio Frequency Radiation) generated from cellular phones. Relation between RFR and protein synthesis is still unclear mechanism continuing to investigate.

The connective tissue protein, collagen, is the most abundant protein in higher animals. Collagen also provides the framework for parenchymal organs such as the liver, kidney, and spleen, either in its fibrous form or organized in basement membranes. The rate of hydroxyproline formation is therefore considered to be a good indication of the rate of collagen biosynthesis. The collagen content of a tissue is determined by measuring the content of protein bound hydroxyproline. Hydroxyproline is necessary for collagen helix formation, and in its absence collagen is unable to be properly secreted from fibroblasts (Irvin, 1981; Craig et al, 1975; Takahashi and Lee, 1987).

The connective tissue protein, collagen, is not only abundant but also significant protein in higher animals since it is charged molecule tend to be directed through electric field applied.. In this research, effects of RFR generated by mobile phones on liver tissue collagen examined by using three different hydroxyproline detection methods.

Material and Method

In this investigation, 3 month-old guinea pigs were exposed to RFR radiated from Nokia 3210 mobile phone operated in GSM DCS 1800 MHz. During the exposure of every Guinea pig, external E fields were measured by NARDA EMR 300 and type 8.3 probe. Measurements were taken for duration of 10 minutes per 2 seconds and the data saved to the computer connected to device via fiber optic cable. The whole data were averaged before statistical analysis.

Guinea pigs were exposed to RFR averaged as 11.2 V/m for 10 minutes a day during 7 days and analyzed for the effects on liver tissue collagen level. Changes of collagen level were analyzed biochemically by three different

hydroxyproline determination method named as “H. Stegemann-K. Stalder” (Stegemann, 1958; Stegemann et al, 1963; Stegemann et al, 1964; Stegemann and Stalder, 1967a; Stegemann and Stalder, 1967b), “I.S. Jamall-V.N. Finell” (Jamall et al, 1981) and “ISO 3496” (TS 6236 ISO 3496, 1997). Also, histological analyzes were accomplished.

Result

The outcome of the biochemical analysis pointed out that hydroxyproline level increased with respect to control but this increase was not statistically significant for all methods ($p > 0.05$). On the contrary, histological analyses showed that RF exposure makes fibrosis in liver tissue increase significantly. In addition to this, difference in hydroxyproline determination accuracy of ISO 3496 method with respect to other two methods was found as statistically significant ($p < 0.05$) (Table 1- Figure 1).

Discussion

In this study, effects of RFR generated by mobile phones on liver tissue collagen examined by using hydroxyproline detection methods. Hydroxyproline is characteristic amino acid whose tissue level is used to determine the tissue collagen level (Dahl and Persson, 1963; Edwards and O'Brien, 1980; Bondjers and Bjorkerud, 1973; James et al, 1990; Neuman and Logan, 1963; Stegemann, 1958; Stegemann et al, 1963; Stegemann et al, 1964; Stegemann and Stalder, 1967a; Stegemann and Stalder, 1967b; Mommersteeg et al, 1993; Reddy and Enwemeka, 1996; Switzer and Summer, 1971; Wood et al, 1990).

Biological effect mechanisms of RFR were analysed as thermally and non-thermally also the cumulative effects which are not clear yet. Increase of the molecular activities when matter interactions with EMF can cause thermal effects' arises. Electrically charged particles as ion, molecular dipole and colloidal particles are always in motion in the unstable fields. Electromagnetic fields affect collagen since it is charged particle. If a low current is applied to the collagen solution in acid solvent, a concave band is formed around cathode which shows that collagen behaves like cation under the effect of electric field. Effects of electric field on hydroxyproline can be explained as collagen consists of hydroxyproline with the ratio of 1/10 (Gustavson, 1956; Ramachandran, 1967a; Ramachandran, 1967b). The physical phenomenon which states that low frequency RFR can penetrate into more internal tissues than high frequency RFR can be active mechanism on which can explain why RF radiation is non-effective on liver tissue collagen. Also, wavelength changes with respect to electrical qualifications of the medium. Certain systems with ionic conductivity can have high dielectric constant in the range of several thousands. For this reason, it is considered that macro molecules can have comparable dimensions with the wavelength of microwaves which express spatial resonances. But, if the frequency increases, resonance of the large dipolar molecules like proteins gets harder with the field. Resonance frequency matching may be the reason why 1800 MHz RFR is not effective on collagen in liver tissue. Besides this study, the evidences in the earlier studies expressed that static and extremely low frequency (ELF) 50 Hz electric fields and magnetic fields applied in different direction and strength affected the hydroxyproline level in liver and some other tissues like kidney, lung, skin and wound (Güler, et al, 1996; Güler and Atalay Seyhan, 1996; Güler and Seyhan, 2001; Canseven and Seyhan, 2005; Canseven and Atalay Seyhan, 1995; Canseven and Atalay Seyhan, 1996; Canseven and Seyhan, 2000, Seyhan et al, 2006).

It is possible to determine the collagen level in tissue by applying hydroxyproline determination methods which should be very accurate since liver tissue collagen level is less than other tissues like skin or bone. In this study, “H. Stegemann-K. Stalder”, “I.S. Jamall-V.N. Finell” and “ISO 3496” were chosen as biochemical methods of liver tissue hydroxyproline level determination after literature search. In each of three methods, tissue hydrolysis hydroxyproline measured by spectrometry after adding Cloramin-T reactive which stains the solution. The wavelength for measuring optic density of solution for “H. Stegemann-K. Stalder” and “I.S. Jamall-V.N. Finell” is 560 nm, but for the method called “ISO 3496” is 558 nm. One of the method named as “ISO 3496” was found as the most accurate method with respect to the other two ($p < 0.05$). This method is nowadays used for determining the absolute value of hydroxyproline in the meat and meat product industry which should be very little collagen content in order to be fine product.

RFR radiated by mobile phones which are daily components of our daily lives, exposed to male guinea pigs 10 minutes daily for 7 days and the increase of hydroxyproline level in liver tissue was found as statistically insignificant with respect to controls. However, although not significant, this increase make a question be asked that what the consequence will be if the exposure period is prolonged because people use their mobile phones more than 1 week and also may use them more than 10 minutes daily.

For this reason, prolonged researches should be done in order to determine the biological effects of RFR.

Abstract

The aim of this study was to evaluate whether low-level, ultra high frequency (UHF) irradiation of 935 MHz influences the cytoskeleton and the cell growth of V79 cells. UHF field was generated inside a Gigahertz Transversal Electromagnetic Mode cell (GTEM-cell) equipped with a Hewlett Packard signal generator. The electric field strength was 8.2 ± 0.3 V/cm, and the average specific absorption rate (SAR) was calculated to be 0.12 W/kg. Cell samples were cultivated in a humid atmosphere at 37 °C in 5% CO₂. Prepared cell samples were exposed to the 935 MHz continuous wave frequency field for 1, 2 and 3 hours. The structure of microtubule proteins was determined using the immunocytochemical method. Cell growth was determined by counting cells for each hour of exposure during five post-exposure days. The experimental procedure included exposed V79 and unexposed control cells. In comparison to the control cells, the microtubule structure of the exposed cells significantly altered after 3 hours of irradiation ($p < 0.05$). Cell growth of the cells exposed for three hours significant dropped 72 hours after exposure ($p < 0.05$). It could be concluded that the 935 MHz low-level UHF radiation affected microtubule proteins, consequently influencing the cell growth.

Introduction

Common concern about biological effects of ultra high frequency (UHF) electromagnetic (EM) fields in the range from 300 MHz to 3 GHz grows with development of telecommunications systems. So far, many reported biological effects of UHF are considered to be simply indeterminate with respect to their significance to health [1]. Therefore, it is important that biological effects of UHF fields be understood at least on cellular level. Numerous *in vitro* biological effects caused by low-level UHF irradiation have been reported, and a number of studies conducted to assess changes at the cellular level reported adverse effects on cell proliferation and cell membrane structure [2, 3]. It was also suggested that UHF could interact with different apoptosis pathways [4]. No other effects have been observed on the cell cycle, enzyme activity, gene expression or DNA and chromosome damage [5-12]. A wide range of studies *in vivo* showed that rat blood-forming system could be affected by low-level UHF fields [13, 14, 15]. In addition, a number of biological effects were observed in animals during non-thermal exposure to the UHF field [16, 17, 18]. It is apparent that studies of mobile phone frequencies often present conflicting results. Accordingly, there is a permanent need for independent and objective research of the UHF biological potency. In addition, Repacholi in 1998, has recommended that the time course of effects should be investigated to determine if they are chronic, acute, or whether the effects disappear after cessation of exposure [19].

The aim of this study was to evaluate whether low-level UHF of 935 MHz frequency field affects the cytoskeleton microtubule structure and cell growth in the continuous line of V79 cells after 1, 2 and 3 hours of exposure.

Material and methods

A continuous cell line of Chinese hamster V79 lung fibroblasts was routinely grown in nutrient medium supplemented with antibiotics and fetal calf serum, (RPMI 1640, SIGMA Chemical CO, St. Louis, USA). The cells were maintained in a humid atmosphere at 37 °C in 5% CO₂, and incubated for 24 hour prior to the beginning of the assay. Electromagnetic field frequency of 935 MHz was generated by a certified Gigahertz Transversal Electromagnetic Mode Cell (GTEM-cell) equipped with a signal generator (Mod. 5402, ETS™

Lindgren, USA and Hewlett Packard HP8657, Palo Alto, USA) [20]. Cell samples were exposed to UHF EM radiation in triplicate for one, two and three hours. Control cells were kept in the same experimental conditions, but were not exposed to UHF EM radiation. Positive control cells treated with 0.1 mM colchicine (SIGMA Chemical CO, St. Louis, USA) were also included into the study. The specific absorption rate (SAR) was averaged to be 0.12 W kg^{-1} for a single cell. SAR was calculated by averaging the individual parameters of the cell substance in accordance with their volume fraction in the live cell according to the Steffensen's mathematical model [21, 22]. Temperature inside the GTEM-cell was measured at 10-minute intervals in order to preserve steady temperature of 37°C during irradiation. Indirect immunocytochemical method was used to determine microtubule proteins in irradiated and control cells [23]. Cell culture samples were initially seeded in total volume of 5 ml in Permanox Lab-Tek Chamber Slides (Nunc, Roskilde, Denmark) at a concentration of 2.5×10^4 cells/ml. After irradiation the cell culture samples were washed in 0.5% triton X-100 and permeabilized with calf albumin (Imunološki zavod, Zagreb, Croatia). Subsequently, cells were fixed in a 4% paraformaldehyde. Microtubule proteins were marked by a primary antibody (IgG anti- β -tubulin, SIGMA Chemical CO, St. Louis, USA). The secondary antibody was represented by a conjugate of anti-mouse IgG and fluorescein isothiocyanate (FITC, Imunološki zavod, Zagreb, Croatia). The smears of cells were mounted on a fluorescent medium. To determine cell proliferation, V79 cells were plated in the concentration of 1×10^4 cells/ml in 24-well plates (TPP, Switzerland). For each hour of exposure, cell proliferation was determined microscopically by cell counts on post-exposure hours 24, 48, 72, 96 and 120 [24]. Collected data were analyzed using Statistica 7.0 (StatSoft Inc., USA). Results were presented as mean values and standard deviations or errors (SD/SE). Pairwise comparisons between groups of data were performed using the analysis of variance ANOVA/MANOVA. Statistical difference was determined at $p < 0.05$.

Results

Figures 1a and 1b show marked microtubule proteins in control and positive control samples V79 cells. Compared to controls, the exposed V79 cells showed time-dependent susceptibility to UHF irradiation associated with microtubule activity. Irregularities were also observed in cell morphology and microtubule protein structure. The observed phenotype changes in irradiated cells were characterized by cytoplasm membrane knobs and cytoplasm bubbles. After one and two hours of exposure, most microtubules were normally developed and their features did not essentially differ from control samples (Figure 2a, 2b). The structure of mitotic spindle remained regular (Figure 3). After the three-hour UHF exposure, the microtubule proteins started to significantly differ from matched control samples ($p < 0.05$). After three irradiation hours cellular microtubule structure changed to more grainy (Figure 2c). Irregularity in microtubule structure was defined by distinct grainy clusters of proteins. These findings suggested that microtubule fiber organization could be acutely dissipated by the 935 MHz UHF irradiation. Figures 4, 5 and 6 show the growth of V79 cells after one, two and three hours of 935 MHz microwave irradiation and the growth of control cells. In comparison to control cells, cells exposed for three hours showed a significant drop ($p < 0.05$) in cell growth 72 hours after irradiation (Fig. 6). The fall in the cell number on the fifth day (120 hours) after exposure seems to be the consequence of cell culture confluence and depletion of medium ingredients, which is confirmed by a decrease in the cell number of matched controls. Each data point at the curves represents the mean value obtained from six separate cell samples.

Discussion

An experiment with whole-body exposure of rats showed that UHF EM irradiation had an effect on the proliferation and maturation of hematopoietic cells [14]. Although the authors propose a reasonable explanation of the UHF EM action *in vivo*, we believe that a precise insight into the mechanism requires an *in vitro* approach to the problem. Microtubule protein fibers are extremely dynamical structures whose function depends on dynamic instability, i.e. on continuous binding of free tubulin proteins in microtubules and their degradation to basic protein units. It is believed that internal electrostatic forces and microtubule dynamic instability can be disturbed by outside electrostatic forces. Depending on the dipole momentum, an external electric field could affect the dynamic instability of microtubules and increase the number of free tubulin proteins in cytoplasm [25]. In our study the 935 MHz UHF exposure seems to have led to time-dependent increases of visible fluorescent grain structures or free cytoplasmatic tubulin proteins. The observed grain

structures revealed noticeable destruction of microtubule fibers. Pacini et al., demonstrated that exposure of cultured human cells to cellular phone radiofrequencies caused massive morphological and functional changes. After one hour of exposure to 902.4 MHz frequency field with the SAR of 0.6 W/kg, a significant increase was reported in gene expression related to the stress response proteins, cell cycle regulators, nuclear receptors, cytoskeleton and proteins of extracellular matrix [26]. The alteration of cytoskeletal actin protein structure in human astrocytoma cell line caused by 835 MHz irradiation and field power density of 40 mW/cm² was reported as well. In the same frequency field an alteration of cell proliferation was observed at 8.1 mW/cm² [27]. Neither Stagg's nor Higashikubo's group observed any other changes through the G1, G2 and S phase, and cell division, immediately after exposure up to modulated 835.62 MHz frequency wave, SAR 0.6 W/kg [28, 29] for 100 hours. According Bohr & Bohr, UHF field affects the kinetics of conformational changes of the protein β -lactoglobulin. Exposure accelerates changes towards the equilibrium state by excitation of collective intrinsic modes in the protein [30]. Electric dipole momentum of microtubule proteins complies with the basic condition for vibration excitation and creation of internal oscillated electric field [31]. It becomes clear that internal oscillated electric field might interfere with outside electromagnetic forces which could finally lead to a measurable biological effect. It could be concluded that under the applied conditions, 935 MHz low-level UHF radiation affects microtubule protein structure, followed by disturbances in cell growth kinetics in a time-dependent manner.

Abstract

This paper proposes an innovative microwave system for the preparation of cytological slides. The system exploits an electromagnetic field to allow the cellular deposition thus reducing the use of the centrifuge. The analysis of the electromagnetic field effects on the cells in solution is of primary importance. In fact, to perform a uniform cell deposition, the generated electric field must not induce deformation of the cell structure and, in particular, the sizes of its nucleus.

A new version of GTEM cell able to generate a uniform and well controlled electromagnetic field has been designed. The cellular solution is inserted inside the GTEM cell by using a container, on the bottom of which the slide is placed. The electric and magnetic field strengths, that best fit the process requirements, have been evaluated by using a commercial computer code able to model the electromagnetic propagation inside the GTEM cell together with the cytological sample. The distribution of the electric and magnetic field modulus has been evaluated to verify the electromagnetic uniformity conditions.

Introduction

The conventional technique for the cytological tests is manual and based on the smear of vaginal cells (PAP TEST). The transfer of the material, captured by a small brush, on the glass is a complex practice. In most cases the smeared cells are not representative of the entire population of captured cells. In fact, all species must be present in reasonable quantities such to be able to represent the whole sample. Moreover, the cellular overlap and the casual disposition of mucus make difficult the PAP TEST preparation.

The most important parameter which is needed to evaluate the cell malignancy is the ratio between its total volume and the volume of its nucleus. In tumoral cells the nucleus, compared with the cell dimensions in its complex, appears enlarged. It is possible to distinguish two types of intraepithelial lesions: HSIL (High Grade Squamous Intraepithelial Lesion) and LSIL (Low Grade Squamous Intraepithelial Lesion). Therefore, the fixing effect can affect the correct interpretation of the cytological solution. In order to overcome this problem, that can compromise the diagnosis, the cytology market evolves in the direction of monolayer-based technologies [1-3]. At present, these technologies are not much spread, because of the required complex techniques, such as filtration and centrifuge steps, for cellular deposition on slide. In fact, because of the filtration step [4] some species, such as bacterium and little particles, could be not present on the slide. On the other hand, because of the centrifuge step, strong forces are involved, that might change the cellular nucleus sizes.

In this paper an innovative system for the preparation of the cytological slides is proposed. This system exploits the electromagnetic (EM) field in order to facilitate the cellular deposition thus reducing or avoiding the

centrifuge step.

Because of to the innovativeness of this technology, the analysis of the electromagnetic field effects on the cells in solutions is of primary importance. We propose a new version of the GTEM (Gigahertz Transverse Electro-Magnetic) cell to be used for the cytology slide preparation able to generate a uniform and well controlled electromagnetic field. The electric field polarization and strength, that best fit the process requirements, have been evaluated. In fact, to perform a uniform cell deposition and to increase the cell mobility, the electric field must not deform the cell structure and, in particular, the nucleus sizes. It is important to assure the uniformity of EM field in the sample. Therefore, the design of the GTEM cell has been aimed to achieve a uniform distribution of electromagnetic field in the test region. For this purpose, the requirement of the $50\ \Omega$ impedance matching condition along the propagation direction and at the terminal sections, must be satisfied.

GTEM cell prototype design

The GTEM cell is a tapered coaxial waveguide commonly used in Electromagnetic Compatibility (EMC) tests to simulate free-space radiation conditions in a shielded and restricted, environment. Accurate and repeatable measures can be performed for operating frequencies up to a few GHz. Additionally, a uniform EM field distribution can be guaranteed in the test region of the shielded overall volume. In absence of resonance and reflection phenomena inside the GTEM cell, a good EM field uniformity can be reached. This implies that the impedance matching condition must be satisfied both along the propagation direction and at the terminal sections by an appropriate design of the GTEM cell as regards its sizes and the absorbing load.

A GTEM cell can actually be considered as a tapered stripline with an offset inner conductor, here referred to as septum, that allows the only TEM mode propagates. Such a cell behaves as a transmission line with an associated characteristic impedance depending on the geometrical parameters of the structure. These have been chosen in order to maximize the test volume [5]: cell length $L = 45$ cm (pyramid height), aspect ratio $(b+d)/a = 2/3$ (in the terminal section we have $a = 24$ cm, $b = 4$ cm and $d = 12$ cm), angles $\theta = 5^\circ$, $\gamma = 10^\circ$ and $\alpha = 15^\circ$. These parameters are shown in Fig. 1. The characteristic impedance of the GTEM cell have been evaluated with the use of a code based on the singular integral technique [6]. A $50\ \Omega$ characteristic impedance occurs in the case of the septum width w to the cell width a ratio equal to $w/a = 0.7$. This impedance is constant because the tapered shape of the GTEM cell allows to hold the same aspect ratio throughout the propagation direction. In Fig.2 the fabricated GTEM cell prototype is shown.

The GTEM cell has been designed by using a full-wave commercially computer code (CST MW Studio), based on the Finite Integration Technique (FIT). Figs. 3 and 4 illustrate the used CST model of the GTEM cell without and with the sample, respectively. A few simplifications are introduced in order to reduce its complexity and the related computation time. The SMA connector, where the signal generator is connected, together with its transition to the GTEM cell septum, have been neglected. According to the CST specifications, a waveguide port has been defined by cutting the GTEM cell pyramidal shape in correspondence of the SMA-connector to the septum transition. A second waveguide port has similarly been defined at the terminal section of the GTEM cell, thus allowing an optimal impedance matching condition at both the input/output load sections.

Electromagnetic analysis

The electromagnetic analysis in the transversal section of the GTEM cell has been carried out by means of a home-made computer code based on the Transverse Resonance Diffraction (TRD) method [7]. In the region under the septum the E-field exhibits an almost uniform pattern along the propagation direction z . However, the tapered shape of the GTEM cell allows the propagation of a few higher-order modes. They can be originated only in correspondence of the larger sections and are responsible for a possible perturbation of the electromagnetic field distribution and uniformity. Further modes can be originated either by cross-sectional discontinuities or by the presence of the biological sample, that introduces inhomogeneous conditions along the propagation direction. These higher-order modes can be neglected, due to their low associated power. Moreover, the contribution of higher-order modes to the whole electromagnetic field can be minimized by suitably choosing the position of the sample in the GTEM cell. Therefore, the optimal position of the cytologic sample must be chosen in order to reduce the number of propagating modes and the induced electromagnetic field perturbation. In fact, the presence of higher-order modes reduces the extension of the test region in the GTEM cell. By means of the TRD method we have verified that for the frequency $f = 0.9$ GHz the monomodality is ensured from $z = 0$ m to $z = 0.30$ m. In fact, the first higher-order mode starts to propagate exactly from $z = 0.295$ m. On the other hand, for $f = 1.8$ GHz the monomodality is ensured only for $z < 0.150$ m. Therefore the best operating frequency is $f = 0.9$ GHz, for which two modes appear at the end section of the GTEM cell, that are the TEM and the TE_{p1} modes. The latter can be neglected, it being excited at the bottom of the GTEM cell and the energy exchange between the two modes being very low. Then, we can consider the only TEM mode without an valuable error. In order to confirm this result, the scattering parameters have been calculated. Fig. 5 reports the S_{11} and S_{21} parameters as a function of the frequency in the range from 0 Hz and 3 GHz. In particular, the S_{11} parameter is everywhere low, thus putting in evidence that the signal reflection is low. On the other hand, the S_{21} parameter assumes unitary value that is equivalent to total power transfer at the terminal section. Moreover, the scattering parameters assume an almost flat behaviour for the frequencies around 1 GHz. Vice versa, for $f > 1$ GHz the scattering parameters assume an oscillating trend, with peaks more and more increasing. In conclusion, for $f < 900$ MHz the reflection phenomena inside the simulated GTEM cell model can be neglected.

The described ideal behaviour modifies by the introduction of the sample into the GTEM cell. To this aim the cellular solution is inserted into the GTEM cell by using a suitably designed holder, shown in Fig. 6, on the bottom of which the slide, devoted to collect the cells, is placed.

The holder has the following geometric parameters: basement of sizes 7.5 cm x 4.4 cm x 0.5 cm; slide of sizes 7.5 cm x 2.5 cm x 0.1 cm; cylinder extern diameter 1.8 cm; cylinder internal diameter 1.6 cm; cylinder height 4 cm. The basement and the cylinder, made of plastic, are characterized by the following electromagnetic parameters: $\epsilon_r = 2.55$ and $\mu_r = 1$; the slide, made of Glass Pyrex by $\epsilon_r = 4.82$ and $\mu_r = 1$. The cylinder has been simulated by considering the presence of cells in watery solution. This solution fills for half height the cylinder and is identified by $\epsilon_r = 49.779$, $\mu_r = 1$ and dielectric tangent $\delta = 0.38$.

Figs. 7 and 8 show the S_{11} and S_{21} parameters as a function of the frequency in the range from 0 Hz to 3 GHz, calculated in the presence of the sample. Fig. 7 shows that the S_{11} parameter assumes low values, while Fig. 8 shows the S_{21} values equal to about 1 for $f < 900$ MHz.

Fig. 8: S_{21} parameter vs frequency for the GTEM cell in presence of the cytological sample.

Electromagnetic field evaluation

Several simulations of the EM field have been carried out by changing the position of the holder in the GTEM cell. The monomodality is ensured from $z = 0$ m to $z = 0.30$ m, but the geometrical sizes of the holder do not allow to place the sample anywhere in the GTEM cell, owing to the presence of the septum. The sample has been placed in seven positions: $z = 0.172$ m, $z = 0.182$ m, $z = 0.204$ cm, $z = 0.220$ m, $z = 0.236$ m, $z = 0.252$ m, $z = 0.262$ m. The distance between two adjacent positions is 1.6 cm, equal to the diameter of the cylinder. For each position the average strength of the electric field components has been calculated in a circular section of the sample placed at a height of 1.5 cm from the bottom of the GTEM cell, having a thickness equal to 1 mm. Fig. 9 reports the average strength of the three E_x , E_y , E_z components of the electric field as a function of the seven positions. The most important electric field component for the cell deposition on the slide is E_y . In fact, in order to deposit the cells on slide without deforming its nucleus, the E_x and E_z components must be negligible with respect to E_y to avoid the deposition of the cells on the walls of the holder. Fig. 10 shows the variance V_E of the average components of the electric field. We can see that the dominant E_y component assumes an almost constant variance in dependence of the z position.

The same analysis has been carried out for the magnetic field and the results are shown in Figs. 11 and 12. The strength of the magnetic field must be very low in order to not give a rotational moment to the cells. On the basis of the obtained results, the sample inside the GTEM cell must be inserted in correspondence of the region within $z = 0.23$ m and $z = 0.25$ m.

In Figs. 13 and 14 the distribution of the electric and the magnetic field modulus is shown in the case of sample placed inside the GTEM cell at $z = 0.236$ m, where the best uniformity condition takes place.

Conclusions

An innovative system for the preparation of cytological slides has been studied. It exploits the electromagnetic field in order to allow the cellular deposition on slides. A new version of GTEM cell, able to generate a uniform and well controlled electromagnetic field, has been proposed and designed. A prototype has been realized by taking into account special test requirements. 50 Ω characteristic impedance has been found by adequately choosing the geometrical parameters. The electromagnetic analysis has been carried out by a Transverse Resonance Diffraction method and by a commercial computer code (CST MWS). The cellular solution has been inserted inside the GTEM cell by using an apposite holder, on the bottom of which the slide has been placed. At the best operating frequency $f = 0.9$ GHz, two modes propagate along the GTEM cell: the TEM and the TE_{p1} modes. This latter can be neglected because the energy exchange between the two modes is practically null. By considering the average electric field at different positions along the GTEM cell, we have evaluated that the best position where the sample must be placed during the deposition is in the region within $z = 0.23$ m and $z = 0.25$ m. In fact, in those section both the electric and magnetic fields are uniform.

Abstract

This study is the analysis of Hands Free Kits SAR measurement results corresponding to 124 different mobile phones. The mobile phones are measured following EN50361 protocol and the Hands Free Kits following a new specific protocol. The comparison between phone SAR and Hands Free Kits SAR is made and we introduce the SAR reduction factor, which is the ratio of the phone and the Hands Free Kits SAR values. The mean value of the SAR reduction factor is about 11 for GSM900 frequency band and 18 for DCS1800, which are very consistent values. The lower values of SAR reduction factor correspond to lower values of phone SAR. Finally, the use of Hands Free Kits decreases statically significantly the SAR value in the user head but the obtained SAR values are not absolutely negligible and it is necessary to study Hands Free Kits SAR.

Introduction

Since a few years the use of Hands Free Kits (HFK) with mobile phones is increasing. The distance between the phone antenna and the user head is larger with HFK and one can think that the RF power deposited in the user head is significantly reduced. However the wire of HFK is metallic and the RF currents induced on this wire can be the sources of power deposition in the user head [1] Supélec carries out dosimetry measurements for HFK since a few years, by the mean of its high sensitivity own dosimetry measurement system [2] (figure 1), and a large data base has been constituted from 2002 to 2004. 124 different mobile phones and HFK, corresponding to 20 different marks, have been tested, 100 of which are classical phones, 21 are clamshells and 3 are PDA. The number of monopole antenna handsets is 37 and the number of integrated antennas is 87.

Measurement protocols

The 124 different mobile phones and their HFK have been measured following EN50361 protocol for the handset and the following described protocol for HFK. There are 6 different measurements for each frequency band, corresponding to 2 different HFK wire configurations and 3 different frequencies: lower, center and upper frequencies. The 2 different wire configurations are 1) tensed wire (figure 2.a), 2) wire with two three cm diameter loops near the phone antenna (figure 2.b), the exact position of which corresponding to an obtained maximum SAR value at the center frequency. The tensed wire configuration corresponds to a "natural" situation and the wire with loops to a worst case. The end of the wire near the earpiece is applied to the SAM phantom head surface close to the ear. The wire length in contact with the phantom is 2cm. The HFK Specific Absorption Rate (SAR) in each frequency band is the maximum obtained value for the 6 measurements.

Measurement results analysis

Phone and HFK SAR

The results of these measurements are shown in figure 3.a for GSM900 frequency band and b for DCS1800 band. The SAR values are very smaller in the case of HFK than for mobile phones for the two frequency band.

Figure 1: Supélec dosimetry facility.

Figure 2.a: Tensed HFK wire configuration.

Figure 2.b: Two loops HFK wire configuration.

Figure 3.a: Maximum SAR values obtained in GSM900 frequency band function of mobile phone number.

Figure 3.b: Maximum SAR values obtained in DCS1800 frequency band function of mobile phone number.

The measurement results have been analysed. Table 1 and fig 4.a and b show the repartition of the SAR values obtained for GSM900 and DCS1800 frequency bands.

Freq.band	Handset		HFK	
	GSM900	DCS1800	GSM900	DCS1800
Mean value	0.62	0.30	0.12	0.044
Standard deviation	0.23	0.19	0.088	0.041
Max.value	1.2	1.6	0.43	0.22
Min.value	0.17	0.018	0.006	0.001

Table 1: Maximum, minimum and mean value for SAR measurement results (W/kg). These values are taken on the different mobile phones.

For the handset SAR, GSM900 frequency band values are larger than DCS1800 frequency band values, in about a 2 to 1 ratio (the emitted power ratio). Phone SAR values are hardly larger than HFK SAR values with a ratio larger than 10.

The table 2 presents the phone proportion giving the maximum phone or HFK SAR value in the GSM900 or DCS1800 frequency band.

Fig. 4.a. Mobile phones SAR distribution function.

Figure 4.b: HFK SAR distribution function.

Freq. band	GSM900	DCS1800
Max. phone SAR	96%	4%
Max.HFK SAR	84%	16%

Table 2: Phones and HFK percentage giving the maximum phone or HFK SAR value in the corresponding frequency band.

A large majority of phones have their maximum phone and HFK SAR values for the GSM900 band, due to the two time higher emitted power.

SAR Reduction factor due to HFK

To evaluate the impact of HFK use on user head exposition, we have calculated the SAR reduction factor, which is the ratio of the handset SAR value and the HFK SAR value for a given frequency band. Table 3 and figure 5 present the SAR reduction factor value repartition obtained from the measurements.

The SAR reduction factor is very significant: the mean value is 11.2 for GSM900 frequency band and 17.4 for DCS1800 band. It can reach 103 and 300 respectively for GSM900 and DCS1800. For one handset, a PDA one, there is no SAR reduction and the SAR reduction factor is 0.63 for GSM900 and 0.36 for DCS1800.

Figure 5: SAR reduction factor distribution function.

Freq. band	GSM900	DCS1800
Mean value	11.2	17.5
Standard deviation	17.2	36.2
Max. value	102	300
Min. value	0.63	0.57

Table 4: Maximum, minimum and mean value for SAR reduction factor. These values are taken on the different mobile phones.

Relation between Handset SAR and HFK SAR

For HFK SAR interpretation we have compared handset and HFK SAR values for each mobile phone. This comparison is done in figures 6.a and b.

Fig. 6.a. Correlation between phone and HFK SAR values for GSM900 frequency band.

Fig. 6.b. Correlation between phone and HFK SAR values for DCS1800 frequency band.

The correlation between phone and HFK SAR values are low, especially for DCS1800 frequency band.

Relation between Handset SAR and SAR reduction factor

The same method has been applied to handset and HFK SAR reduction factor comparison. The figures 7a and b show this comparison.

Figure 7a: Correlation between phone SAR and SAR reduction factor values for GSM900 frequency band.

Figure 7b: Correlation between phone SAR and SAR reduction factor values for DCS1800 frequency band.

SAR reduction factor and phone SAR are also moderately correlated, but the lower values of SAR reduction factor corresponds to lower value of SAR phone values and higher values of SAR reduction factor corresponds to higher value of SAR phone values.

Conclusion

The use of HFK decreases significantly the phone user head exposition with a factor larger than 11 for GSM900 frequency band and 17 for DCS1800. There is quite no correlation between the phone SAR and the HFK SAR. HFK SAR are relatively low but not absolutely negligible. Consequently, it is interesting to measure systematically HFK SAR and to study it. We are now working to a new HFK dosimetry protocol in the french RNRT research program Adonis. Mobile phones manufacturers have also to consider this problem for HFK SAR reduction.

This research was sponsored by the french operator Bouygues Telecom.

Abstract

The real exposure to the RF radiation of a given mobile phone depends upon several parameters: emitted power level, TDMA pulses density, position of the handset, frequency bandwidth... The normative value for the SAR corresponds only to a given configuration at maximum power. The emitted power of a mobile phone can vary over a 30dB dynamic range due to Power Control (PWC). For GSM, when no information has to be transmitted, the TDMA pulses density can decrease with a factor 10 or more. The result of this is the potential variation of the mean emitted power of a mobile phone over a dynamic range larger than 40dB. Then the real SAR value can be significantly lower than the normative value.

The SAR meter performs real time in situ measurements of mobile phone radiated power, allowing the evaluation of the real exposure of the user head. This set up is portable and consists of a sensor, a receiver and a laptop microcomputer which performs data acquisition, signal processing and results visualization. A lot of measurements have been made and the order of magnitude of the real emitted power of mobile phones has been evaluated.

Introduction

The real exposure to the RF radiation of a given mobile phone depends upon several parameters: emitted power, TDMA pulses density, position of the handset, frequency bandwidth... The normative value for the SAR (EN50361) corresponds only to a given configuration at maximum power. The emitted power of a mobile phone can vary over a 30dB dynamic range due to Power Control (PWC). For GSM when no information has to be transmitted, the TDMA pulses density can decrease with a factor 10 or more. The result of this is the potential variation of mean emitted power of a mobile phone over a dynamic range larger than 40dB.

Real exposure

This paper describes a device allowing the evaluation of real mobile phones exposure of the user head. The principle of this device is to analyse the signal transmitted by the phone antenna by the mean of a low perturbing reception antenna. The received power is proportional to the phone emitted power. At the beginning of the communication the power is maximum (P_{max}), and we can use this value to normalize the emitted power (P) at a given time. Then, we obtain a reduction coefficient on the emitted power (C_{rp}).

$$C_{rp} = P/P_{max}$$

When all the TDMA pulses are present, their frequency is $F_{max}=209Hz$. This value allows the normalisation of the real frequency (F) of the TDMA pulses leading to the density (D) of the TDMA pulses.

$$D = F/F_{max}$$

In these conditions the mean emitted power (P_m) is decreased with a factor C_{rmp} in comparison with the maximum mean emitted power (P_{mmax})

$$C_{rmp} = P_m/P_{mmax} = C_{rp} D$$

The SAR is proportional to the mean emitted power and C_{rmp} is also the reduction coefficient on the SAR.

The device

The device consists in the low perturbation antenna, a specific receiver and a laptop micro computer [1]. The weight of the receiver and the antenna is about 1kg. The receiver uses 4 different channels: one wideband channel and 3 selective channels corresponding to GSM900, DCS1800 and UMTS frequency bands (figure 1). Each channel uses a detector followed by a low noise and high stability amplifier. The receiver dynamic range is

larger than 45dB. The antenna is a resistive loaded dipole. The sensitivity variation of this antenna in function of frequency is about 3dB. The figure 2 shows the antenna output signal corresponding to 11 different mobile phones emitting at the maximum power level in the GSM900 and DCS1800 frequency bands. The power variation of this signal in function of mobile phones is less than 10dB for each frequency band and less than 15dB for the two frequency bands.

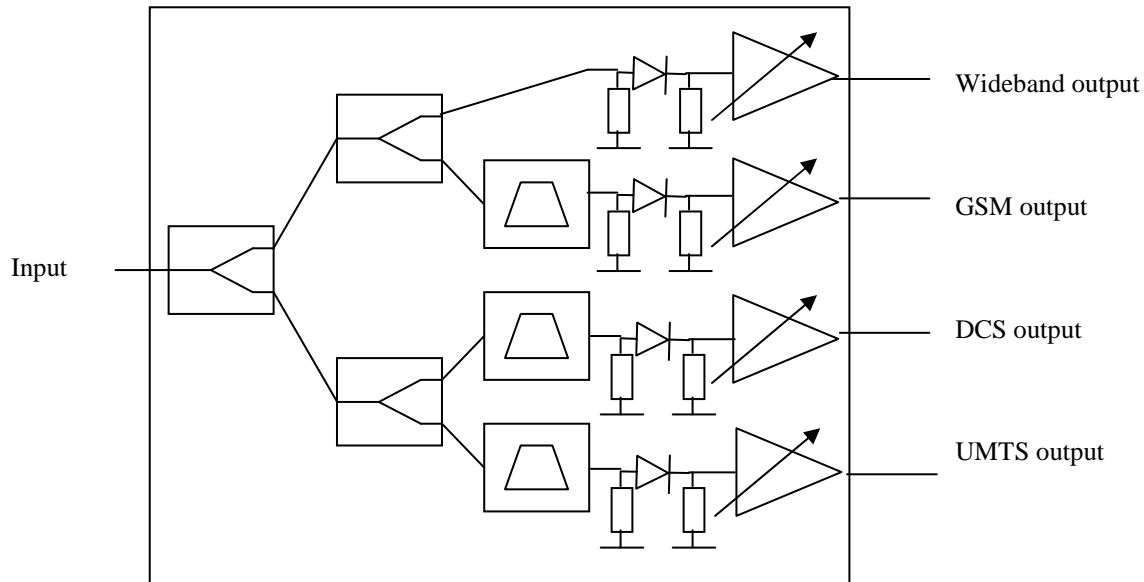

Figure 1: Receiver: overview with its four ways..

Figure 2: Antenna output signal corresponding to 11 different mobile phones for the GSM900 and DCS1800 frequency bands.

The laptop micro computer performs data acquisition and processing, with a specific software which has been developed with National Instrument Labview development system (figure 3). The power is measured on the broadband channel. Then, the reduction coefficient on the emitted power, the pulse density and the reduction coefficient on the mean emitted power, for a given duration are calculated. These three coefficients are displayed in real time during the measurement. The comparison between the different selective channels signals allows the determination of the used frequency band. The measured power and the frequency band are written in a file for each TDMA period for all the measurement duration. The figure 4 presents the entire SARmeter.

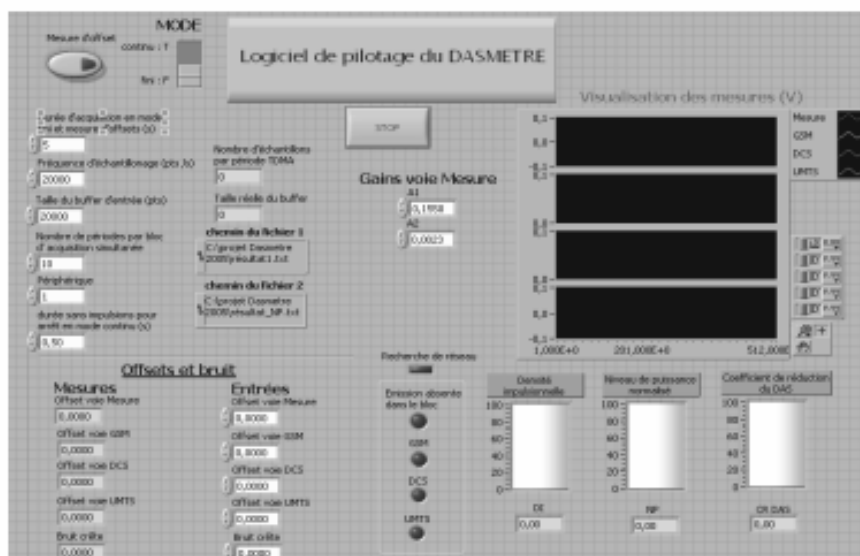

Figure 3 : Window of the SARmeter software.

Figure 4: The SARmeter.

Result example

The figure 5 shows the variation of the emitted power in function of time for a pedestrian user on the Montparnasse Street in Paris [2]. The dynamic range of the emitted power is about 30dB and it is possible to see the different used power levels.

Figure 5: Example of measurement result: variation of emitted power in function of time.

Conclusion

Real exposure to RF radiation of mobile phone may hardly differ from normative SAR value. The SARmeter constitutes an efficient portable tool to determine in situ real exposure. Its use allows especially the real exposure comparison between several different networks or mobiles phones.

Abstract

The current experiment studies the EMC issue that occurs when a simulated GSM base station is situated in the area where an electroencefalographer is functioning.

The experimental setup was situated in an anechoic chamber so that no electromagnetic interference would affect the measurements. The amplifier room, outside the anechoic room, situated the other part of the experimental apparatus. 32 electrodes entered a low-pass filter placed at the boundary wall of the Faraday screen room. The signal was amplified, before entering a 32-bit analogue to digital converter. The recording frequency was at 1 kHz.

The simulated GSM base station operated at the frequency of 1800 MHz emitting a GSM signal at the EIRP of 17dbm. The used piece of equipment is generally called DAS (Distributed Antenna Signal) and is used to simulate the signal emitted by one of the antennas of a GSM base station or for indoor coverage.

The results showed that the measured signals are significantly different both in frequency and in energy context.

Introduction

Issues regarding electromagnetic interference and medical devices continue to be popular topics in the technical world of electromagnetic interference. Reports of medical device failure from electromagnetic interference have increased [1, 2, 3]. This is due to the increasing number of electronically controlled medical devices in hospitals as well as the increasing number of the radiofrequency (RF) sources of radiation. The modern instruments are often more sensitive to electromagnetic interference (EMI) because they incorporate low power integrated electronic circuitry that can be much more sensitive to electromagnetic fields than their electrical and electromechanical predecessors. Digital wireless communications systems often utilize pulsed amplitude modulation, a type of modulation that can enhance the potential for EMI.

The European Union has gotten much of attention with regard to the regulation of electromagnetic compatibility (EMC) and medical electronics. Today, most medical EMC regulations originate within the International Electro technical Commission (IEC). The standard EN60601-1-2 [4] defines limits for emissions and levels of immunity and was updated to encompass the frequencies used by mobile. The IEC standard states that electronic medical equipment must operate normally in electric field intensity of 3 V/m and at a 10 V/m threshold for life – sustaining equipment.

The Electroencephalograph (EEG) is a recording equipment of brain signals with typical voltage of 100 μ V and frequency range (EEG bands) beginning from 0.5 Hz up to several hundreds Hz. The EEG is connected directly to the patient in order to detect these small physiological signals which are then amplified. The EEG is known to be very sensitive to EMI due to the fact that the pulsed RF signals maybe demodulated by non-linear elements in amplifier circuits. [5].

The most recent problems of electromagnetic interference (EMI) with medical equipment arise from the widespread use of GSM signals in the hospitals [6]. Global System for Mobile communications (GSM) is an open, digital cellular technology used for transmitting mobile voice and data services in the 900MHz (890 MHz - 960 MHz) and 1.8GHz bands in Europe and Asia and the 1.9GHz PCS (Personal Communications Services) band in the US[7]. GSM uses digital technology and time division multiple access transmission methods (TDMA), which utilize schemes that produce 100% amplitude modulated pulses of the RF carrier at frequencies within the EEG frequency range. Recently, warnings have been published concerning the use of wireless communications equipment in the clinical environment. Morrissey et al. reported distortion of EEG bands throughout the 0-70 Hz range during full power exposure to CDMA and GSM signals for both frequencies of 1.800 and 1900 MHz at distances of between 0.25 to 0.5 m. [8]. Also a study by Tri et al. of Mayo Clinic revealed increase of the noise of the EEG waveform measured in the presence of a GSM signal [9].

Taking into account the above considerations, in our current work, we study the EMC status that involves the usage of an electroencephalograph in an environment infested with electromagnetic radiation produced by a GSM base station. The purpose is to observe the effects of the GSM signal on the EEG signal.

Materials and Methods

The experimental setup (Fig 1) was situated in a Faraday chamber so that no electromagnetic interference would affect the measurements. A head phantom was placed in the chamber and the signals were recorded from thirty two electrodes (Fp1, Fp2, Fpz, AFz, F2, F3, F4, F7, F8, FC1, FC2, FC5, FC6, C2, C3, C4, A1, A2, CP1, CP2, CP5, CP6, P3, P4, Pz, T3, T4, T5, T6, O1, O2, Oz) with a surface of Ag/ AgCl, which were placed on the scalp of the model-head. The electrodes were positioned according to the International 10-20 system of electroencephalography [10]. The measured magnitude was the voltage at the edges of a 2 k Ω resistance placed between each electrode and a common ground. The total electrode impedances were below 5 k Ω . The amplifier room, outside the Faraday room, situated the other part of the experimental apparatus. The electrodes entered a low-pass filter placed at the boundary wall of the Faraday screen room. The filter cut frequencies over 35 Hz so that the signal of the power supply network which is at 50 Hz would not interfere with the signal. The signal was amplified by a Braintronics DIFF/ISO-1032 amplifier, before entering a 32- bit analogue to digital converter which has a GPIB output. The digitized signal comprises an input for a Data Acquisition Card. The PC with the DAQ Card ran a LabView program for the recording of the signals, which can be monitored by an on-screen graphical representation. The recording frequency was at 1 kHz. Another PC, connected with the one described above, ran a program which triggered the other PC to save the brain signals

whenever the user wanted. The recording time was 1.5 sec so the saved signal consisted of 1500 values. The total task consisted of 55 repetitions.

Figure 1. Experimental setup

A GSM TEMS Transmitter was placed at a distance of 1m from the head phantom. The GSM TEMS Transmitter was used to simulate the indoor coverage of a GSM base station within a cellular network. The GSM TEMS Transmitter sends out Frequency Correction Channel (FCCH), Synchronisation Channel (SCH) and optionally Broadcast Control Channel (BCCH) and Paging Channel (PCH) signaling, on a GSM carrier of human voice (900 MHz or 1800 MHz band). Prior to taking a measurement, the instrument was calibrated and adjusted. Scanning of the radio spectrum was performed in order to find a channel suitable for transmission. The Transmitter was equipped with four attenuators (3dB, 6dB, 10dB and 20 dB) suitable to connect between the Transmitter and an external antenna used with it. By combining the attenuators in all possible ways, output power levels from 17 dBm down to -22 dBm can be achieved. At the experiment the power level of 17dBm and frequency 1812,8 MHz (Absolute Radio Frequency Channel Number 550) was applied.

The electromagnetic field strength at the point where the head phantom was situated was 1,6 V/m.

The experimental procedure was done twice. The first time the GSM base station was off and practically the noise of the device was measured and the second time the GSM base station was functioning.

Finally in order to optimize the signal to noise ratio (SNR) the grand average across the 55 repetitions for each channel was calculated according to the following equation:

$$\bar{V}_t = \frac{1}{55} * \sum_{j=1}^{55} V_{jt}$$

Where V_{jt} is the value that results after the subtraction of the amplification and the average referencing and corresponds at the time t of the trial j . This SNR optimization procedure is considered a standard practice when it comes to brain signal measurements, which are generally considered to be quite noisy [11].

The final data for analysis for each radiation condition consisted of 1500 amplitude values for each electrode, expressed in μ Volts corresponding to the 1500 msec of the time period as described above.

For each electrode, the following magnitudes were also calculated:

- the energy E of the recorded signals ($E = V_t^2$)
- the amplitude in the frequency domain by using the Fourier Transform (FFT).

Statistical analysis

The amplitudes at the thirty two electrodes were subjected to Independent Samples t-test for the two radiation conditions (GSM off – GSM on). The mean values of the amplitudes for each electrode and radiation condition were also calculated. Statistical significance was set at 0.05.

Results

The data analysis showed that the energy of the recorded signals was significantly increased when the GSM Transmitter was operating. Figure 2 shows this increase at all electrodes except the C3 electrode. The white bars denote the calculated energy in the absence of the GSM signal while the black bars denote the signal energy in the presence of the GSM signal.

Figure 2. Averaged Energy at each electrode and each radiation condition. . The white bars denote the calculated energy in the absence of the GSM signal while the black bars denote the signal energy in the presence of the GSM signal.

The statistical analysis revealed that the presence of the GSM signal had significant effect on the amplitudes of the signals at the thirty two leads. Table 1 is quite helpful in explaining this effect, showing the mean values of the recorded signals at each electrode for the two radiation conditions.

Electrodes		Mean Values	
Number	Name	GSM off	GSM on
1	FC6	-1.61	8.25
2	FC2	-0.85	7.57
3	F8	-0.95	7.77
4	F4	-0.95	6.05
5	F2	-0.90	6.20
6	AFz	-1.55	4.87
7	Fp2	-0.59	8.38
8	Fpz	-0.78	8.18
9	Fp1	-1.90	5.72
10	P3	-1.78	7.41
11	T3	-0.76	7.09
12	A1	-0.77	3.72
13	FC1	-0.99	5.41
14	FC5	-1.36	6.67
15	F3	-1.03	7.34

27	Pz	-1.42	7.50
28	C2	-0.89	6.95
29	T5	-1.63	8.04
30	CP1	-0.99	-1.73
31	CP5	-1.50	8.69
32	C3	-6.72	6.06

Table 1. Mean values of the amplitudes of the recorded signals for each electrode for the two radiation conditions.

Energy at frequency domain

Figure 3. Calculated Energy of F8 electrode at frequency domain. The thin continuous black line denotes the calculated energy in the absence of the GSM signal while the discontinuous denotes the signal energy in the presence of the GSM signal.

Except the regarded increase of the amplitudes of the recorded signals in the time domain, the FFT calculation revealed that there was also a change in the frequency domain. A spike of the energy at the span of 1-2 Hz is observed in all electrodes. Figure 3 shows indicator this fact at one of the 32 electrodes

Discussion

In the present study we focused on the electromagnetic interference of a GSM base station might on an electroencephalograph. The results of this study revealed that in the presence of radiation of the GSM transmitter the energy of the recorded signals was in average 38 times higher than the energy calculated in the absence of radiation. Also an alteration at the frequency domain was observed at the presence of GSM signal.

These effects are very important in view of the fact that the EEG energy as well as the frequency bands are magnitudes evaluated by doctors and related to brain activity [12, 13, 14, 15] so it is absolutely necessary to be measured accurately in order to achieve the right diagnosis.

These findings are similar to those reported by Morrissey et al [8] where distortion of EEG bands was observed. Also the studies of Sibakov and Appelqvist (1998) [16], Barbaro et al. (2000) [17], and Hietanen et al. (2000) [18] referred device sensitivity. However these findings were observed at the presence of GSM signals with higher power and at closer distance than this applied to our experiment. This is rather worrying, because EMI problems occurred even with less electromagnetic field strength.

It should be noted that although the testing was performed in a shielded environment, this doesn't exclude the influence of the measurements by some factors, such as coupling between electrodes and the presence of radiation reflecting or absorbing objects in the neighbouring area.

Moreover the source of radiation had constantly 17dBm power. This factor has to be taken into account in studies about EMI of GSM signals on Medical Equipment because most studies refer to GSM cell phones which are designed to quickly reduce their power when the channel paging stops.

According to our findings it seems that the distance of 1m and the 17dBm signal power are not sufficient to protect an electroencephalograph from EMI of GSM signals. The indoor GSM base stations are necessary inside buildings as relay stations. However before installing such a communication system an EMI study is essential in order to ensure the immunity of the medical equipment. The efficient distances of the base stations from the devices must be kept so that the electromagnetic field (EMF) power and field levels would be under the recommended values [19]. Technology does exist to protect or "harden" medical devices from radiation emissions including shielding, grounding, and filtering. These modifications are not always costly and are even less problematic if incorporated by the manufacturer during assembly.

EMC is a concern not just for manufacturers, but also for those who install, use, modify or maintain medical equipment. The existence of directives and standards has encouraged good EMC design practices, but should not be relied on to prevent EMI problems owing to the nature of the hospital electromagnetic environment. Mobile telecommunication systems are very convenient and useful to doctors, nurses and patients and studies must be done to promote awareness of EMI and its underlying coupling mechanisms.

NUMERICAL DETERMINATION OF TRANSMEMBRANE VOLTAGE INDUCED ON IRREGULARLY SHAPED CELLS

GORAZD PUCIHAR, TADEJ KOTNIK, BLAŽ VALIČ, DAMIJAN MIKLAVČIČ

Faculty of Electrical Engineering, University of Ljubljana, Tržaška 25, SI-1000, Ljubljana, Slovenia.

e-mail: gorazd.pucihar@fe.uni-lj.si, tadej.kotnik@fe.uni-lj.si, blaz.valic@fe.uni-lj.si, damijan.miklavcic@fe.uni-lj.si

Abstract

The paper presents an approach that reduces several difficulties related to the determination of induced transmembrane voltage (ITV) on irregularly shaped cells. We first describe a method for constructing realistic models of irregularly shaped cells based on microscopic imaging. This provides a possibility to determine the ITV on the same cells on which an experiment is carried out, and can be of considerable importance in understanding and interpretation of the data. We also show how the finite-thickness, nonzero-conductivity membrane can be replaced by a boundary condition in which a specific surface conductivity is assigned to the interface between the cell interior (the cytoplasm) and the exterior. We verify the results obtained using this method by a comparison with the analytical solution for an isolated spherical cell, obtaining a very good agreement. In addition, we compare the ITV computed for a model of an irregularly shaped CHO cell with the ITV measured on the same cell by means of a potentiometric fluorescent dye. Finally we confirm that electroporation occurs in those areas of cell membrane, where the absolute value of ITV is the highest.

1. Introduction

Induced transmembrane voltage (ITV) forms on the cell membrane when the cell is exposed to the external electric field [1-3]. The ITV is proportional to the amplitude of electric field and with a sufficiently strong field, a sudden increase in membrane permeability occurs, a phenomenon termed electroporation. During the state of high permeability it is possible to deliver membrane impermeant ions and molecules into the cell.

In many applications of electroporation an efficient and at the same time reversible permeabilization is essential (e.g. DNA electrotransfer [4-6]). Thus, a careful planning of the experiment, which involves the estimation of the amplitude of ITV leading to cell permeabilization, is required. It was demonstrated experimentally that ITV determines the regions of the membrane where electroporation occurs [1, 2]. Namely, increased permeability is observed only in regions of the membrane where ITV exceeds a critical value. As already stated ITV is proportional to the electric field, varies with the position on the cell membrane, and is influenced by cell geometry and physiological characteristics of the medium surrounding the cell [3, 7-10]. For an isolated cell of simple shape, such as a cylinder, a sphere, or an ellipsoid, ITV can be described analytically [3, 8, 11 – 14]. However, when cell geometry is more complicated (e.g. cells in tissues) an analytical description is in general not attainable and ITV can be determined either experimentally [15-20] or numerically [21-28].

Usually, numerical models are constructed using simple geometrical shapes, e.g. hemi-spheres, hemi-ellipsoids or combination of simple shapes [22, 23, 28, 29]. These models can be realistic for cells in suspensions, but cells growing in a dish or in tissues typically have profoundly irregular shapes, and combinations of several simple geometrical objects are not usable anymore. In this study, we present a method for construction of more realistic models of irregularly shaped cells from their cross-section images. We also present a method to replace a cell membrane in the model with a boundary condition. We then calculate the ITV on the model of an irregularly shaped cell and compare it to the ITV determined experimentally by means of fluorescent dye. In addition, the course of permeabilization of this cell is monitored and regions of membrane where permeabilization occurred are determined.

2. Methods

2.1 Construction of a three-dimensional model of a cell

Three-dimensional models of irregularly shaped cells were constructed from a sequence of microscopic fluorescence images representing cross-sections of a cell attached to the cover glass. The models presented in the study were built from CHO cells, but the method can also be applied to other cell types. Fluorescence images were obtained by staining the cell with a fluorescent dye di-8-ANEPPS. The dye emits a strong fluorescence when it binds to the membrane, therefore making the cell edges visible. The cross-sections were obtained by shifting the focus on a fluorescence microscope (Zeiss AxioVert 200, objective $\times 100$, oil immersion, Zeiss, Germany) in constant steps of $2\ \mu\text{m}$ from the bottom to the top of the cell (Figure 1A). The images were acquired using a cooled CCD camera (VisiCam 1280, Visitron, Germany) and MetaMorph 5.0 software (Visitron, Germany), and converted from grayscale (8 bit) to black and white (1 bit, Figure 1B) in Corel PhotoPaint 11.0 (Corel Corp., Ottawa, Canada). Using FEMLAB 3.1 package (COMSOL Inc., Burlington, MA, USA) with MATLAB 6.5 (MathWorks Inc., Natick, MA, USA), the contours of the cell were detected using *flim2curve* (Figure 1C), transformed to solid planes with 35 edges with *solid2*, and the planes were connected into a 3D object using *loft* to obtain the model of the cell. This model was then imported to the FEMLAB workspace, where it was positioned to the bottom of a rectangular block, thereby mimicking the cell attached with its bottom to the cover glass (Figure 1D). To construct a model of several cells, or a cell cluster, this procedure is repeated for each cell separately [30]. In case of a cell cluster, individual cells are, after they are imported to FEMLAB, merged together to form a cluster.

2.2 Modeling the cell membrane

Direct incorporation of a realistic cell membrane (i.e. a layer of very small, yet non-zero thickness surrounding the cell) into the model is technically very problematic. Unless the distribution of the electric field, current density, and/or electric potential within the membrane is of interest, this can be avoided. Namely, the effect of the membrane on these electric quantities in the cell interior and exterior is equivalent to the effect of a corresponding surface conductivity assigned to the interface between the interior and the exterior. More precisely, as the specific conductivity of the membrane – typically about $5 \times 10^{-7}\ \text{S/m}$ [31] – is at least five orders of magnitude lower than the specific conductivities of the media surrounding it, the current flows through the membrane practically orthogonally to its surface. Consequently, in the membrane the total current density is virtually equal to its normal component alone (J), which is given by:

$$J = \frac{\sigma_m (V_o - V_i)}{d}, \quad (1)$$

where σ_m is the specific membrane conductivity, d is the membrane thickness and V_o , V_i are the electric potentials at the outer and inner surface of the membrane, respectively. Here J , V_o , and V_i are functions varying with the position on the membrane, while σ_m and d are constants. For the purpose of determining ITV, the events inside the membrane layer are not relevant, and the ratio σ_m/d can be treated as a single entity — the specific surface conductivity, $\kappa_m = \sigma_m/d$. The interface between the cell interior (the cytoplasm) and the cell exterior is then characterized by

$$J = \kappa_m (V_o - V_i). \quad (2)$$

Despite the membrane as such being absent from the model, the drop of electric potential at such an interface is equivalent to ITV on a membrane with a specific conductivity σ_m and thickness d . In models constructed in this way, the mesh of finite elements is generated without difficulty, as very small elements corresponding to the membrane itself are avoided [30].

2.3 Settings of the model and subsequent computations of induced transmembrane voltage

The computation of the functions J , V_o and V_i was performed in FEMLAB by introducing two application modes, the cell exterior (extracellular medium) being active in the first, and the cell interior (cytoplasm) in the second mode. Both application modes were of a static current density type. For models containing several cells, an additional application mode active in the cytoplasm of each cell must be introduced, and the functions J_1 , J_2 , ... and V_o , V_{i1} , V_{i2} , ... are then computed.

Figure 1. Construction of a 3D model of an irregularly shaped CHO cell. (A) Fluorescence images (8 bit) of an irregularly shaped CHO cell stained with di-8-ANEPPS. The images represent four cross-sections of the cell, acquired from bottom to the top of the cell in 2 μm steps. Bar represents 10 μm . (B) Black and white (1 bit) images. (C) The corresponding contour of the cell edge for a given cross-section. (D) The three-dimensional geometry of the cell model constructed from the cross-sections. The interior of the rectangular block represents the extracellular medium, the grey-shaded faces are the electrodes, and the other four faces are insulating.

The specific conductivity of the cell interior was set to 0.3 S/m [32], and the specific conductivity of the rest of the block (the cell exterior) to 0.14 S/m [33]. Two of the opposite vertical faces of the block were modeled as electrodes, which was done by assigning fixed electric potentials to both electrodes (one was usually set to ground) to obtain the voltage-to-distance ratio of 100 V/cm. The remaining four faces of the block were modeled as insulating surfaces, the bottom one representing the cover glass. At the boundary surface between the cell interior and exterior, the normal component of the current density was set corresponding to Eq. 2 with a negative sign ($-J$) in the mode corresponding to the cell exterior, and with a positive sign in the mode corresponding to the cytoplasm (or, with several cells, in all such modes). The specific surface conductivity was set at $\kappa_m = 100 \text{ S/m}^2$, which is the ratio between a specific membrane conductivity of $5 \times 10^{-7} \text{ S/m}$ and a membrane thickness of 5 nm [34].

After the mesh was generated, the electric potential was computed using finite elements method with FEMLAB's stationary nonlinear Conjugate gradients solver with Algebraic multigrid preconditioner. ITV was calculated as the difference between electric potentials on the two sides of the boundary surface separating the inside and outside of the cell, i.e. as $\text{ITV} = V_i - V_o$. ITV was then plotted as a function of relative arc length.

2.4 Measurements of induced transmembrane voltage

To experimentally determine ITV we used di-8-ANEPPS, a fast potentiometric fluorescent dye. The dye binds to the cell membrane, which causes a considerable increase in its fluorescence. With the change in ITV, the fluorescence of the dye then varies linearly [15-17]. CHO K1 cells were grown on cover glasses in culture medium. Six to eight hours latter the culture medium was replaced with SMEM medium containing 30 μM of di-8-ANEPPS and 0.05% of Pluronic. After staining for 12 min at 4°C, the cells were washed thoroughly with pure SMEM to remove the excess dye. Before the experiments, SMEM was replaced with an isoosmotic pulsing buffer (10 mM $\text{K}_2\text{HPO}_4/\text{KH}_2\text{PO}_4$, 250 mM sucrose, 1 mM MgCl_2 , [33]). Cells were then exposed to a voltage of 40 V applied for duration of 100 ms on two parallel wire electrodes with a 4 mm distance between them (voltage-to-distance ratio 100 V/cm). Before and during the pulse, the fluorescence image of the lowermost level of a cell or a cell cluster was acquired, with excitation at 490 nm and emission detected at 605 nm. The procedure was repeated five times, with a 2 s delay between pulses. The control image was then subtracted from the corresponding pulse image and the corrected images were averaged to increase the signal-to-noise ratio. The changes in fluorescence of the dye in the membrane were quantified by measurements of grey levels along the region of interest, which was a 5 pixel wide line encircling the cell at the site of the membrane. Using a calibration curve obtained in a separate experiment (6% of fluorescence change per 100 mV, not shown [30]), fluorescence changes were transformed to the values of ITV, which were plotted on a graph as a function of the normalized arc length. The images were acquired using the same imaging system as described in Section 2.1.

2.5. Monitoring the course of electroporabilization

Cells (CHO K1) were grown and prepared as described in Section 2.4. Prior to experiments, the culture medium was replaced with pulsing buffer, which contained 100 μM of fluorescent dye Propidium Iodide (PI, Sigma, Saint Louis, USA). The dye is essentially membrane impermeant, but can enter the electroporabilized cells, where its fluorescence increases significantly, making it suitable to detect electroporabilization of cells. The electrodes were positioned to the bottom of cover glass. A 400 V, 200 μs pulse was delivered to the electrodes, and fluorescence from cells was monitored in 100 ms time steps. The imaging system was the same as described in Section 2.1.

3. Results and discussion

3.1 Validation of the model by comparison with analytical solution for a spherical cell

The method introduced in Section 2.1 was first verified by comparing the calculations of ITV on a model of a spherical cell with the analytically derived ITV for the same cell. Under physiological conditions, the ITV induced by an electric field E on a spherical cell with outer radius R is given by Schwan's equation [3]:

$$ITV = f_s ER \cos \varphi \quad (3)$$

where φ is the angle between the direction of the field and the line connecting the center of the cell to the point of interest and f_s is a function reflecting the electric and dimensional properties of the cell and the surrounding medium [8]:

$$f_s = \frac{3\lambda_o [3dR^2\lambda_i + (3d^2R - d^3)(\lambda_m - \lambda_i)]}{2R^3 (\lambda_m + 2\lambda_o) \left(\lambda_m + \frac{1}{2}\lambda_i \right) - 2(R-d)^3 (\lambda_o - \lambda_m)(\lambda_i - \lambda_m)} \quad (4)$$

In Eq. 4, λ_o , λ_i , and λ_m are the specific conductivities of the extracellular medium, cytoplasm and the membrane, respectively, and d is the thickness of the membrane. Schwan's equation provides a precise description of the ITV on a single spherical cell, and was as such used as the first test of the method of numerical determination of the ITV described in this paper. Figure 2B shows the ITV computed using this method and Figure 2C shows the error with respect to Schwan's equation (note that the y-scale is much smaller than in 2B). On the basis of these results we can conclude that the numerical computation of ITV using our method is sufficiently accurate for any practical purpose. Both the analytical and the numerical solution were determined for a spherical cell with $R = 10 \mu\text{m}$, $\lambda_o = 1 \text{ S/m}$, $\lambda_i = 0.2 \text{ S/m}$, $\lambda_m = 5 \times 10^{-7} \text{ S/m}$, and $d = 5 \text{ nm}$. The cell was exposed to an electric field of 100 V/cm, which was, in the numerical solution, generated by applying 1 V to a pair of rectangular parallel plate electrodes 0.01 cm apart.

Figure 2. (A) Geometry of a spherical cell. The arrow denotes the start and the direction of the path along which the normalized arc length is measured. (B) Computed ITV for a spherical cell with a membrane modeled as a boundary condition. (C) The difference between the computed and analytically derived ITV. The calculations were performed for a spherical cell with $R = 10 \mu\text{m}$, $\lambda_o = 1 \text{ S/m}$, $\lambda_i = 0.2 \text{ S/m}$, $\lambda_m = 5 \times 10^{-7} \text{ S/m}$, $d = 5 \text{ nm}$, and $E = 100 \text{ V/cm}$.

The main advantage of replacing the cell membrane with a boundary condition is that the mesh elements corresponding to the membrane are avoided. This efficiently reduces the time for mesh generation and time needed to solve the problem. If the membrane is instead modeled explicitly, its thickness must typically be exaggerated by an order of magnitude or more, otherwise the number of mesh elements is far too large to be handled by a computer. To compensate for this, the membrane can be assigned a correspondingly higher specific conductivity [30].

3.2 Comparison with fluorescence measurements

The model of an irregularly shaped cell was constructed from four cross-sections of the cell photographed under a microscope, as described in detail in Section 2 (Figures 1A-1D). The distribution of electric potential was first computed (Figure 4A) and the ITV was then calculated as the difference between the electric potential in the cell interior and exterior. The results are, for the lowermost layer of the cell, shown in Figure 3C with dashed curve. Figure 4B shows the areas of the cell where the absolute value of ITV is the highest (within arbitrarily chosen range of 15% of the maximal value). The calculations of ITV were then compared with measurements of ITV on the same cell using a potentiometric fluorescent dye di-8-ANEPPS. The changes in fluorescence of dye upon exposure of cell to the electric field are presented in Figure 3A and are hardly noticeable. They become visible after subtraction from the control image (without electric field) as shown in Figure 3B. In this figure, the side of the cell colored in white represents an increase in fluorescence, and the side of the cell colored in black, a decrease in fluorescence. Fluorescence changes were transformed to ITV using a calibration curve (see Materials and Methods) and are presented with solid curve in Figure 3C as a function of the normalized arc length. The results are shown for two opposing orientations of external electric field (100 V/cm). For the investigated cell, ITV changes along the cell membrane between approximately 75 mV and -65 mV for electric field directed from left to right and between -80 mV and 55 mV for the opposite direction of the field (Figure 3C) and is in qualitative agreement with the calculated ITV. Small differences between the amplitudes could be attributed to the variations of the slope of calibration curve between different cells, the differences between the actual and implemented parameters of the model (especially the membrane permeability), and the experimental setup.

3.3 Monitoring the course of electroporation

In the presence of the membrane-impermeant fluorescent dye Propidium Iodide, the same cell was then exposed to a single unipolar rectangular 400 V pulse (1000 V/cm) with 200 μs duration. The changes in fluorescence of the cell were observed 100 ms after the pulse application on both sides of the membrane, denoting the regions where permeabilization occurred. With time, cell interior becomes more fluorescent indicating continuous dye uptake into cell after permeabilization. The fluorescence regions of the membrane on the first image (100 ms) were compared with calculations of ITV (shown in Figure 4B). A good agreement between the observed fluorescence increase and the regions where the absolute value of ITV was the highest was obtained (cf. Figure 4B and Figure 5A).

Figure 3. Measurements of ITV on an irregularly shaped CHO cell. First row shows the results for the electric field E directed to the right and the second row for the opposite direction. (A) The 8-bit fluorescence images of a cell stained with di-8-ANEPPS and acquired during the exposure to 40 V (100 V/cm), 100 ms rectangular pulse. Bar represents 10 μ m. (B) Changes in fluorescence of cell obtained by subtracting the control image (not shown) from the image with pulse and shifting the grayscale range by 50%. White arrow shows the path along which ITV was measured. (C) ITV as a function of normalized arc length. Solid curve – measured values, dashed curve – numerically calculated values. The changes in fluorescence were transformed to ITV by using a 6%/100mV calibration curve.

Figure 4. (A) The calculated distribution of the electric potential around and inside the cell in the lowermost x-y plane of the cell. The black curves represent the equipotentials and the arrow marks the path along which the potential was measured. The scale is in volts. (B) Regions of the membrane where the absolute value of ITV, calculated as a difference between the potentials on both sides of the membrane ($ITV = V_i - V_o$), is the highest (within arbitrarily chosen range of 15% of the maximal value).

Figure 5. Monitoring of cell electropermeabilization. (A) Fluorescence of the cell 100 ms, (B) 1500 ms, and (C) 3 min after pulse delivery. The images were corrected for the background fluorescence and the brightness was automatically enhanced. The cell was exposed to a 1×400V, 200 μ s (1000 V/cm) rectangular pulse. Propidium Iodide was added to suspension before the pulse was applied to visualize the permeabilized regions. Bar represents 10 μ m.

4. Summary

We demonstrated how to construct realistic models of irregularly shaped cells from their cross-section images. This allows determination of the ITV on the same cells on which the experiment is carried out, and can be of considerable importance in understanding and interpretation of the data. We also presented a method to replace a cell membrane in the model with a boundary condition. Such replacement efficiently eliminates the number of elements of the mesh and consequently time needed to solve the problem. To validate the method, the computed ITV for a spherical cell was compared with the analytical expression describing the ITV for the same cell, showing a very good agreement between both solutions. This can be considered as the evidence that this method is a reliable and accurate one. We then showed that the ITV computed for a model of an irregularly shaped cell is comparable to the ITV measured on the same cell. Finally, we confirmed that electroporation occurs in those areas of cell membrane, where the absolute value of ITV is the highest. The presented methods of model construction from cross-section images and replacement of the membrane by a boundary condition can also be used to study more complicated cell geometries, such as several cells in contact, which represent a simple model of a tissue.

Abstract

Effects of 900 MHz CW on human immortalized keratinocytes (HaCaT) were investigated. Cells kept in a CO₂ independent medium were exposed inside a cell-culture incubator at 37 °C. Sham samples were in the same environmental conditions. Exposure durations ranged from 2 up to 18 hours, and dose-response investigation was performed at average SAR levels of 0.7 mW/kg and 3 mW/kg.

The inhibition of proliferation and viability reached its maximum for exposures of 2^h15^m duration (21% at lower SAR level and 12% at highest one), and for exposures of 18^h duration (40% at lower SAR level and 20% at highest one). Less marked effects were observed with exposures of 4 and 9 hours to the SAR level of 3 mW/kg.

To test the dependence on calcium of the effect, experiments were performed in Ca-depleted medium (KCl 1mM was added to keep the right ionic strength). Exposure to EMF for 18 hours in these experimental conditions caused a further 10% increase in cell growth inhibition, regardless SAR levels.

Moreover we studied the effect of EMF on the structure of tissue Transglutaminase (tTG), a calcium-dependent enzyme involved in wound healing and epithelial differentiation. Indeed, after 2 hours exposure at the SAR level of 0.7 mW/kg, the fluorescence spectrum of tTG (excited at 293 nm) was differentially modulated in comparison to sham samples. EMF treatment seems to induce a conformational change similar to that observed during its activation which occurs upon calcium addition.

Introduction

Several authors reported about the alteration of cell membrane surface charges exposed to low frequency electromagnetic fields (EMF) and conflicting results have been reported on the probably consequent mobilization of intracellular calcium. However only little studies have been reported on the effects of radiofrequencies (900 MHz) on calcium metabolism in normal human cells. The role of calcium ions in several biological pathways has been supported. In the case of EMF it could be hypothesized that EMF exposure, by disturbing intracellular calcium availability and fluxes, can interfere with biological cellular pathways. Additional mechanism of interaction of EMF with biological tissue could be traced to the different permeability of certain ions, like calcium, through the canals of the membranes that permit the passage of salts (called ionic canals); today of fundamental importance for the study of brain cells and of other neurological diseases (Marchionni et al., 2006). Moreover, exposure to EMF is able to change *in vitro* protein conformation and enzyme activity suggesting a great influence in cellular metabolism (Barteri et al., 2005). It has been reported also that 900 MHz do not modulate the signal transmission in the peripheral nervous system, whereas 50/60 Hz are effective. Moreover biphasic actions depending on frequencies and intensities have been reported (Marchionni et al., 2006).

Following the previous results assessing that exposure to 900 MHz could trigger a differentiation program in HaCaT cells (Duranti et al, 2004; Duranti et al., 2005), in the present work, we investigated *in vitro* the EMF-induced effects in relation to calcium concentration. We choose a human normal immortalized keratinocytes cell line (HaCaT), since keratinocytes are naturally exposed to both mechanical and thermal stimuli, and skin is usually exposed to electromagnetic radiation at considered frequency more than inner tissues. We examined the cell proliferation at different times of EMF exposure in the presence or absence of calcium and at different SAR exposures. Moreover we observed, by spectrophotometric determination, a modification in the structure of tissue transglutaminase (tTG) a calcium-dependent enzyme involved in wound healing and epithelial differentiation.

Altogether, our results suggest an involvement of the intracellular Ca²⁺ availability in the cell response to 900 MHz EMF exposure.

Materials and Methods

Reagents

Cell culture media (Dulbecco's MEM mix F-12 and CO₂-independent media) were obtained from Invitrogen, Carlsbad, CA, USA; heat-inactivated fetal bovine serum FBS and trypsin were obtained from HyClone, Oud-Beijerland, Holland. Tris (hydroxymethyl)-aminomethane, HCl, were obtained from Fluka (Buchs, Switzerland), Calcium-free keratinocyte growth medium from Cambrex-Clonetics (Baltimore USA). Primary and secondary antibodies were obtained from Santa Cruz (Santa Cruz, CA USA). All the other reagents, unless otherwise specified, were from Sigma Chemical (St. Louis, MO, USA).

SAR determination

Computational simulations have been carried out by employing the electromagnetic commercial simulator Microwave Studio (MWS) by CST-Germany, based on the Finite Integration Technique (FIT). This numerical method, developed by Weiland in 1977, provides a discrete reformulation of Maxwell's equations in their integral form suitable for computers and it allows simulating real-world EMF problems with complex geometry. In order to numerically solve Maxwell's equations, a finite calculation domain is defined. By creating a suitable mesh system, this domain is splitted up into small cubes, so-called grid cells. In combination with the FIT, MWS employs the Perfect Boundary Approximation (PBA) for the spatial discretization of the simulated structure that allows an accurate modelling of bend-shaped structures.

In order to simulate in vitro tests, the exposure set up was represented as two parallel metallic plates of (80 x 99) mm size, at 27 mm of distance and 4 Petri dishes or 2 flasks were inserted between the plates. In simulation for exposure to 900 MHz EMF, the plexiglas dishes were of 35 mm of diameter, height of 8 mm and 1 mm of thickness. Each culture medium was then parameterized as dish of 33 mm of diameter and 3.5 mm of height for a total liquid volume of 3 ml. In the simulation of exposure to 1.8 GHz EMF the flasks were represented by means of a plexiglas parallelepiped of (35 x 35 x 20) mm size and of 1 mm thickness for each wall. Consequently each culture medium was parameterized as a parallelepiped of (33 x 33 x 3.7) mm size, for a total liquid volume of 5 ml.

Cell cultures and EMF exposure

Human keratinocytes (HaCaT) were grown in T25 cell culture flask (SARSTEDT) in a 1:1 mixture of minimal essential medium (Dulbecco's MEM) and Ham's F-12 medium supplemented with 10% (v/v) heat-inactivated foetal calf serum, 1% non-essential amino acids, at 37°C with 5% CO₂ in a humidified atmosphere. No antibiotics were used. Cells were split 1:6 twice weekly and fed 24 hours before each experiment.

Cells were seeded (8.000 cells/cm²) in culture medium and allowed to recover physiological growth conditions in a 5% CO₂ atmosphere at 37°C for 24h. Then medium was replaced with calcium-free keratinocyte growth medium and KCl (1mM) was added to keep the right ionic strength, then samples were transferred in a 37°C incubator without CO₂ and exposed to EMF for different times.

Shame samples prepared exactly as the exposed were in the same incubator out of radiation field. All samples were in duplicate. All the results are the mean with standard deviation of at least 3 independent experiments.

Cell proliferation

HaCaT cells, were exposed to an EMF of 900 MHz with different intensities ranging between 1.5 and 12V/m for different times (2h-72h). To assess HaCaT viability and proliferation, cells were counted at 72h after EMF exposure by a Burkner chamber and viability was evaluated by trypan blue exclusion assay. Briefly, cells were trypsinized, collected in 1 ml PBS and mixed 1:1 with trypan blue solution (0.8 mM in PBS). Viable cells exclude trypan blue while dead cells stain blue due to trypan blue uptake.

Spectroscopic Assays

tTG from guinea pig liver was dissolved in Tris-HCl 50 mM buffer, pH 7.5, containing 5 mM EDTA. Steady-state fluorescence was measured with a ISS-K2 fluorometer (ISS, Champaign, IL) thermostating the sample at 20°C by an external bath circulator. The emission spectra was detected through a WG 305 cut-off filter to suppress scattered light.

Protein expression level

10-20 µg of cellular proteins (in 25 mM Tris-HCl pH 8, 0.5% SDS, 0.05% mercaptoethanol, 2.5% glycerol and 0.001% bromophenol blue) were denaturated at 100°C for 5 minutes, subjected to SDS-PAGE on a 10% polyacrylamide gel and then electroblotted onto a PVDF membrane at 130 V for 1 hour. Blots were blocked with 5% non-fat dry milk (Biorad, Hercules, CA) and then incubated with specific primary antibodies, p-ERK (Santa Cruz CA USA) and β-tubulin (Santa Cruz CA USA). After washing and incubation with the horseradish peroxidase-conjugated secondary antibody, detection was carried out with ECL (Amersham).

CALCIUM DEPLETION MODULATES EMF-INDUCED EFFECTS ON HUMAN KERATINOCYTES

Results and Discussion

Effects of 900 MHz CW on HaCaT cells were investigated. Exposure for 18 h to 900 MHz at different intensities in a range between 1.5 and 12 V/m corresponding to a maximal SAR of 3 mW/kg caused a cell growth inhibition not directly related to the intensity (Table 1).

Table 1. HaCaT proliferation after exposure for 18 h to 900 MHz at different intensities

	V/m (SAR:mW/kg)			
	1.5	3	6 (0.7)	12 (3)
Sham	1	1	1	1
Exposed	0.95±0.04	1.0±0.1	0.73±0.04	0.82±0.08

The antiproliferative effect of EMF was evaluated at 72h after different times of exposure ranging from 2 up to 72 hours. As shown in table 2, maximal effects were found for short exposure times, whereas at 72h of exposure, no cell growth inhibition could be detected.

Table 2. HaCaT proliferation after exposure to 900 MHz for different times

	Time of exposure (hours)					
	2.15	4.30	9	18	24	72
Sham	1	1	1	1	1	1
Exposed (0.7 mW/kg)	0.79±0.12	n.d.	n.d.	0.80±0.1	n.d.	n.d.
Exposed (3 mW/kg)	0.74±0.1	0.86±0.03	1.05±0.04	0.82±0.08	0.84	0.97

The inhibition of proliferation and viability reached its maximum for exposures of 2h15m duration (21% at the lower SAR level and 26% at the highest one), and for exposures of 18h duration (20% at the lower SAR level and 18% at the highest one) (Table 2). Less marked effects were observed with exposures of 4 and 9 hours to the SAR level of 3 mW/kg (Table 2).

Since it has been reported an involvement of ion channels in the effects of EMF exposure on biological materials, we investigated the dependence on calcium of the effects of EMF at SAR level of 3 mW/kg as above reported. Thus we performed some experiments in Ca-depleted medium. Exposure to EMF for 18 hours in these experimental conditions caused a further 10% increase in cell growth inhibition (Table 3).

Table 3. Cell proliferation after exposure to 900 MHz EMF (3 mW/kg) for 18h in the presence or absence of Ca^{2+} . Cell number was determined at 72h after the end of exposure.

	Cell number $\times 10^3$	
	+ Ca^{2+}	- Ca^{2+}
Sham	520 \pm 26	407 \pm 32
Exposed	467 \pm 28	313 \pm 19

This result suggests that a modification of intracellular calcium concentration would affect the antiproliferative activity of 900 MHz EMF. Ca^{2+} modulates several signaling pathways. In epidermal growth factor receptor stimulation, calcium is required for the activation of the extracellular signal-regulated kinases (ERK) (Pusl *et al.*, 2002). ERKs, in turn, phosphorylate the transcription factor Elk-1 which becomes active. Activation of Elk-1 leads to the transcription of growth-related genes (Sharrocks, 2001) (Fig.1). We therefore examined the level of phospho-ERK expression by western blot analysis. A barely detectable decrease of phospho-ERK expression was found immediately after EMF exposure with respect to the control sham cells. This effect was more evident for exposures performed in the absence of Ca^{2+} , supporting a role for calcium in keratinocytes proliferation and differentiation. After 72h recovery, p-ERK expression in exposed cells rise to sham level suggesting that the decrease in ERK phosphorylation was due to the presence of the EMF (Fig. 2). Additional experiments are required to determine the role of EMF in such process.

Fig.1 Effect of High (H) and Low (L) calcium concentration on ERK phosphorylation.

CALCIUM DEPLETION MODULATES EMF-INDUCED EFFECTS ON HUMAN KERATINOCYTES

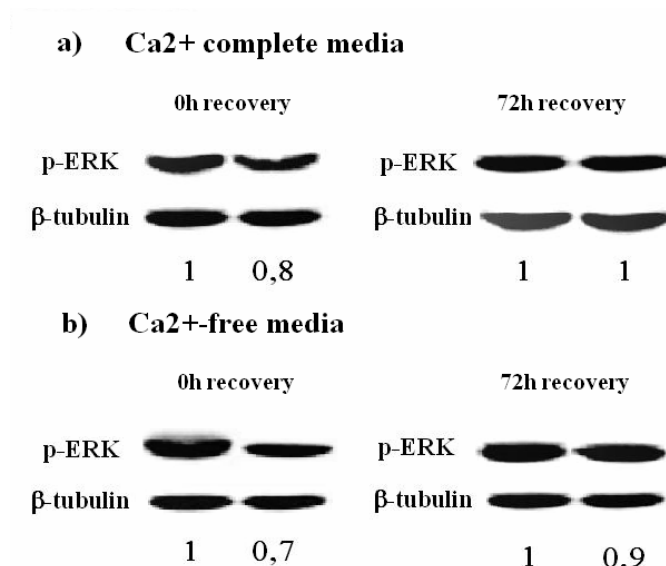

Fig. 2 – Phospho-ERK expression after exposure to 900 MHz EMF for 18h in the presence or absence of Ca²⁺. Western blot analysis was performed immediately after exposure and 72h after exposure in Ca²⁺ complete medium (a) or in Ca²⁺ free medium (b). Tubulin is reported as control of loading. Numbers indicate the normalization of p-ERK band in exposed samples versus sham samples.

Transglutaminases are a class of enzymes that induce cross-link between proteins by catalyzing the formation of an isopeptidyl bond. They are involved in processes like apoptosis, differentiation, wound healing. Tissue transglutaminase (tTG) is activated by a conformational change induced by calcium which is necessary for its activation (Folk *et al.*, 1967). It has been reported that calcium binding to tTG can be monitored because it alters the steady-state protein fluorescence spectra (Di Venere *et al.*, 2000). We found that after 2 hours exposure at the SAR level of 0.7 mW/kg, the fluorescence spectra of tTG was altered in comparison to sham samples in a way resembling calcium binding to the enzyme. Therefore EMF treatment seems to induce a conformational protein change similar to that observed during its activation. It is interesting to note that EMF could exerts this effect in absence of calcium. Further studies are needed to clarify the mechanism and the effects on cell metabolism.

Fig. 3 – Steady state fluorescence spectra of tTG exposed at 900 MHz EMF for two hours (solid line) compared to sham (dotted line). Excitation wavelength at 293 nm.

Altogether, our results suggest that the cellular response to EMF could be mediated by intracellular Ca²⁺ availability.

Abstract

The effects of ultra high frequency EMFs with biological systems were investigated by *in vitro* studies in human immortalized keratinocytes (HaCaT). Cells were exposed to 900 MHz CW at average SAR level of about 1-5 mW/kg, and 1.8 GHz CW at average SAR level of about 10 mW/kg, for different periods of time. Exposures to 900 MHz CW, at durations of 2^h15^m and 18^h caused a reduction in the cell growth, whereas same duration exposures to 1.8 GHz CW caused an increase of cell proliferation. Cell cycle perturbations were observed in both cases, with a decrease of G1 phase after 18^h exposure. Longer exposure durations (72^h) were ineffective, suggesting a cellular adaptation to these stress conditions.

Preliminary studies showed that the effects of 900 MHz exposure were independent of temperature (34°C or 38°C), but dependent on calcium concentration in the medium. The effects of exposure on the redox balance were examined. Short time (2^h15^m) 900 MHz exposure evidenced a decrease of Total Antioxidant Status (TAS) values, whereas 1.8 GHz was ineffective, regardless the higher SAR level. Our results suggest that exposure to different frequencies and SAR levels caused different effects on biological systems. Cell cycle perturbations and oxido-reductive response seem to be involved.

Introduction

Electromagnetic field (EMF) exposure from sources such as power lines, mobile phones, TV and radio transmitters, and from new and emerging technologies, is frequently seen as a potential source of risk for people and environment. While significant EMF research has been conducted over the past years, technological changes have been so rapid that science has been unable to sufficiently assess potential health risks in a timely manner [1]. The effect of extremely low-frequency electromagnetic field (ELF/EMF) exposure on human health has been widely debated. A number of epidemiological studies have pointed to a slight increase in malignant diseases in populations exposed to electromagnetic fields through the vicinity of power lines. A significant positive association was observed between childhood leukemia and exposure of children to magnetic fields during the night [2-4]. Our previous studies showed a low but reproducible antiproliferative effect of 50 Hz magnetic field on human leukemia cells [5] while no long term effects were found in human breast carcinoma cells [6]. The increasing number of epidemiological observations prompted us to a study on the impact of electromagnetic fields on biological parameters of a human normal keratinocytes cell line, to verify whether there exist significant effects induced by the exposure to high frequency EMF in a controlled and reproducible experimental condition (biological and physical). HaCaT (human keratinocytes) cell line has been chosen as an excellent model to study the biological effect of radiations since they are cells which receive, in the first line, the energy associated to radiations. We already reported that exposure to 900 MHz could trigger a differentiation program in HaCaT cells [7,8]. We examined the eventual effects of two different high frequencies (900 MHz and 1.8 GHz) on cell proliferation, cell cycle progression and oxidative response of these cells after different times and intensities exposures. The aim was to examine the biological effects of exposures to a wide range of SAR values. Thus, we started the study by exposing cells to very low levels of SAR such as 1mW/kg at 900 MHz and 10mW/kg at 1.8 GHz.

Interestingly we observed an increase in cell growth after exposures to 1.8 GHz and an inhibition of cell growth after exposures to 900 MHz. Exposures till 24 h caused differences in the considered biological parameters whereas after longer times of exposure a kind of adaptation and a decrease of the effects, which revert to control values, was found. The involvement of temperature and of calcium concentration was also examined.

Materials and Methods

SAR determination

Computational simulations have been carried out by employing the electromagnetic commercial simulator Microwave Studio (MWS) by CST-Germany [9], based on the Finite Integration Technique (FIT) [10]. This numerical method, developed by Weiland in 1977, provides a discrete reformulation of Maxwell's equations in their integral form suitable for computers and it allows simulating real-world EMF problems with complex geometry. In order to numerically solve Maxwell's equations, a finite calculation domain is defined. By creating a suitable mesh system, this domain is splitted up into small cubes, so-called grid cells. In combination with the FIT, MWS employs the Perfect Boundary Approximation (PBA) for the spatial discretization of the simulated structure that allows an accurate modelling of bend-shaped structures [11].

In order to simulate *in vitro* tests, the exposure set up was simplified. In fact in the numerical model only the exposure zone of the two set up was modelled, presuming that the detailed description of the adaptive section was not relevant for SAR evaluation purposes. Each exposure set up was then represented as two parallel metallic plates of (80 × 99) mm size, at 27 mm of distance and Petri dishes or flasks were inserted between the plates. In simulation for exposure to 900 MHz EMF we have four plexiglas dishes of 35 mm of diameter, height of 8 mm and 1 mm of thickness. Each culture medium was then parameterized as dish of 33 mm of diameter and 3.5mm of height for a total liquid volume of 3 ml. In the simulation of exposure to 1.8 GHz electromagnetic field we have two polystyrene flasks. Each flask was represented by means of a plexiglas parallelepiped of (35 x 35 x 20) mm size and of 1 mm thickness for each wall. Consequently each culture medium was parameterized as a parallelepiped of (33 x 33 x 3.7) mm size, for a total liquid volume of 5 ml.

Cell cultures and EMF exposure

Human keratinocytes (HaCaT) were grown in D-MEM/F-12 medium (Invitrogen, Carlsbad, CA, USA), supplemented with 10% (v/v) heat-inactivated foetal calf serum (HyClone, Oud-Beijerland, Holland) and non-essential aminoacids 1%, at 37°C in a 5% CO₂ humidified atmosphere. No antibiotics were used. Cells were seeded (8.000 cells/cm²) in culture medium and allowed to grow in physiological conditions in a 5% CO₂ atmosphere at 37°C for 24 h. Then medium was replaced with CO₂-independent medium (Invitrogen) to maintain the correct pH and samples were transferred in a 37°C incubator without CO₂ and exposed to EMF for different times.

Sham samples, prepared exactly as the exposed, were in the same incubator out of radiation field. All samples were in duplicate. The results are the mean with standard deviation of at least 3 independent experiments.

Cell proliferation and Cell cycle analysis

HaCaT cells, were exposed to an electromagnetic field of 900 MHz with different intensities ranging between 1.5 and 12 V/m or 1.8 GHz at 25 V/m for different times (2 h-72 h).

Cell proliferation was evaluated at 72 h after EMF exposure by counting, in a Burkner chamber, trypan blu excluding cells (alive cells).

For cell cycle analysis, samples were washed in PBS (phosphate buffered solution) and stained with a solution of propidium iodide (PI) (20 µg/ml) (Sigma-Aldrich, St. Louis, MO, USA) e RNase (Sigma) 1 mg/ml in PBS. Cell cycle distribution was analyzed by a FACScan cytofluorimeter equipped with an argon laser for fluorescence excitation at 488 nm (Becton Dickinson, Mountain View, CA, USA) after 30-60 min of incubation. Analysis of the percentage of cells in each phase of the cell cycle was performed by means of Cellfit software (Becton Dickinson).

Total Antioxidant Status

Total antioxidant status (TAS), including enzymatic and non-enzymatic cellular systems, was measured in cells homogenates as Trolox Equivalent Antioxidant Capacity (TEAC), with the modification of ABTS-cation radical method [12].

After exposure, cells were trypsinized, centrifuged, and the cell pellets were resuspended in 100 µl PBS with 1 mM PMSF. After sonication, 10 µl of cellular homogenates was immediately tested.

Briefly, 300 µl ABTS (500 µM), 36 µl metamyoglobin (70 µM), 487 µl PBS, 10 µl sample (0.6 mg of proteins) were mixed and then the reaction was started by adding 167 µl H₂O₂ (450 µM). This method is based on the reactivity of intracellular antioxidant compounds relative to a 1 mM Trolox (vitamin E analogue) standard. A Trolox-calibration

curve by three concentrations was performed during each experiment. The reaction was followed spectrophotometrically at 734 nm for 15 minutes. All compounds were from Sigma-Aldrich.

Protein level expression

10-20 µg of cellular proteins (in 25 mM Tris-HCl pH 8, 0.5% SDS, 0.05% mercaptoethanol, 2.5 % glycerol and 0.001 % bromophenol blue) were denatured at 100°C for 5 minutes, subjected to SDS-PAGE on a 10% polyacrylamide gel and then electroblotted onto a PVDF membrane at 130 V for 1 hour. Blots were blocked with 5% non-fat dry milk (Biorad, Hercules, CA) and then incubated with specific primary antibodies, HSP-70 (Chemicon International) and β -tubulin (Abcam plc, Cambridge, UK). After washing and incubation with the horseradish peroxidase-conjugated secondary antibody, detection was carried out with ECL (Amersham-GE Healthcare).

Results and discussion

SAR determination

By applying the above reported computational simulation for SAR determination, we verified that with an EMF at 900 MHz with an electric field between 1.5 and 12 V/m, the mean value of SAR in our samples was between 1 and 5 mW/kg. In samples exposed to 1.8 GHz at an electric field of 25 V/m, the mean value of SAR was 10 mW/kg.

Cell growth

HaCaT cell growth was determined by cell counting at 72 h after different times of EMF exposure. As shown in Fig. 1 (panel A) exposures to 900 MHz caused a reduction in cell growth at least till 24 h, whereas exposures to 1.8 GHz caused an increase of cell proliferation. In both cases longer times of exposition to EMF were ineffective on cell proliferation. Moreover (Fig.1, panel B), exposures to 900 MHz to different intensities were ineffective till 3 V/m, whereas 6 and 12 V/m caused a marked decrease in cell growth.

Fig. 1 HaCaT cell growth at different times of exposure to EMF 1.8 GHz 25 V/m (dotted line) or 900 MHz 12 V/m (solid line) (panel A), or 900 MHz and different intensities for 18 h (panel B).

Thus next experiments were performed after short time exposures (2.15 or 18 h) and at 12 V/m (SAR = 5 mW/kg) of intensity for 900 MHz and 24h of exposure to 25 V/m (SAR = 10 mW/kg) for 1.8 GHz.

As shown in table 1, exposure to EMFs of 900 MHz or 1.8 GHz caused a modification in S phase, immediately after exposure to 900 MHz for 18 h. The decrease in S phase after 900 MHz exposition and increase in the same phase after

1.8 GHz are in agreement with the respective decrease and increase in cell proliferation. At longer times of exposure (not shown) or of recovery after a 18 h exposure, values similar to sham control samples were found in all experimental conditions.

Table 1. Effect of 18 h EMF exposure on cell cycle distribution after different times of recovery. The percentage of cells in each phase is reported.

	0 h of recovery			24 h of recovery			48 h of recovery		
	G1	S	G2	G1	S	G2	G1	S	G2
Sham	44	41	15	44	41	14	48	40	12
900 MHz (5mW/kg)	50	31	19	46	42	14	49	40	11
1.8 GHz (10mW/kg)	38	46	16	43	42	15			

Since modification of temperature induced by EMFs could be involved in the observed modification in cell proliferation and cell cycle progression, cell growth after incubation for 18 h at 34°C or 38°C was evaluated. As shown in table 2, no modifications in cell cycle distribution were observed nor at 34°C nor at 38°C, indicating that the EMF effects were not related to the temperature.

Table 2. Effect of EMF on cell cycle distribution at different times of recovery after 18 h of exposure to different temperatures. The percentage of cells in each phase is reported.

		% of cells		
		G1	S	G2
0 h of recovery	37°C	44	41	15
	34°C	38	43	19
	38°C	40	41	19
24 h of recovery	37°C	44	41	14
	34°C	45	40	15
48 h of recovery	37°C	48	40	12
	34°C	44	43	13

Results are from one of two independent experiments.

A dependence of EMF antiproliferative effect on Ca^{++} was found. Indeed in the absence of Calcium (replaced by K^+) a higher reduction of cell growth in comparison to that of cells exposed in normal culture conditions was observed (Fig 2). This result suggests that an inhibition of calcium-dependent enzymes could synergize with the antiproliferative effect of EMF.

Fig. 2 – Cell proliferation after exposure to 900 MHz EMF for 18 h in the presence or absence of Ca^{++} . Cell number was determined at 72 h after exposure.

To deeply understand the mechanism of the induction of the cellular response observed in EMF exposed cells, we examined the redox balance after 2.15 h and 18 h of 900 MHz exposure. As shown in Fig. 3 a decrease in the total antioxidant status was found mainly after 2.15 h of exposure. At longer times (18 h of exposure) a less marked reduction was observed.

Fig. 3 – Total Antioxidant Status of HaCaT cells after exposure to 900 MHz EMF for 2.15 h or 18 h.

Then the expression level of HSP-70, a stress induced protein, was detected. In agreement with the above reported results an increase in HSP-70 expression was found in cells exposed for 2.15 h to 900 MHz (Fig. 4). Again, after 18 h of cell exposure to EMFs, the expression level of this protein was similar to sham samples.

Fig. 4 – HSP-70 protein expression. Protein level was determined at 0 h and 72 h after 18 h of EMF exposure. Tubulin is reported as control of loading. Numbers indicate the normalization of HSP-70 band in exposed samples versus sham samples.

In conclusion the biological effects of the two different high frequencies (900 MHz and 1.8 GHz) examined in the human normal cell line HaCaT after exposures for different times and to different intensities were quite different. Indeed, we observed an increase in cell growth after exposures to 1.8 GHz and an inhibition of cell growth after exposures to 900 MHz. These modulations were reduced (10-25 %) but reproducible. Temperature, often reported as the cause of biological effects of EMF [13] was ineffective, in range between 34°C and 38°C on this cell system suggesting the lack of its involvement in the response of HaCaT cells. On the contrary, an increase EMF antiproliferative effect was found in the absence of calcium, suggesting a dependence of biological effects of EMF on calcium concentration.

Moreover the inhibition observed after 900 MHz exposure was related to an increase in the expression of HSP-70 a protein related to the cellular stress and to the antioxidant status of the cell. The observation that these parameters reverted to control levels after longer times of exposure or of recovery after exposure to EMFs support the hypothesis of other authors of an “adaptation” of cells to the effects produced by electromagnetic energy on the biological matter.

From this study it emerges that an interaction between EMF and cell systems exists even at very low levels of exposure. Moreover they confirm that frequency, intensity, and time of EMF exposure are parameters markedly affecting the biological response for which is not easy to find a model of correlation.

Abstract

Standard models of cells for studying their interaction with electromagnetic fields are based on shelled spheres or ellipsoids with characteristic electrical parameters –permittivity and conductivity– for each homogeneous region. However, many biological cells present a complex surface structure with microvilli, blebs, folds, etc., that make these models inadequate to correctly describe the field effects.

In this work we examine the dielectric response of 2D dielectric particle models with surface roughness in quasi-static approximation, using a BEM method based on the integral formulation for the induced polarization charges on the interfaces. Different mathematical surface morphologies are considered: sinusoidal or fractal corrugations, characterized by their corresponding height and correlation length. Results are interpreted by comparing with the standard BEM approach for the electrostatic potential.

Introduction

The dielectric behavior of materials depends sensitively on the characteristics of their surfaces. These characteristics have influence on important phenomena and applications, such as the dielectric breakdown of insulating materials, the development of capacitors with very high capacitance using fractal surfaces or the electrorheological response of particle suspensions [Klingenberg and Cooper 1995]. On the other hand, it is well established that most examples of surfaces exhibit certain degree of roughness. The inclusion of the surface structure in the models that describe the electrical response of colloidal suspensions, can be of help in the characterization of particles using dielectric spectroscopy or electrokinetic measurements, as well as for designing purposes in the development of new applications in these or related fields. In the high frequency range, scattering by rough surfaces have been extensively investigated using Kirchhoff theory, based on a local application of Fresnel laws, using the tangent plane approximation [Caron et al. 2002]. At lower frequencies, where the roughness size is comparable or greater than the field wavelength, the incorporation of the detailed morphology of surfaces in the numerical treatment of the electromagnetic field at dielectric interfaces poses a great challenge for the capability of existing computational methods. This is probably the main reason behind the fact that there are very few studies that consider realistic rough surfaces in the dielectric modeling of particles in spite of its obvious interest.

Methods

In order to investigate the dielectric response of particles with complex surface structure, we have applied two approaches with complementary characteristics. They consist of boundary element (BE) formulations that give information on the potential and charge density distributions. For the sake of clarity, a brief account of the basis of these methods is given below. The interested reader is referred to publications for more details.

i) BEM for the quasi-static potential

This method is based on the following integral equation [Poljak and Brebbia 2005]

$$\frac{\varepsilon_i + \varepsilon_j}{2} \phi(\mathbf{r}) = \phi_0(\mathbf{r}) + (\varepsilon_i - \varepsilon_j) \int_L \phi(\mathbf{r}') \frac{\partial G(\mathbf{r}, \mathbf{r}')}{\partial n'} dl' \quad (1)$$

where ϕ is the electric potential at a point of a dielectric interface between media of complex permittivities ε_i and ε_j , immersed in an external potential ϕ_0 and the integral extends to the interface contour. $G(\mathbf{r}, \mathbf{r}')$ is the Green's function, defined by $\nabla^2 G = \delta(\mathbf{r}, \mathbf{r}')$. For a 2D problem, $G(\mathbf{r}, \mathbf{r}') = \ln|\mathbf{r} - \mathbf{r}'|/2\pi$. The singularity in the integrand when $\mathbf{r} = \mathbf{r}'$ has been integrated and the integral in the r.h.s. of (1) is to be interpreted in the sense of Cauchy principal part. The formulation can be easily extended to the case of several dielectric interfaces.

The problem is discretized by dividing the contour into N sub-elements of length Δ and equation (1) correspondingly converted to an algebraic equation. The coefficients A_{ij} have a simple analytical expression,

$$A_{ij} = \int_{\Delta} \frac{d}{dn} (\ln|\mathbf{r} - \mathbf{r}'|) = \int_{\Delta} \frac{\cos \theta}{|\mathbf{r} - \mathbf{r}'|} dl' = \varphi \quad (2)$$

where φ is the angle subtended by the element j from the center of the element i . The algebraic system of equations for the potentials at the N points on the contour is solved by a triangulation method.

ii) BEM for the charge density on the interfaces

For certain types of applications, especially those related to ponderomotive effects produced by electromagnetic fields, we have shown that a BEM formulation based on the charge density induced by the external field can be advantageous. The corresponding integral equation is in that case [Sancho et al. 2003]

$$\frac{\varepsilon_i + \varepsilon_j}{2} \sigma(\mathbf{r}) = (\varepsilon_i - \varepsilon_j) \sigma^0(\mathbf{r}) + (\varepsilon_i - \varepsilon_j) \int_L \sigma(\mathbf{r}') \frac{\partial G(\mathbf{r}, \mathbf{r}')}{\partial n} dl' \quad (3)$$

where $\sigma(\mathbf{r})$ is the complex charge density at the point \mathbf{r} of a dielectric interface and $\sigma^0(\mathbf{r}) = \varepsilon_0 E_{ij}^0(\mathbf{r})$, $E_{ij}^0(\mathbf{r})$ is the normal component of the electric field, pointing from medium i to medium j . The complex character of the permittivity of each medium, depending on the magnitudes of their real permittivity and conductivity, gives rise to complex charge densities, phase shifted with respect to the applied field. As in equation (1), the integral in (2) is interpreted in the sense of the Cauchy principal value.

Results

A measure of the response of a dielectric particle to an external electric field is given by its complex polarizability $\tilde{\alpha}$. This property is related to the dipole moment induced on the particle by means of the expression:

$$\tilde{\mathbf{p}}_{eff} = \tilde{\alpha}(\omega) \tilde{\mathbf{E}} \quad (4)$$

where $\tilde{\mathbf{p}}_{eff}$ is the effective dipole moment of the particle, $\tilde{\mathbf{E}} = \mathbf{E}_0 e^{-i\omega t}$ is the external electric field applied and ω the angular frequency of the field. These magnitudes are frequency dependent, so they are complex quantities. In this work we deal with the response of a particle to a field strength of 1V/m at a fixed frequency of 10^5 Hz, in order to pay attention to the effects of surface roughness, a question hardly taken into account in previous studies about dielectric particles under electric fields.

The polarizability of 2D circular dielectric objects in an external field is representative of very long dielectric circular cylinders with the electric field applied perpendicularly to the cylinder axis.

As a first approach to this problem, we have investigated how the polarizability of the particle is dependent on the depth of a sinusoidal roughness all around the cylinder surface. We have first considered the case of a lossless particle with a permittivity $\varepsilon_1 = 10\varepsilon_0$ immersed in the vacuum. As indicated in the cross section of the

SURFACE ROUGHNESS EFFECTS

schematic draw in Figure 1, the particle is characterized by a radius $a = 1 \mu\text{m}$ and a roughness extent given by the parameter h . The figure also shows the results of the transverse polarizability of the cylindrical particle when two different numbers of undulations are considered. We can observe that when the roughness is getting smaller with respect to the radius, the results are becoming similar in both cases, and tend to the value for a circular particle.

Figure 1. Transverse polarizability of a dielectric circular cylinder with sinusoidal surface roughness. Cylinder permittivity $\epsilon = 10\epsilon_0$; N_L is the number of undulations.

For the sake of comparison, we have analyzed the induced superficial charge and potential over both a soft and a rough surface of the particle. The results are given in Figure 2(a) and (b), respectively.

Figure 2. Induced surface charge (a) and induced potential (b) along the surface points by an electric field of 1V/m on both soft and rough dielectric surfaces; the number of undulations is $N_L = 10$, the total number of points $N = 1000$ and the ratio $a/h = 20$.

The next step for the 2D analysis of the roughness surface effects consists on the study of the polarizability of a layered particle, as a typical biological cell. The cell has been modeled as a particle of $1 \mu\text{m}$ of radius

surrounded by an undulating shell –the membrane– with 10 nm of thickness. This characterization of the cell membrane as a roughness surface is a first improvement in the approach to the reality of the complex cell envelope. The cell is considered immersed in an external continuous medium formed by electrolytes in free water with the dielectric properties of physiological saline. All the results presented in this work have been obtained by using typical values for the electric properties of the internal layer, membrane and external medium. These values are based on interpolations of impedance measurements on tissues and theoretical calculations [Gabriel et al. 1996]. Table 1 shows the electrical parameters for the non conductive membrane and the highly polarizable internal layer considered for the cell as well as those for the external medium. In Figure 3 the obtained polarizability of a particle as a function of the roughness relative height, a/h , is shown.

Layer	Parameter	Value
Internal Layer	ϵ	50
	σ	0.5
Membrane Uniform shell $d = 10$ nm	ϵ	10
	σ	1×10^{-6}
External Medium	ϵ	80
	σ	1.5×10^{-3}

Table 1. Electrical parameters for the different layers of the cell model: relative permittivity ϵ and conductivity σ (S m^{-1}).

Figure 3. Variation of the polarizability of a shelled particle with sinusoidal undulated membrane as a function of a/h ; the number of undulations is $N_L = 80$.

Further improvement in the approach to the real, highly irregular surface of a cell with different protrusions and microvilli, has been realized by means of a different morphology based on fractal surfaces. The fractal description provides a very general, scale-invariant, characterization of the electrical response of a biological membrane. It has been applied to the analysis of impedance measurements of human lymphocytes by Bordi et al. [1990]. A fractal surface topography can be generated using a modified (truncated) Weierstrass-Mandelbrot function that can be written as [Yan and Komvopoulos 1998]

$$f(r) = \sum_{n=-n_{\max}}^{n_{\max}} b^{-n(2-D)} [1 - k \cos(b^n r + \varphi)] \quad (5)$$

In this equation $f(r)$ is the rough profile, b is a frequency multiplier factor (with a typical value between 1.1 and 3), φ is a randomly generated phase, D is the fractal dimension (it has a non integer value between 1 and 2), and k is a form factor used to modify the profile.

SURFACE ROUGHNESS EFFECTS

The dielectric response of a cell with fractal surface has been analyzed using the BEM for surface charge. Average results, obtained using five different random phases, for typical membrane topography are shown in figure 4. Variable h is the square mean value of the roughness height.

Figure 4. Variation of the polarizability of a shelled particle with a fractal membrane of fractal dimension $D = 1.5$ as a function of a/h . Form factor $k = 1.9$.

Discussion and Summary

We have analyzed the electrical response of plain and coated particles characterized by a rough surface using a superficial 2D model. Sinusoidal and fractal surfaces have been generated and their electrical characteristics have been studied using BE methods. We have found that both the potential and the induced charge experience changes following the surface topography. As a consequence, the polarizability is in general markedly enhanced as the roughness height increases. The trends for sinusoidal and fractal topography are similar, except in the region of intermediate roughness height, where the polarizability for the sinusoidal case is lower, probably due to correlations in the induced charges on neighbor undulations. Although the results have been obtained for 2D models, similar conclusions can be expected for globular cells such as lymphocytes or spiculated red blood cells. In fact, it has commonly been obtained that the specific capacitance of these cells derived from electrorotation (ER) data, is greater than the typical cell membrane value of 1 mF/m^2 . Work on full 3D models that allows to interpret these ER studies is in progress.

ACUTE EXPOSURE TO WEAK, 800 HZ MAGNETIC FIELD DOES NOT ALTER SKIN MICROCIRCULATION OR PRESSURE PAIN THRESHOLD IN HEALTHY VOLUNTEERS

VEIT SCHNABEL AND LARS ARENDT-NIELSEN

DEPARTMENT OF HEALTH SCIENCE AND TECHNOLOGY,
AALBORG UNIVERSITY, FREDRIK BAJERSVEJ 7 D3, 9220 AALBORG, DENMARK

Abstract

The therapeutic application of weak electromagnetic fields (EMF) is often targeted at improving circulation or alleviating pain. This double-blind, cross-over study was aimed at quantifying the effects of acute exposure to a weak EMF in healthy volunteers.

20 healthy volunteers participated in the experiment in two sessions (at one week interval). Two coils, 4 cm in diameter, were placed laterally on both ankles (device manufacturer Actera A/S, Denmark). The frequency was 800 Hz (monopolar, triangular waveform). The flux density ranged from 0.2 mT, at the center between the coils, to 6 mT directly underneath the coils (RMS values). There were three placebo devices and one active device. The subjects were treated with two devices (one at each ankle) in each session, and the order and position of the devices was randomised. Pain thresholds to pressure were determined before and after 30 minutes exposure. Cutaneous microcirculation was monitored with thermography and laser-Doppler-flowmetry.

The repeated measures ANOVA test showed no effect of the device treatment factor for either pain thresholds or cutaneous microcirculation.

This study demonstrates that, in healthy volunteers, acute exposure to a weak (below 6 mT), 800 Hz magnetic field has no effect on cutaneous microcirculation or pressure pain thresholds.

Introduction

The therapeutic application of magnetic or electromagnetic fields is gaining in popularity and the range of treated ailments is increasing (Shupak et al., 2003). By the year 2004, more than 2 million patients had been treated worldwide for a large variety of injuries, pathologies and diseases, with an 80% success rate and practically absent side effects (Markov, 2004). Despite this high success rate, electromagnetic therapy is still not fully accepted as standard clinical practice. This is partly because some of the clinical trials are based on small sample sizes or have methodological shortcomings (Podd et al., 1998; Cullum et al., 2001), and partly because there is no consensus as to which biophysical or biochemical mechanisms are involved (Polk et al., 1996; Stavroulakis, 2003; Swanson et al., 2006). It has been shown theoretically and experimentally that strong magnetic fields (over about 1.5 T) can have direct cardiovascular effects in humans (Jauchem, 1997). For magnetohydrodynamic interactions, even stronger fields are required, about 5 to 10 T (Kinouchi et al., 1996). Exposure to an electromagnetic field, that induces currents in the body that are about 25 to 40 times stronger than those used in the present study, evokes a pain sensation with muscle contraction, accompanied by a reduction in skin blood flow in the fingertips (Ueno et al., 1986).

The beneficial effects of electromagnetic therapy are often explained by improving blood circulation, thereby reducing pain and inflammation, and enhancing soft tissue repair (McMeeken, 1992). This study seeks to quantify, in healthy volunteers, the acute effects of a weak (below 6 mT) magnetic field.

Methods

Study Design. The study was performed as a double-blind, randomised, placebo controlled trial with cross-over. The experiment had been approved by the local ethics committee "Den Videnskabetiske Komité for Viborg og Nordjyllands Amter", case number VN 2005/62.

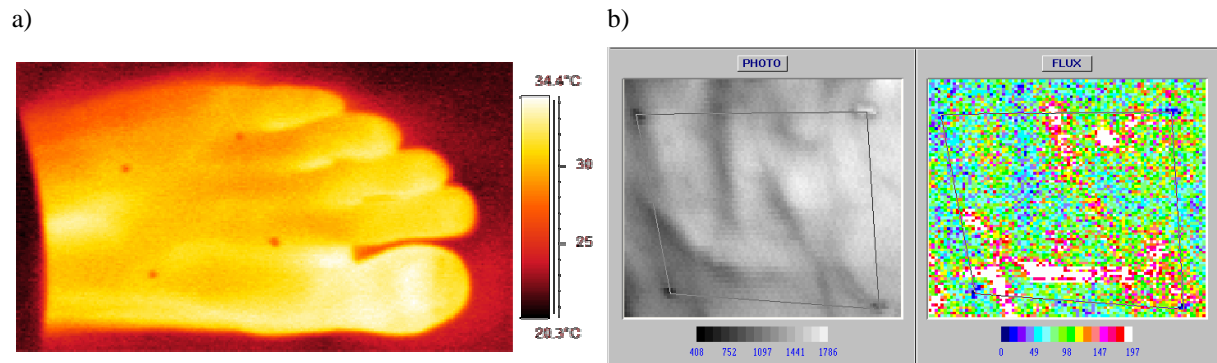

Fig. 1 Examples of pictures as recorded with thermography, a), and laser-Doppler-flowmetry, b). The corners of a 4×4 cm square were marked with a silver pen, visible on both pictures. Mean values of temperature and blood perfusion over this area were calculated and stored for analysis. The cork shield, used for covering the coils, is visible on the left side of a).

Subjects. 20 healthy volunteers (14 male, 6 female) were recruited through on-campus advertisements. The mean age was 24 years (range 22–30 years), mean BMI was 22.2 ± 2.9 kg/m². Subjects were only admitted to the experiment if they were healthy, not pregnant, and not taking any form of medication. None of the participants had tried any form of magnetic or electromagnetic therapy before. None of the participants were heavy smokers or had excessive use of tea/coffee/alcohol. The subjects were instructed not to drink tea/coffee/alcohol, nor to smoke, for a period of 2 hours prior to the experiment. All subjects gave signed written informed consent before conducting the study. All subjects received a compensation (600 DKK) for their participation in the experiment.

Magnetic Field Exposure Condition. The devices used for this study were Actera ELMS-3 stimulators (Actera A/S, Aalborg, Denmark). These devices consist of two applicator coils, approximately 4 cm in diameter, and a control unit. The positions “high” intensity, 800 Hz frequency, and 30 min duration were chosen, resulting in a non-uniform magnetic field with flux densities ranging from 0.2 mT, at the centre between the coils, to 6 mT directly underneath the coils (RMS values). The produced magnetic field was monopolar (about 20% static offset) and had an asymmetric, saw-tooth like waveform repeated at 800 Hz (duty cycle 100%). There was one active device and three placebo devices, with labels A–D. The placebo devices looked and behaved exactly like the active device, but did not produce any magnetic field. It was not possible to see, hear, feel, or sense in any other way which of the devices was active or placebo. The devices were provided by Actera A/S, and only their Chief Technology Officer knew which of the devices the active one was. The blinding was maintained until after the experiment had been concluded and the statistical analyses had been completed.

Assessment of Blood Flow. Skin temperature and cutaneous microcirculation were measured with thermography (Thermovision, Scanner 900 SW-TE, AGEMA Infrared System, Sweden) and laser-Doppler-flowmetry (LDI, Moor Instruments, Devon, UK), respectively, on a predefined area (4×4 cm), proximal and centred to the base of the middle toe. The thermography camera records the infrared emission of the skin as a measure of the skin temperature, which is affected by both cutaneous and deeper lying (muscular) structures as a result of blood perfusion and metabolic processes. A temperature-coded colour picture of the foot was taken, and the mean temperature over the predefined area was calculated and stored. Cork shields were used to cover the magnetic coils when taking the thermographic pictures, because the electrical current flowing through the active device slightly heats up the coils (by about 2°C after 30 minutes), which could not be felt by the subjects but might have unveiled the active device on the thermographic pictures. Laser-Doppler-flowmetry uses a low power laser beam to scan the skin in a raster pattern. Moving blood in the microvasculature causes a Doppler shift in the laser beam, which is processed to build up a colour coded image of blood flow in relative perfusion units (PU). Laser-Doppler-flowmetry measures the cutaneous microcirculation in the superficial layers of the skin within a depth of a few hundred of microns, as a product of number and velocity of the erythrocytes. The mean perfusion value over the predefined area was calculated and stored. Both measurements were non-contact at about 40 cm distance. In Fig. 1, examples of pictures as recorded with thermography and laser-Doppler-flowmetry are shown.

Assessment of Pressure Pain Threshold (PPT). PPT measurements were performed with a hand-held electronic algometer (Somedic AB, Stockholm, Sweden) mounted with a 1-cm diameter circular rubber probe calibrated in kilopascals. To assess the PPT, the probe was held perpendicularly and pressure increased at a constant rate of 30 kPa/s. The PPT, defined as the value where the subject felt the first change from pressure sensation to pain, was recorded. When PPT was reached the volunteers were instructed to press a button that froze the actual pressure on a digital display. The median of three measurements on each point was recorded as

NO EFFECT OF EMF ON SKIN BLOOD CIRCULATION IN HEALTHY VOLUNTEERS

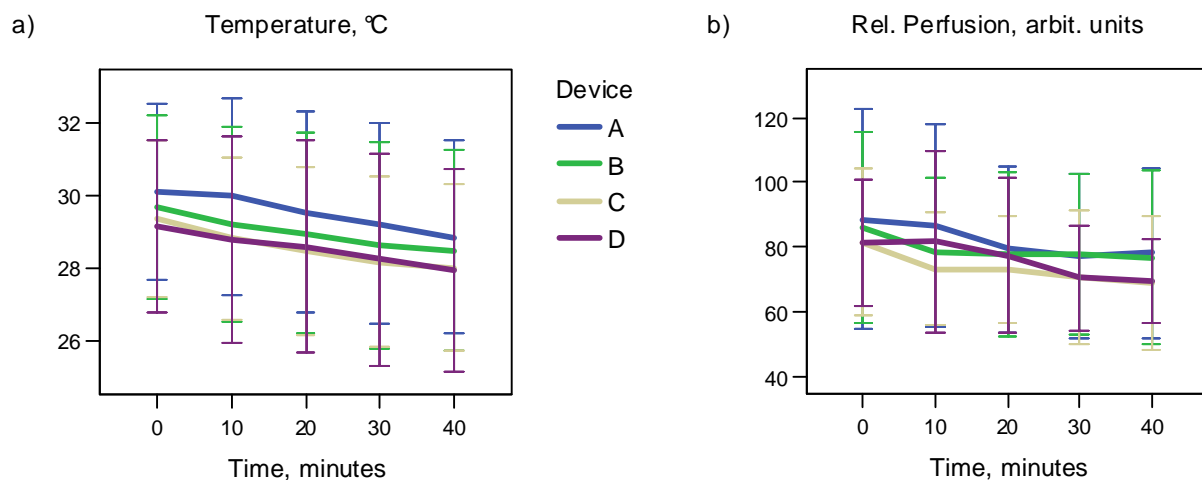

Fig. 2 Profiles of skin temperature and blood perfusion in the dorsum of the foot, at baseline (0 min), 10 and 20 min after start of stimulation, at the end of stimulation (30 min), and 10 minutes post-stimulation (40 min). Values are means \pm standard deviation ($n = 20$).

threshold value. PPT values were measured on the top of both feet (mostly skin and bone) and on the centres of the tibialis anterior muscles.

Assessment of Vaso-Motoric Reaction to Mild Heat. A small (approximately 1 cm²) metal plate was heated up to 41°C (computer-controlled) and was applied to the skin for 30 seconds, 4 cm medial to the centre of the tibia. Cutaneous microcirculation was measured in a predefined area (4×4 cm) around the heat stimulation site, both before and after the heat impulse, with thermography and laser-Doppler-flowmetry (see above). The heat impulse resulted in vasodilatation in the superficial layers of the skin, increasing the blood perfusion. The increase of the mean temperature and flux profiles due to the heat impulse was recorded (difference post-pre impulse).

Experimental Procedures. Each subject participated in two sessions with one week interval (on the same time of the day). In each session, the subjects received stimulation (active and/or placebo) from two devices, one for each ankle. The order and position of the four devices was randomised according to a random permutation table, prepared with a computer programme (MATLAB 7, The MathWorks Inc., Natick, MA, USA). The room temperature in the laboratory ranged from 21 to 23°C, and all experiments were performed under normal illumination conditions (fluorescent light). The subjects were in supine position, with bare legs and feet, throughout the experiment. The vaso-motoric reaction to mild heat was measured on the right and left leg, followed by determination of the PPT on right foot, right leg, left foot, and left leg. After a 10 minute rest period, the coils were placed laterally on both ankles, and baseline values for the blood flow (temperature and blood perfusion) in the right and left foot were determined. Then, the electromagnetic therapy devices were switched on. After 10, 20, 30 (end of stimulation), and 40 minutes (10 minutes post-exposure), temperature and blood perfusion were measured in the right and left foot. Finally, vaso-motoric reaction to mild heat and PPT were determined as mentioned before. One experimental session lasted in total between 1.5 to 2 hours.

Statistical analysis. The results were expressed as means and standard deviation (means \pm SD) in the text and figures. The statistical procedures performed, for the analysis of the blood flow, were multivariate (skin temperature and blood perfusion) repeated measures ANOVA, with within-subject factors “device” (4 levels) and “time” (5 levels). For the analysis of PPT values and vaso-motoric reaction to mild heat, multivariate (foot PPT, leg PPT, increase in skin temperature, and increase in blood perfusion) repeated measures ANOVA was applied, with within-subject factors “device” (4 levels) and “time” (2 levels). The software used for the statistical analysis was SPSS 14.0 (SPSS Inc., Chicago, IL, USA). A value of $P < 0.05$ was considered as significant.

Results and Discussion

There were no drop-outs in this study, and complete measurement sets were obtained for all 20 subjects. No side effects were observed in this study. None of the participants felt any discomfort, paresthesia, or pain during or after the magnetic field exposure. Only three participants felt warmth in one of the legs after the exposure, but the indicated leg was receiving placebo stimulation in all three cases. None of the participants guessed the active

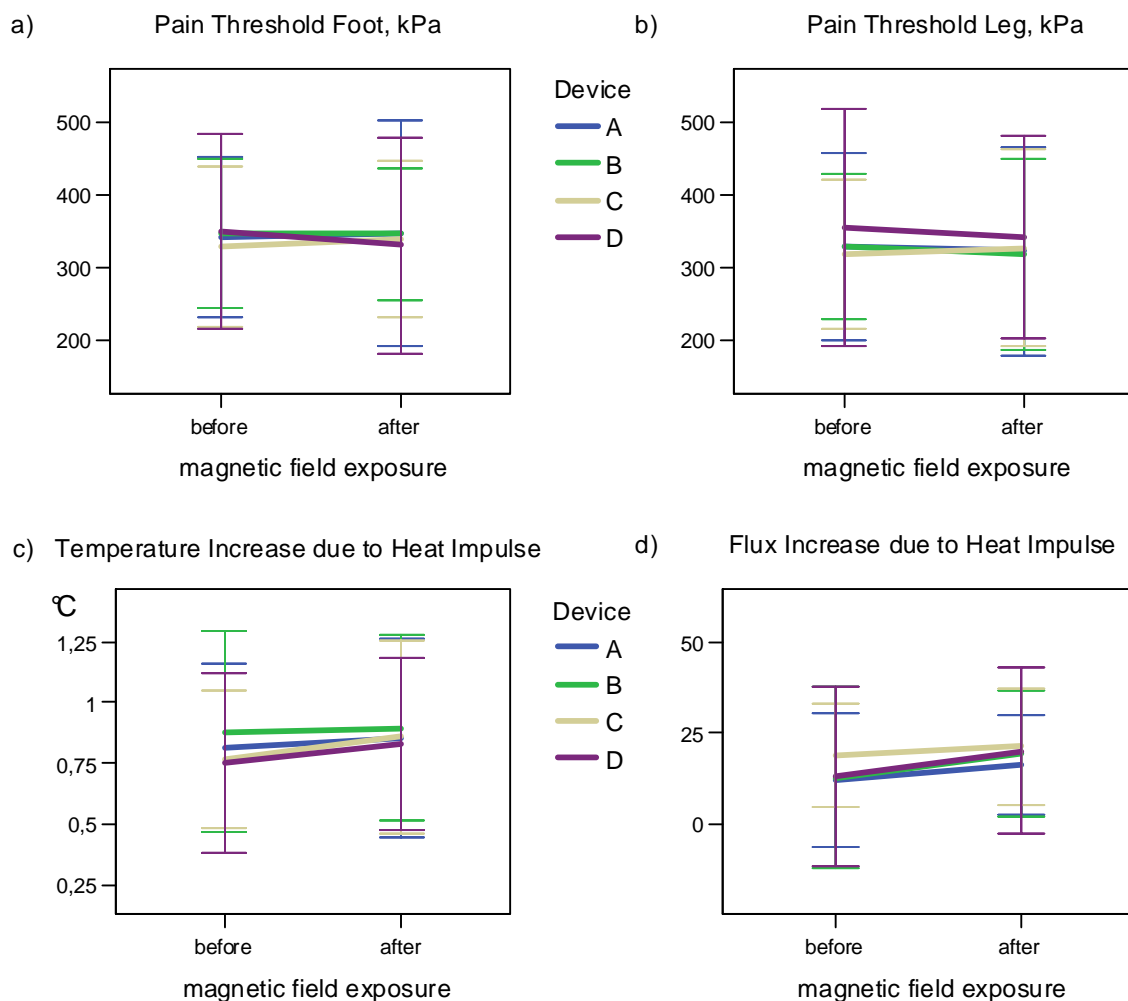

Fig. 3 Profiles of pain thresholds: on dorsum of foot, a), and on the centre of the tibialis anterior muscle, b). Profiles of vaso-motoric reaction to mild heat: temperature and blood perfusion increase caused by a 41°C heat impulse, c) and d). Measurements were done 15 minutes before and 15 minutes after magnetic field exposure. Values are means \pm standard deviation ($n = 20$).

device correctly (only three of the participants tried to identify the active device). A few of the participants became sleepy, and four of them fell asleep during the experiment.

Skin Temperature and Blood Microcirculation (Fig. 2). At baseline, the mean value (averaged over all four devices and all 20 subjects) of the foot temperature was $29.6 \pm 2.3^\circ\text{C}$ (mean \pm SD, $n = 80$), and the mean value of the foot blood perfusion was 84.3 ± 26.6 arbitrary units. At the end of the experiment, the mean values decreased to $28.3 \pm 2.6^\circ\text{C}$ and 73.4 ± 22.4 , respectively. Profiles of the mean values for the four devices at each time point are shown in Fig. 2. The multivariate (dependent variables temperature and blood perfusion) within-subject repeated measures (factors time and device) ANOVA test showed a statistically significant effect for the time factor ($p < 10^{-8}$; partial $\eta^2 = 0.36$), but failed to reach statistical significance for the device factor ($p = 0.40$; partial $\eta^2 = 0.053$; observed power = 0.40) and the time \times device interaction ($p = 0.44$; partial $\eta^2 = 0.051$; observed power = 0.82). The univariate tests confirmed the statistically significant effect ($p < 0.001$) of the time factor on both dependent variables, temperature (partial $\eta^2 = 0.56$) and blood perfusion (partial $\eta^2 = 0.36$).

Pain Thresholds and Reaction to Mild Heat (Fig. 3). Before magnetic field exposure, the mean value (averaged over all four devices and all 20 subjects) of the pain threshold in the foot was 342 ± 112 kPa (mean \pm SD, $n = 80$), mean pain thresholds in the leg was 332 ± 124 kPa, mean temperature increase due to mild heat stimulation was $0.80 \pm 0.35^\circ\text{C}$, and mean blood perfusion increase due to mild heat stimulation was 14.25 ± 20.74 arbitrary units. The post-exposure values of the means were 342 ± 126 kPa, 327 ± 135 kPa, $0.86 \pm 0.38^\circ\text{C}$, and 19.24 ± 17.57 arbitrary units, respectively. The corresponding mean values for the four devices are shown in Fig. 3. The multivariate (dependent variables foot PPT, leg PPT, temperature increase, and

NO EFFECT OF EMF ON SKIN BLOOD CIRCULATION IN HEALTHY VOLUNTEERS

increase in blood perfusion) within-subject repeated measures (factors time and device) ANOVA test did not reach statistical significance, neither for the factors time ($p = 0.22$; partial $\eta^2 = 0.29$; observed power = 0.39) or device ($p = 0.30$; partial $\eta^2 = 0.08$; observed power = 0.66), nor for the time \times device interaction ($p = 0.89$; partial $\eta^2 = 0.04$; observed power = 0.30).

Unblinding. Device A was the active device.

Discussion. The only statistically significant effect in this study was observed for the time factor. This means, that over time both the temperature and the blood perfusion changed. Since the subjects were in a passive supine position for 40 minutes with bare legs and feet, it was expected that the temperature would decrease over time. The results show that this was indeed what happened (see Fig. 2). This is consistent with other studies (Schuhfried et al., 2005). There are other forms of application of electromagnetic fields where either the intensity or the frequency is high enough to heat body tissue due to eddy currents (Ueno et al., 1986; Alekseev et al., 2005). But the magnetic field used in the present study is too weak to evoke eddy currents in the body of the required amplitude. Direct heating of the skin with the magnetic field device might also occur due to ohmic heating of the applicator coils (McMeeken, 1992). McMeeken (1992) observed a temperature increase of the applicator coil of 3.7°C after 15 minutes of operation, which led to a temperature increase of 0.5°C in the skin underneath the applicator (due to infrared radiation), without affecting the blood flow. In the present study, we observed a temperature increase of the applicator of 2°C after 30 minutes of operation.

There was no statistically significant effect of the device factor in the present study. If there were an effect of the device factor, then baseline values would have to be different for the different devices (different intercepts in Fig. 2 and 3). However, this is not a reasonable assumption.

It would be reasonable to assume different slopes of the profiles, e.g. if the leg treated with the active device cooled less than the leg treated with the placebo device. This is tested by the time \times device interaction, which did not reach statistical significance. The observed power of this test was 82%. Therefore it is concluded that a magnetic field (only present in the active device) of strength and frequency as used in the present study does not change temperature and blood flow in healthy volunteers. This is consistent with other studies (McMeeken, 1992; Schuhfried et al., 2005; Wenzel et al., 2005).

Summary

This study shows that, in healthy volunteers, acute exposure to a weak (below 6mT) magnetic field with a specific waveform, repeated at 800 Hz, does not change skin blood flow and temperature, nor pressure pain thresholds.

Acute exposure of healthy volunteers was chosen in this study in order to detect (and quantify) a possible basic, direct effect of magnetic fields. Prolonged or repeated exposure might show different effects. Patients receiving the magnetic field stimulation might show different effects, because the biological response to electromagnetic field exposure depends on the state of the biological target tissue (Mayrovitz et al., 2001). It was shown that patients react differently than healthy people to electromagnetic therapy (Giordano et al., 2000).

The results of the present study do not allow drawing conclusions about the possible effects of electromagnetic therapy in patients. Therefore, this study can not answer the question whether enhanced microcirculation might or might not be an effect of electromagnetic therapy in patients. However, this study shows that there is no direct (acute) effect of exposure to a magnetic field, of strength and frequency as used in this study, on microcirculation in healthy subjects.

Abstract

The level of serum alkaline phosphatase(alp),as a a possible promoter of bone or tumor disease was studied in 80 rats exposed to microwave radiation(2450 mh with power density of 1 and 10mw/cm²), for a period of one year. The animals were devided to 5 groups of 16 each(8males and 8 females), 4 for treatment and one for control group. First two treated groups were exposed to microwave radiation at power density of 1mw/cm² in different period (30 minutes for one group and 5 minutes for another one), daily. Next two treated groups were exposed to microwave radiation at power density of 10 mw/cm² in different period (30 minutes for one and 5 minutes for another group), daily. Control group were kept under the normal condition without any microwave exposure. Animals were observed daily and body weight and food and water consumption was assessed weekly too. In the end of study the blood sample were taken from the heart of animals under ether anesthesia and alp analysis was performed on blood serum of animals. According to the test result and statistical analysis the level of alp in groups exposed To microwave radiation at power density of 10 mw/cm² was significantly increased ($p<0/011$), but in other treated groups,the statistical results has not been significant in comparison with control group.

Introduction :

Alkaline phosphatase is a group of enzymes found primarily in the liver and in bone.It also is produced by the placenta and to a lesser extent by the intestines and kidney.

In this study, the gole of measuring alkaline phosphatase is to check the possibility of bone or liver disease in rat after a period of one year exposure to 2450 mh microwave radiation at incident power densities of 1and 10 mw/cm² for 5 and 30 minutes daily.

INFLUENCE OF MICROWAVE RADIATION ON SERUM ALKALINE PHOSPHATASE

Method of study :

Animals

80 sprague Dawley rats with 5 week age were used in this investigation for a period of one year. The animals were housed individually in polycarbonate cages under standard conditions with free access to tap water and standard food (1,2,3,4,5). the rats were divided to 5 group , each containing 16 rats (8 male and 8 females) , as follows :

Group D and E : exposed to microwave radiation with power density of 1 mw/cm² for 30 minutes daily for group D and 5 minutes daily for group E .

Group F and G : exposed to microwave radiation with power density of 10 mw/cm² for 30 minutes daily for group F and 5 minutes daily for group G .

Group H : as a control group were kept under the same condition without any microwave exposure .

Records and Control :

The rats were weighed before experiment and weekly and recorded. Any clinical abnormality were noted and recorded .

Food and water consumption were controlled weekly too .

Method of ALP Measurement :

In the and of study the blood sample were taken from the heart of animals after 12 hours fasting under ether anesthesia .

The level of alp was measured by enzymatic method. the enzyme splits off the phosphate group from 4-NPP to form free 4-nitrophenol. Thus the rate of formation of 4-NP by the action of the enzyme on 4-NPP at 37°C can be monitored with a recording spectrophotometer(6,7,8):

4-nitrophenylphosphate + H₂O $\xrightarrow{\text{ALP}}$ phosphate + 4-nitrophenol

Statistical analysis :

Statistical evaluation of data for comparison of treated and control group were made by using one way analysis of variance (anova) technique , followed by a multiple comparison , the one way anova was applied using the F distribution to assess significance at the level of 0/05

Results and discussion :

Clinical observation : there was one death related to group E.

Body weight and food and water consumption : according to the results , the percentage of body weight and food consumption was reduced in treated groups in comparison with control(9), but the *percentage of* water intake was increased in treated groups especially in group F in comparison with control.

Serum ALP Level :

As illustrated in fig 1-3 , the level of ALP in group male of G and mixed group male and female of G that were exposed to microwave radiation at power density of 10 mw/cm² for 5 minutes daily was significantly increased (P < 0/01) , but as statistical analysis is showed in table 1-3 increasing of ALP in other treated groups was not significant in the level of 0/05 , in which microwave exposure at 10 mw/cm² is suspected as a possible promoter of bone or tumor disease that should be considered (6,10,11,12)

Abstract

80 sprague Dawley rats were exposed to 2450 mhz microwave field for a period of one year. The experiment groups were divided to 5 groups,each 16(8 males and 8 female), 4 for treatment,and one,for control(D,E,F,G,H).

The incident power density of the first two experiment groups was $1\text{mw}/\text{cm}^2$,and, for next two groups,was $10\text{mw}/\text{cm}^2$.The daily exposure time,was 5 minutes for groups F and G,and 30 minutes for groups,D and F. The animals in control group(H) were under normal condition without any microwave exposure.

In the end of the study the blood samples were taken from the heart of animals under ether anesthesia,and determination of blood parameters were performed by cell counter auto analyser.

According to the statistical results the level of RBC in male groups of F and G,and percentage of PCV in female and male groups of F,and content of HB,in female groups of F,in comparison with control group were significantly increased and variation of results in other groups were not significant.

Introduction :

The aim of this study was to investigate and check the possibility alteration of some blood parameters in rats after a period of one year exposure to 2450 Mh microwave radiation at power density of 1 and 10 mw/cm^2 for 5 and 30 minutes daily and also to compare the treated groups with that of control group .

Method of study :

Animals

80 sprague dawley (SD) rats with 5 weeks age were used this study for a period of one year. The animals were housed individually in polycarbonate cages under standard condition with free access to tap water and standard food (1,2,3,4,5).the rats were divided into 5 groups (4 treated and 1 control) of eight male and eight female rats each .Two first experimental groups were exposed to 2450 mh microwave radiation with field powers density of $1\text{mw}/\text{cm}^2$ for 30 minutes daily for group (D) and 5 minutes daily for group (E) .

Next two treated groups were exposed to 2450 mh microwave radiation with filed power density of $10\text{mw}/\text{cm}^2$ for 30 minutes for group (F) and 5 minutes for groups (G) daily.Control group(H) were under normal condition without any microwave radiation exposure.

Records and control :

The animals were weighed before experiment and weekly and recorded .

Any clinical abnormality were cared and recorded. Food and water consumption were also weekly controlled .

Blood analysis :

In the end of study the blood samples were taken from the heart of animals under ether anesthesia and the blood samples were mixed with ethylenediamine tetraacetic acid (EDTA) and then analysed by auto analyser of cell counter .

Statistical analysis :

The differences between groups were analysed using appropriate one way analysis of variance (anova) technique , followed by a multiple comparison .

The one way anova was applied using the F distribution to assess significance in the level of 0/05

Fig 1- mean difference of R B C in female groups

Fig 2- mean difference of R B C in male groups

Fig 3- mean difference of P V C in female groups (%)

Fig 4- mean difference of P V C in male groups (%)

Fig 5- mean difference of Hb in male groups (g/dl)

Fig 6- mean difference of Hb in female groups (g/dl)

**Summary :**

The data presented in this study indicate that there is increasing of blood parameters of RBC , PVC and Hb in treated groups exposed to microwave radiation at power density of 10 mw/cm² in

EFFECT OF MICROWAVE EXPOSURE ON SOME HEMATOLOGICAL PARAMETERS

which microwave exposure in this field is a probable agent for stimulation of proliferation processes in red bone marrow, may be due to hypoxia and releasing of erythropoietin hormone, that can be considered. Our data also indicate that the test results of same blood parameters in treated rats exposed to microwave radiation at 1 mw/cm² power density has not been significant in comparison with that of control group.

Abstract

PURPOSE: We examined the apoptotic effects of extremely low-frequency electromagnetic fields (EMFs) on murine thymus gland and testis after whole-body irradiation.

METHODS: Thymus gland and testis are highly susceptible to ionizing irradiation (IR). When suffered to apoptosis by IR, the apoptosis-related signal molecules including nuclear transcription factors and cytoplasmic caspases are activated. Here, we measured the expression levels of nuclear transcription factors such as ATF-3 and p53 and a caspase-3-cleaved product LyGDI/GDI-D4/RhoGDI2/RhoGDI β in thymus gland and testis after whole-body EMFs irradiation.

RESULT: Both transcription factors, ATF-3 and p53, were not up-regulated according to time course and dose-response of EMFs. The caspase-3-cleaved product, N-terminal deleted 21-kDa fragment of LyGDI (Δ N(1-19)LyGDI), was also not induced by EMFs. Besides, in immunoblotting of Δ N(1-19)LyGDI, we noticed an unexpected 55-kDa band which was disappeared by EMFs although this epitope has not been identified.

CONCLUSION: Apoptotic signals mediated by DNA strand breaks are not generated in whole-body irradiation of EMFs. Instead of this, an unknown intracellular signalling may possibly be provoked in EMFs-irradiated thymic gland and testis.

Introduction

An association between residential extremely low-frequency electronic and magnetic fields (EMF) and childhood leukemia was first reported in 1979 by Wertheimer and Leeper¹. In Japan also epidemiologic studies recently showed that residential power-frequency magnetic fields levels above 0.4 micro T exposure was associated with a higher risk of childhood leukemia (acute lymphoblastic leukemia)². Experimentally, we found that the offspring mice coming from late pregnant mice exposed to a 500mG 50Hz developed chronic

myelogenic leukemia with chronic exposure³⁾. Exposure to a 60-Hz magnetic field at 0.001mT for 24 hr was reported to cause a significant increase in DNA single-and double-strand breaks in the brain cells of rats⁴⁾.

As a general mechanism, apoptotic cell death is triggered by DNA strand breaks. When apoptotic signalling caused by ionizing radiation (IR) is generated in the cells, transcription factors such as ATF-3 and p53 are up-regulated. Subsequently, as post-mitochondrial signals, caspases are activated to execute apoptosis. LyGDI, also known as GDI-D4/RhoGDI2/RhoGDI β , is a substrate of caspase-3 and is cleaved by activated forms of this during IR-induced thymic apoptosis⁵⁾. Therefore, the cleaved product, N-terminal deleted Δ N(1-19)LyGDI, becomes a marker for the activation of caspase-3. To examine whether EMFs provoke such an apoptotic signalling, we measured the expression levels of either transcription factors and Δ N(1-19)LyGDI in thymic gland and testis from whole-body irradiation of EMFs. The presented data clearly indicate that EMFs do not induce the apoptotic signalling in both thymic gland and testis. Besides, an unidentified immunoblot band, which is reactive to N-terminus of Δ N(1-19)LyGDI, has been found to respond to EMFs in both organs.

Materials and Methods

Animal: C57BL/6NCrCrIj male mice were purchased from Charles River Japan Inc. at 6 weeks of age.

EMF exposure: The exposure facility was produced by Chugoku electronics (Hiroshima, Japan). Magnetic fields were provided by electromagnet which has air gap of 10cm cubic and exciting coli of 1400 turns. Sixty Hz magnetic fields of 100mG, 500mG, 1G, 5G and 10G were generated for exposure. Animals in the air gap were kept under constant conditions of temperature($24\pm 2^{\circ}\text{C}$) and humidity($50\pm 10\%$).

Experimental procedure:

- 1) To investigate expression of Δ N (1-19) LyGDI and full-length LyGDI in the exposed cells, mice were exposed to 60Hz field 5G for 6 hours. Then thymus and testis were aseptically taken out from sacrificed mice.
 - 2) Time-dependent p53 and ATF-3 were studied with 60Hz field of 10G, at 0, 3 and 6hr, respectively.
 - 3) Dose-dependent p53 and ATF-3 were examined with 60Hz field of 0, 0.1, 0.5, 1, 5 and 10 G, respectively for 6hr.
- Mouse thymus irradiated with 5 Gy was used as positive control in expression of ATF-3 and p53.

Antibodies:

Primary antibodies used in the present study is summarized in Table 1.

Table 1. Primary antibodies used in the present study

Recognized molecule	antibody	Source	Type number
Full length LyGDI	goat polyclonal antibody	Santa Cruz	sc-6047G
N-terminal deleted form of LyGDI	monoclonal antibody	Active Motif	40941
p53	goat polyclonal antibody monoclonal antibody	Santa Cruz Cell Signaling	sc-6243G 2524
ATF-3	rabbit polyclonal antibody	Santa Cruz	sc-188
α -tubulin	monoclonal antibody	Cederlane	L9002T

EFFECT OF EXTREMELY LOW FREQUENCY ELECTROMAGNETIC FIELDS ON MOUSE THYMUS AND TESTIS

Protein analysis:

To extract total protein, thymus and testis was homogenized with ice-cold sodium dodecyl sulfate(SDS) sample buffer (pH 6.8) consisting of 25mM Tris-HCl, 5% glycerol and 1% SDS. The homogenized solution was sonicated five times for 5 s on ice and centrifuged at 15,000 rpm for 1min at 4°C. The supernatant was then used for Western blot analysis. After extraction, the protein concentration was determined using a BioRad protein assay Kit. Then Protein of 20 micro gr per lane were applied to a 12% SDS-polyacrylamino gel, after which whole cell lysate and the fractionated samples were resolved by electrophoresis and transferred to Immobilon-P membrane. The gels were probed with primary antibodies, followed by secondary antibodies. Horseradish peroxidase-conjugated anti-goat rabbit antibody and horseradish peroxidase-conjugated anti-mouse or anti-rabbit donkey antibodies were used as secondary antibodies. Proteins were visualized on X-ray film using ECL Western Blotting Detection Reagent.

Results and discussion

To elucidate the apoptosis-inducing signal of exposed thymus and testis cells, we first investigated the cleavage of LyGDI. In mouse LyGDI, cleavage by caspase 3 and caspase 1 occurs after the Asp¹⁸ and Asp⁵⁴ residues, respectively, resulting in the production of two truncated protein, 21-kDa and 17-kDa products. Thus the products of truncated LyGDI indicates which caspase are activated in exposed cells. But as Figure 1 shows, truncated LyDGI was not detected in both of thymus and testis with 5 G exposure for 6hr. Interestingly, unknown substance (55kDa) reactive antibody recognized the N-terminal amino acids of the deleted ΔN (1-19) LyGDI, was detected in thymus and testis cells and indicated decrease in exposed both the cells(Figure 1-B).

Figure1. Truncation of LyGDI and full-LyGDI after magnetic irradiation for 6hr. Panel A: Full-LyGDI was detected in both of thymus and testis with 0 and 5 G. Panel B: Truncation of LyGDI was not found in both of thymus and testis with 0 and 5 G, respectively. Unknown substance was detected in about 55KDa with antibody of ΔN -LyGDI.

Figure 2. Variation in the protein level of p53 and ATF-3 in thymus and testis with time after exposure with 10 G.

EFFECT OF EXTREMELY LOW FREQUENCY ELECTROMAGNETIC FIELDS ON MOUSE THYMUS AND TESTIS

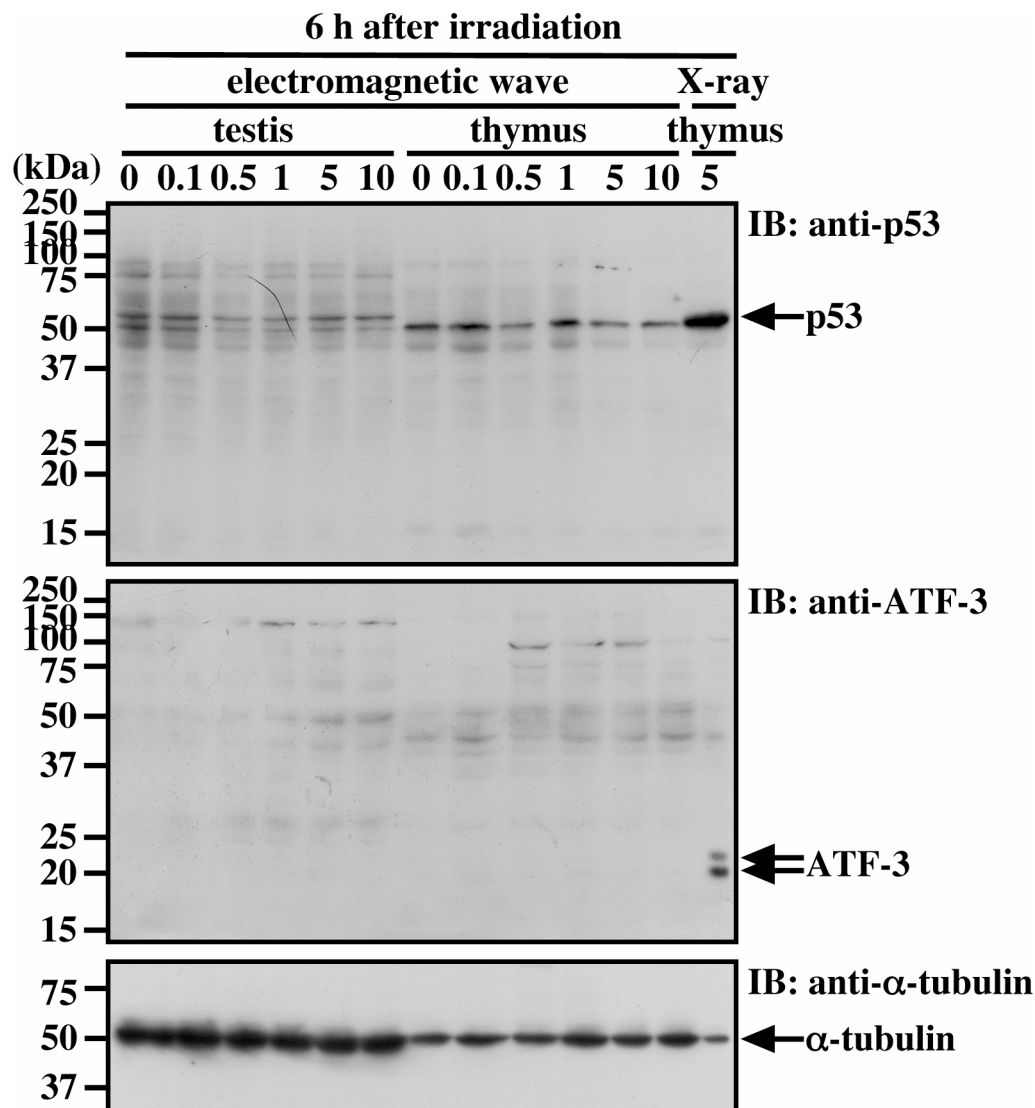

Figure 3. Effect of the exposed dose on activation of p53 and ATF-3 of thymus and testis in 6hr after exposure.

ATF3(activating transcription factor 3)is a member of the ATF/CREB subfamily of basic-region leucine zipper(bZIP) protein and is induced in response to endoplasmic reticulum stress or amino acid starvation⁶. ATF3 is a novel stress-activated regulator of p53 protein stability/function providing the cell with a means of responding to a wide range of environmental insult⁷. It is also reported that regulation of ATF3 induction after DNA damage utilizes both the p53-dependent and-independent pathways, and may also involve MAP kinase signalling pathway⁸. In this study we could not detected significant expression of AFT3 and p53 of thymus and testis in time- and dose-dependent variation. The important role of ions, particularly of Ca^{2+} , in the apoptotic process of the exposed cells is considered⁹, and then there may be another p53-independent pathway in magnetic field action on apoptosis.

Those result indicated that that there may be another signaling pathway to produce the effects of EMF, although EMF-induced signaling cascade that mediates apoptosis was not found.

Abstract

We examined the viability of bacteria *Escherichia coli* and yeast *Saccharomyces cerevisiae* after their exposure to radio-frequency electromagnetic field. The frequency of the field was $f=867$ MHz, the maximal power was 10W and the maximal duration of irradiation was 48min. The exposure took place at laboratory temperature. We measured the viability using optical spectrography of microbial culture in broth and we also used the CFU (colony forming units) counting on agar plate. We observed the decrease of viability both for bacteria and yeasts. According to our previous results for ELF-EMF the electromagnetic field effect showed the saturation and the viability decrease of bacteria was bigger compared to decrease in viability of yeasts.

Introduction

High frequency electromagnetic fields (HF-EMF), very often called as radio-frequency (RF), are electromagnetic fields with frequency in the range of GHz. It consists of GSM range (0.9-2.1 GHz) and microwaves (up to 3000 GHz). The wave length in vacuum is from 0.33m – 0.1 mm.

The effect of high frequency electromagnetic fields on living organisms is subjected to research. The importance of investigation grows with increasing use of different high-frequency devices, mainly cell phones, that produce potentially harmful radiation. Controversy and contradiction still surround the question whether HF-EMF cause any detectable biological effects. In spite of great deal of results it is necessary to observe that it is often difficult to obtain a good repeatability of data among different laboratories, thus generating conflicting results about possible effects. It is important to perform all experiments in well-defined experimental conditions. Searching in the databases we must have on mind that the results depend on the power of electromagnetic field, on the examined cells or tissue, on the duration of exposure and on the other parameters. We can bring in works showing the HF-EMF effects (1-3), or showing no EMF effect (4,5) on living organisms.

Electromagnetic fields can have negative effects on human. International Commission on Non-Ionizing Radiation Protection, part of WHO, estimated on the base of plenty scientific studies the exposure limit for HF-EMF $SAR=0.4W/kg$ (6). There are not clear evidences whether long-term exposures under the limit are harmful for health. The mechanism of acting is not still clarified. The possible way to understand it could be experiments on microorganisms *in vivo*.

Microorganisms – bacteria and yeasts seem to be good biological objects to study electromagnetic fields effects. Bacteria, their life cycle and metabolic paths are well-examined and described. Short replication time enable us

to study more bacterial generations. Similar properties have also yeasts. They are the simplest eucaryotic organisms. Using microorganisms we study effects both on cell level and the reaction of the whole organisms. The EMF effects on bacteria has been studied for many years (7-10).

In our previous studies we applied low-frequency electromagnetic fields (50 Hz, $B_m=10\text{mT}$, duration of exposure till 1h) on different bacterial strains (for example *Escherichia coli*, *Leclercia adecarboxylata*, *Staphylococcus aureus*...) and on the yeasts (*Saccharomyces cerevisiae*). We observed the decrease of viability of exposed bacteria and yeasts. The decrease was strain-dependent, the effect was higher for rod-like bacteria, spherical bacteria were more resistant to electromagnetic field exposure (11-15).

In this work we used HF-EMF on the same microorganisms. The electromagnetic field was the same as was for exposure of neurodefective C3H mice. The acute effect of HF EMF on the central nervous system excitation and inhibition and some histochemical (NADPH diaphorase) and immunohistochemical (c- Fos) characteristics were investigated. The acute exposure to HF EMF had no significant effect on these parameters but the long-term irradiation (3hours daily, 1-2 months, 880MHz) had. (16). The exposure induced the difference in NADPH-diaphorase activity in hippocampus in C57B1/7 mice and shifted spontaneous cortical and LTH hippocampal activities to lower frequencies (17).

Experimental

Bacteria

Bacteria *Escherichia coli* K12 Row, genotype 58-161 *metB1rpsL* 1⁺ F^{def}(P.Fredericq) from Department of biology of Faculty of Medicine of Masaryk University Brno (Czech Republic) were used. Bacteria were cultivated in TY broth (8 g tryptone, 5 g yeast extract – HiMedia Lab, Bombay; 5 g NaCl –Lachema Brno/ 1 l water). The growth in closed system took place in laboratory temperature (25°C)

Yeasts

The prototrophic tetraploid strain α/A of yeast *Saccharomyces .cerevisiae* CCY 21-4-59 (yeast collection, Institute of Chemistry, Slovak Academy of Science, Bratislava) was used. Yeast cultures were grown in Malt extract Broth (2% Malt extract broth – Fluka, 2% Glukose – Lachema Brno) laboratory temperature (25°C). Number of microorganisms was determined using spectrophotometry.

For all experiments fresh yeasts and bacteria cultures were used.

Spectrophotometry

Spectrophotometer Libra S 22(Biochrom) was used to measure optical density (OD) at the wavelenghts 570 and 620nm. As a reference sample the distilled water was used. The calibration curve was repeatedly measured by taking values of OD₅₇₀ or OD₆₂₀, and counting of corresponding number of CFU (see bellow). The logarithmic calibration curves were calculated by the method of minimal squares from 36 measured data.

HF-EMF Exposure

Electromagnetic field was generated by HF generator with HF amplifier. Frequency of the field was 867 Hz (close to the frequencies used in mobile phones). The wave (TEM 111) was directed by a waveguide to the place of exposure). The power output was 10W. The system microorganisms in broth were exposed 4.5-5h since its inoculation to field with SAR=2W/kg. The density of cells during the exposure was approximately 10⁶ cells/ml.

Statistics

The data are collected from 5 experiments. Each experiment consists of 3 measurements. The Student's statistics (P=0.95) and t-test were used to analyse.

Results and discussion

Bacteria *E.coli* were exposed to electromagnetic field for 12min, 24min and 48 min. Fig. 1 shows the growth curve of bacteria. The number of bacteria is expressed in units optical density (OD), it means relative absorbance of bacterial culture compared with the absorbance of reference (water). Time T=0 h marks the beginning of exposure. The decrease of number of bacteria in solution was observed for all exposed samples. The decrease of viability is adequate to duration of exposure.

Yeasts *S.cerevisiae* were exposed to electromagnetic field by the same way as bacteria. The growth curves are presented on Fig. 2. Comparing growth curves *E.coli* and *S.cerevisiae* we can observe smaller effect of EMF on yeasts. The significant changes in growth curve were observed for 24 min and 48 min exposures.

Fig.1. Growth curves of bacteria *E.coli* after magnetic field exposures.

Fig.1. Growth curves of yeast *S.cerevisiae* after magnetic field exposures.

These results show that

- EMF decreases the number of cells in broth.
- EMF effect is stronger in bacteria cells
- the decrease of the number of cells is apparent in the first serie of measurement after exposure.
- the number of cells in affected cultures is growing with time, but the growth is slower than in control culture.
- the effect of HF-EMF on the observed parameters is similar to the effect of ELF-EMF (11-13)

From the results it seems that EMF kill part of cells in broth. The growth of affected cultures is retarded by the smaller initial number of cells continuing to division process. The next progress of exposed cultures continues by the normal way, with the same rate of division.

It would be useful to perform the experiments measuring the number of cells during the EMF action.

Abstract

There is a lot of epidemiological studies showing possible effects of magnetic fields on the living systems. The ICNIRP limit for maximal magnetic field exposure was established by WHO to protect people before not-fully understood and not-fully proved harmful magnetic field effect on human. The public transportation is a place where we meet magnetic fields.

We measured magnetic fields in tramways, trolleys and buses in Brno city, tramways, trolley and buses in Ostrava city and subway and tramways in Prague. In addition the magnetic fields in intercity trains were measured.

Our results stated that the measured values do not exceed the ICNIRPs limit.

Introduction

Man-made low-frequency magnetic fields became an important part of our environment. They occur in our biosystem everywhere where low-frequency electric field is produced. Magnetic field exposure is in vicinity of electric equipments including electric engines in means of public transport. The passenger are exposed to magnetic fields. The ICNIRP (International Committee for Non Ionising Radiation Protection) limits of magnetic field exposure are highly protective and are based on all the available scientific evidence. For 50 Hz field is limit ICNIRP 100 μ T (1).

The passenger's magnetic field exposures were studied in London (2) and in Toronto (3). Our study shows the results from public transportation in three cities in Czech Republic to determine whether the ICNIRP limit is fulfilled and to compare magnetic fields in different means of transport.

Experimental

The EnviroMentor Magnetic Field Meter BMM-3000 (produced by EnviroMentor AB, Sweden) was used for used for measurement of magnetic induction.

The device is able to measure magnetic field in low-frequency range 5 - 2000 Hz and five induction ranges (200 nT-2 mT).

Tramways:

T3 (m=16 000 kg, P= 4 x 40 kW, capacity 110 passengers, 1961-1990, produced by Tatra ČKD Smíchov, Czech Republic, measured in Brno, line 1),

K2 (m=21 800 kg, P= 4 x 40 kW, capacity 157 passengers, 1966-1989, produced by Tatra ČKD Smíchov, Czech Republic, measured in Brno, line 1, 4),

KT8D5 (m=38 000 kg, P= 8 x 45 kW, capacity 231 passengers, 1999 –, produced by Tatra ČKD

Smíchov, Czech Republic, Brno, measured in line 1) and

Anitra (m=24 200 kg, P= 4 x 90 kW, capacity 155 passengers, 2000-present, produced by Škoda Plzeň, Czech Republic, measured in Brno, Ostrava, lines 1).

Trolleys:

14Tr and 14TrM (m= 10 000 kg, P= 2x100 kW, capacity 145 passengers, 1974-1984, produced by Škoda Ostrov, Czech Republic, measured in Brno, line 30),

15 Tr (m= 15 900 kg, P= 100 kW, capacity 80 passengers, 1983, produced by Škoda Ostrov, Czech Republic, measured in Brno line 26 and Ostrava line 104) and

22 Tr (m= 18 000 kg, P= 2x132 kW, capacity 140 passengers, 2002, produced by Škoda Ostrov, Czech Republic, measured in Brno line 26).

Metro trains:

81-717.1 (m= 33 500 kg, P= 4x110 kW, capacity 260 passengers, 1977-1990, produced by Mitishchinsky engineering factory, Soviet Union, measured in Prague lines A, B)

2MT (m= 31 000 kg, P= 110 kW, capacity 262 passengers, 1996-present, produced by Škoda Plzeň, Czech Republic, measured in Prague lines A, B)

M1 – Siemens (m= 27 900 kg, P= 141.5 kW, capacity 284 passengers, 2000-present, produced by Siemens AdTranz, Czech Republic, measured in Prague line C)

Intercity train:

Pendolino 680 (m= 385 000 kg, P= 4000 kW, capacity 333 passengers, 2003, produced by Alstom Ferroviaria, Italy, route Prague – Děčín - Prague).

Results

Tramways

Totally 12 600 values, 3012 during stops, 9588 operating. The maximal value of magnetic induction was 7.23 μT (operating) or 1.16 μT (standing).

Trolleys

4369 data, 1030 – standing, 3339 – operating. The maximal value was 3.23 μT (operating) or 1.03 μT (standing).

Metro

10136 data, 2269 – standing, 7867 – operating. The maximal value was 8.17 μT (operating) or 0.09 μT (standing).

Train

6648 measured values. The maximal value was 0.14 μT (operating) or 0.002 μT (standing).

The comparison of all used means of public transport is summarized in Fig.1. The maximum peak value was measured in metro (8.17 μT), then it decreased in order tramway>trolley>train (0.139 μT). The different order is if we take in the account average value. In that case trolleys have the biggest induction (3.18 μT) and than tramway>metro>train (0.002 μT).

The average values of different means of transportation differ depending on the type of tram, trolley or metro. It depends also on the external sources of magnetic fields, on the driver's style and on the profile of track. The engine draws maximal electric energy during acceleration or during breaking. In other cases the train uses inertia. The maximal values of magnetic induction are reached in a very short time just before changes in its velocity.

As for magnetic field exposure, the public transportation in Czech Republic is safe. All data are below ICNIRP limit, which is 100 μT for 50Hz fields.

MAGNETIC FIELDS IN PUBLIC TRANSPORTATION OF CZECH REPUBLIC

Abstract

The aim of the present study is to investigate whether radio frequency electromagnetic fields (RF-EMF) exposure induces acute effects on brain microcirculation being transiently observed only during RF-EMF radiation period in juvenile rats. As a model of juvenile and adult rats, we used 4 and 8 weeks old male Sprague-Dawley rats, respectively. All rats were subjected to cranial window implantation prior to the experiments and intravital-microscopic observation under anesthesia. Rat's head in RF group was locally exposed to 1,457MHz electromagnetic near-field by an "8"-shaped loop antenna. RF-EMF exposure intensity was maintained at an averaged SAR (2.0W/kg) in parietal targeted area. Three microcirculatory parameters (BBB-function, plasma velocities, and vessel diameters) in pial venules were measured every 10 min for 50min exposure period. In 4 weeks juvenile rats, no changes in any of the three microcirculatory parameters were elicited by the RF-EMF exposure. No statistical changes were recognized between those values obtained from RF group and sham exposed group. These negative effects in juvenile rats were also confirmed in adult rats. The results reveal that there were no RF-EMF exposure effects at least on our measured brain microcirculatory parameters in either juvenile or adult rats under the present exposure conditions.

Introduction

Possible adverse health effects of radiofrequency electromagnetic field (RF-EMF) exposure during mobile phone uses on the brain are one of the public health concerns, especially, the effects on the developing brain in the children. However, few studies have evaluated this possible effect using juvenile animals. Our previous studies focused on the brain microcirculation during RF-EMF exposure, and showed no noticeable change in parameters including blood-brain barrier function, vessel diameters or plasma velocities was found in adult rats. The aim of the present study is to investigate whether RF-EMF radiation affects the brain microcirculation in juveniles or not.

We used 4-week-old male Sprague-Dawley rats as juvenile animals. The rats were divided into two groups: RF group was exposed to RF-EMF and Sham group was not exposed to any RF-EMF. All rats were subjected to cranial window implantation prior to the exposure experiments and intravital-microscopic observation under anesthetic. To compare the results of juvenile animals with those of adult animals, we also performed the same preparation and experiments in 8-week-old SD rats.

Rat heads were locally exposed to 1,457MHz electromagnetic near-field TDMA (time division multiple access) signal for PDC (Personal Digital Cellular, Japanese cellular telephone standard) systems by the "8"-shaped loop antenna placed 4 mm upward to the cranial window. RF-EMF exposure was maintained at 2.0 W/kg of the averaged SAR in parietal targeted area (Table 1).

Table 1 Averaged SAR (W/kg)

Age	Target area	Whole brain	Whole body
4-week-old	2.0	0.59	0.057
8-week-old	2.0	0.54	0.032

The pial microcirculation within cranial windows was observed using a fluorescent microscope equipped with an EBCCD camera. In order to measure four microcirculatory parameters, BBB function, plasma velocities, leukocyte behaviours, and arteriole vasomotion, we used rhodamine 6G for leukocyte behaviours and FITC-Dx (70k or 2000k) for the other three parameters.

We prepared two experimental protocols. Arteriole vasomotion was observed for 12 min experimental period including 3 min RF-EMF exposure. The other three microcirculatory parameters, BBB-function, plasma velocities, and leukocyte behaviours in pial venules were measured every 10 min during 80 min experimental period including 50 min RF-EMF exposure. The results were compared between RF and Sham group. The statistical analysis was performed by Student's t-test or ANOVA.

BBB permeability was evaluated by extravasation of FITC-Dx (70kDa) from pial microvessels. After intravenous injection of FITC-Dx, the fluorescence intensities of brain surface area (0.74 mm^2) were measured every 10 min during pre- and during RF exposure period. As a result, there was no significant difference in the intensity changes between sham and exposed group in either juvenile or adult rats (Figure 1).

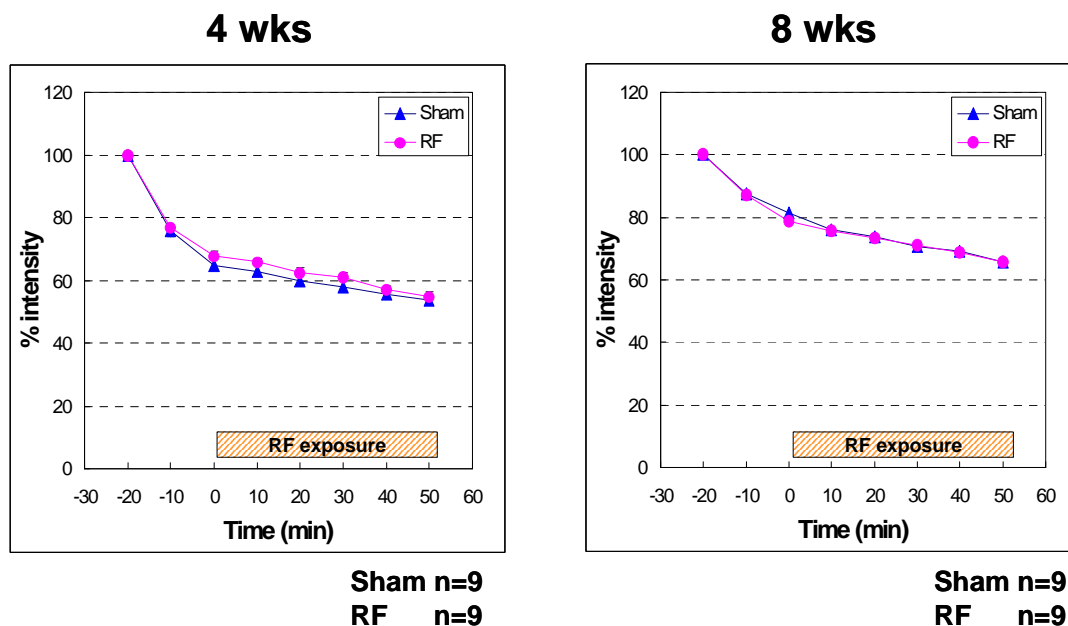

Figure 1 BBB permeability changes during RF-EMF exposure

The numbers of rolling and sticking leukocytes stained with rhodamine 6G were counted at 0, 10, 20, 40 min after RF exposure. As a result, no significant difference in these counts was found between sham and exposed group even in juvenile rats.

The velocities of plasma flowing in the pial venules were measured using Dual-Slit technique. We compared the velocities of each period with those of 20 min before RF exposure. But there was no significant difference in the plasma velocity between sham and exposed group even in juvenile rats.

The arteriolar vasomotion was monitored pre-, during, and post- RF exposure. As a index for dynamic changes in the vasomotion, we calculated the mean values of arteriolar diameter for each experimental period and showed them as a relative (%) diameter of pre-exposure. As a result, no significant difference in the arteriole diameter was found between two groups even in juvenile rats.

Conclusions

The results reveal that there were no effects of RF-EMF exposure on brain microcirculatory parameters, at least on BBB-function, leukocyte behaviours, blood flow or arteriolar vasomotion, in either juvenile or adult rats under present exposure conditions.

Abstract

To evaluate the possible alterations of the human cochlear activity to the GSM 915 MHz electromagnetic fields (EMF) exposition in a significant statistically human subjects group, the transient evoked otoacoustic emissions (TEOAEs) have been measured.

130 volunteers took part in the experiment; they were randomly divided into two groups (group X, exposure to EMF consisting of 85 people; group Y, control consisting of 45 people) and underwent TEOAEs measurements two times. Participants were healthy young adults (18–40 years old) without any evidence of hearing or ear disorder. In group X the TEOAEs were recorded before and throughout 6 minutes EMF exposition (average power irradiated: 1Watt), while for group Y the TEOAEs were recorded for two consecutive intervals of six minutes without EMF.

The TEOAEs were measured in the time domain while the corresponding analysis have been carried out by the estimate of the density power spectrum relating to each waveform using the Welch's method. Comparing the results obtained in the case-control groups the variations of the density power spectrum found in the exposed subjects are not significant statistically respect to ones in the control group. Therefore the external hair cells activity is not modified by GSM cellular phones.

Introduction

The explosive increase in the use of mobile phones during the last years has aroused suspicions about their adverse effects on human health. Normally the cellular phone antenna is positioned near the human head and in particular close the ear causing a part of the electromagnetic energy emitted from the antenna to be absorbed by the auditory apparatus. Some authors studied the interaction between the electromagnetic fields (EMF) generated by cellular phone and inner ear, in particular the cochlear outer hair cells measuring the otoacoustic emission in humans [1], [2] [3]. Sometimes significant variations on the otoacoustic emission due to the presence of the electromagnetic fields have been reported while in other cases any variations has been noticed. In addition to these conflicting results must be considered that in the studies above reported the number of subjects examined was very low.

In this paper the study of the effects of the electromagnetic fields generated by 915 MHz GSM cellular phones on the otoacoustic emission in a statistically significant number of subjects is reported. The volunteers that took part at the study were divided randomly in two groups: control and exposed group. All the subjects underwent transient evoked otoacoustic emission (TEOAE) measurements. The TEOAE signals are generated by the movement of the outer hair cells on the Corti's organ when the auditory periphery is stimulated by an acoustic click. The TEOAEs are present in 100% of normal hearing subjects and constitute an expression of a normal cochlear functionality. To evaluate the alterations brought on by the EMF on the auditory responses the power spectral density (PSD) estimation of each TEOAE have been calculated. Since these signals are noise corrupted the classic FFT algorithm is not indicated for the PSD estimation but it is advisable to apply the periodogram method and in particular the Welch method. Finally in order to evaluate the presence of statistically significant variations in the exposed group respect to the control group the Chi square test has been carried out.

Experimental procedure and set-up

The OAE are stimulated by the application of a sound stimulus in the ear channel. A rectangular stimulus (click) has been chosen because it is very brief and has a broad-range frequency spectrum, so that a complete and simultaneous stimulation of the Corti's organ can be obtained down its entire length.

The experimental activity was performed using the ILO88 system by Otodynamics. It is composed of analog-to-digital converter, a preamplifier, an acoustic probe (microphone) and software to manage the stimulus and to collect and elaborate data. As the probe position can modify the stimulus' shape, checking the noise floor level, shape, spectrum and intensity level of the stimulus is compulsory. The probe fit was evaluated by measuring the adequacy of stimuli, i.e., flat acoustic spectrum across the frequency range of 0.5 – 5 kHz. The OAEs were obtained with stimuli consisting of clicks of 80 μ s duration. The stimulus level in the outer ear was set at 80 ± 3 dB SPL. The click rate was 50 click per second and post-stimulus analysis was in the range of 2 to 20 ms. A total of 700 sweeps, corresponding about 6 minutes, was averaged above the noise rejection level of 47 dB.

The responses were filtered with the use of a II order high pass filter, with cutoff at 500 Hz, and a low pass IV order filter with cutoff at 5 kHz and sample rate of 25000 samples/s for a total of 512 samples. A response is valid if its amplitude is higher than noise floor level plus 3 dB.

The TEOAE was recorded in ASCII files and analysed later with a suitable Matlab® computer programme [4].

The exposition system was composed by: a vector signal generator SMIQ02B by Rohde&Schwarz for the generation of the TDMA mobile radio standard signals as GSM, GSM-EGDE etc., operating in the 300 kHz - 2.2 GHz frequency range; to amplify the signal generated at the desired level a 5 W linear amplifier, operating in the frequency range 860 MHz – 960 MHz, it was cascade connected to the signal generator; to measure the transmission and reflection power from the antenna a mobile power measurement, with NRT sensor and PC card adapter NRT-Z4 by Rohde&Schwarz, it was interposed between the amplifier and the antenna; at the end of the generation and transmission chain a short dipole antenna to radiate the signal was connected. The positioning of the antenna near the ear was realized by a suitable plastic support mounted on an modified earphones.

The average power at the antenna input was fixed to 1 Watt and the exposition frequency at 915 MHz.

Subjects

130 subjects volunteers took part in the investigation; they were informed in detail about the purpose and procedures of the study and a written informed consent was obtained. Participants were healthy young adults (18–40 years old) without any evidence of hearing or ear disorder, corresponding to the ISO standard definition of otologically normal to exclude middle ear pathology that may impair OAE measurements.

The rationale was to test a group that was representative of the population of young otologically normal people. Absence of pre-existing hearing or ear disorder maximizes the sensitivity of the study to detect small changes that may occur. Acceptance as participants was based on otoscopy, audiometry by air conduction (0.5, 1, 2, 3, 4, 6, 8 kHz) and bone conduction (0.5, 1, 2 kHz), tympanometry and acoustic reflex testing, and a simple screening questionnaire concerning medical and otological history.

The subjects were randomly divided into two groups (group X, exposure to EMF consisting of 85 people; group Y, control consisting of 45 people) and underwent TEOAEs measurements twice. In group X the TEOAEs were recorded before and throughout 6 minutes EMF exposition (average power irradiated: 1Watt), while for group Y the TEOAEs were recorded for two consecutive intervals of six minutes .

Signal detection

To analyse TEOAEs, the signals revealed by the microphone are averaged by time-locking to the transient stimuli and alternatively storing them into two separate buffers (A and B). Thus each of the two waveform A and B (see Fig.1) corresponds to an average of 700 accumulated responses without any intervening time lag.

The two waveforms of each signal collected in separate buffers were cross correlated by means of a product moment correlation coefficient. The entity of correlation is considered as a measure of the response reliability and hence as a score of the functional efficiency of the auditory system. In the ILO88 test, an correlation index, called "Repro", between two waveforms of an OAE signal is considered. An index value > 70 % is considered as physiological, therefore if this condition should not occur the examination would not have considered.

In Fig. 1 two waveforms related to TEOAE response with "Repro"=90% is shown. Each waveform is composed by 512 points graphically interpolated and the differences among the waveforms A and B are due to the noise overlapped to the signals.

Power spectrum density estimation

In order to quantify the TEOAE response alterations the power spectral density (PSD) estimate associated with

each TEOAE has been calculated. There are several approaches to calculate PSD estimates; the most widely used PSD method analysis it is based on the application of the well know FFT algorithm while other use the periodogram method which is know as classic way to estimate PSD.

Widely, the PSD estimate of a time varying signal is obtained by computing first the frequency spectrum of the sampled data through the Discrete Fourier Transform (DFT) then the square module amplitude of the frequency spectrum. In case of signal corrupted by noise it is appropriate to compute power spectral density estimate of the signal using the Bartlett and Welch periodogram methods [5]. These methods make no assumption about how data was generated and, hence, are called nonparametric [6].

Fig. 1. Waveforms of a click evoked otoacoustic emission signal: A and B are two waveforms of a typical TEOAE signal recorded by the ILO88 system.

In the Bartlett method the N-point time domain sequence $x(0), x(1), x(2), \dots, x(N-1)$ is divided into P no overlapping segments, where each segment has length D.

For each segment, the periodogram is computed and the Bartlett power spectral density estimate is obtained by averaging the periodograms for the P segments, as in the following formula:

$$S_B(f) = \frac{1}{P} \sum_{p=0}^{P-1} \frac{1}{DT} \left| T \sum_{n=0}^{D-1} x^{(p)}[n] \exp(-j2\pi f n T) \right|^2 \quad (1)$$

By this averaging of the spectrum the variance of the spectrum estimation is reduced by a factor P, however at the expense of a reduction of the frequency resolution by a factor P.

Welch has modified Bartlett's method by using windowed data segments overlapping in time. The overlapping is used for further reducing the periodogram variance while the windowing is applied to reduce the spectral leakage associated with finite observation intervals. The frequency spectrum calculated by the Welch periodogram is given by:

$$S_W(f) = \frac{1}{P} \sum_{p=0}^{P-1} \frac{1}{UDT} \left| T \sum_{n=0}^{D-1} w[n] x^{(p)}[n] \exp(-j2\pi f n T) \right|^2 \quad (2)$$

U is the discrete-time window energy of the used window function $w[n]$ as defined as follow:

$$U = T \sum_{n=0}^{D-1} w^2[n] \quad (3)$$

In our case the Welch method has been applied with a 50% overlapping and Hamming window selected.

In Fig.2 an example of PSD estimate computed by the Welch's method is shown. It has been calculated using a Matlab[®] software toolbox with A and B TEOAE signals as input data. The numerical computation output are two column vectors called $[P_x^{(A)}(f)]$ and $[P_x^{(B)}(f)]$ with dimension 256x1. The elements of $[P_x^{(A)}(f)]$ and $[P_x^{(B)}(f)]$ represent the power spectrum density estimates calculated for each frequency value of the column vector $[f]$ of same dimension.

The example reported in Fig.2 shows the Power Spectrum Density (PSD) estimates in Watt/Hertz (W/Hz) vs. frequency (f) in Hertz (Hz) of the TEOAE signals reproduced in Fig.1.

Fig.2. Example of Power Spectral Density estimate computed by Welch's method: these curves are relative to the TEOAE waveforms shown in Fig.1

Data analysis procedure

The data analysis for the exposed group has been carried out following the below procedure:

1. Estimation of the PSD using the Welch's function available on Matlab[®] software for the A and B TEOAE signals;
2. Evaluation of the average power associated to each signal by numerical integration of $[P_x^{(A)}(f)]$ and $[P_x^{(B)}(f)]$ above the frequency range 500 Hz – 5 kHz;
3. Calculation of the mean between the two power values determined in the previous step and evaluation of the mean relative deviation;
4. Repetition of the steps 1 – 3 considering the TEOAE registered in presence of electromagnetic fields;
5. Comparison between the means calculated with and without EMF;
6. The difference computed in the 5 step is defined "Significant" when its absolute value is greater than the addition of the relative deviations calculated in the two cases with and without EMF.

As regard the data analysis of the control group the procedure is the same of the exposed group with the only difference that the subjects are not exposed to EMF.

Results

In Tab.I an example of the numerical result obtained applying the first 5 steps of the above procedure is reported. In particular the average power for the two TEOAE signals relative to a single subject in both the exposition and no exposition conditions are calculated. Moreover the mean and the mean relative deviation it is also computed for both conditions. All the power values are expressed in decibel (dB).

Tab.I – Example of average power calculated for a single subject with and without EMF				
Subject XXX	Average power signal A [dB]	Average power signal B [dB]	Mean [dB]	Mean relative deviation [dB]
No exposed	37,47	37,73	37,60	$\pm 0,13$
Exposed	37,98	37,72	37,85	$\pm 0,13$

In order to compare the results obtained in the two conditions the difference between the means has been calculated and the result is shown in Tab.II, where "Mean (NoEx)" indicates the mean of the average powers in the 'no exposed' condition while "Mean (Ex)" indicates the mean of the average powers in 'exposed' condition.

Tab.II – Difference of the means and "Significant" variation test		
Subject XXX	Absolute value difference [dB]	"Significant" variation
Mean (NoEx) – Mean (Ex)	0,24	NO

In the same table the result of the "Significant" variation test is also reported. In the test, the absolute value of the

difference is compared with the addition of the relative deviations respect to the corresponding means obtained in the two condition above mentioned. The result of the test is a Boolean variable which value is “YES” when the difference absolute value is greater than the addition of the relative deviations. In the example shown in Tab.I the addition of the relative deviations is 0,26 dB while the difference absolute value is 0,24 dB, thus in this case the test response is “NO”.

Repeating the procedure for all the subjects included in the exposed and control groups the results obtained are summarized in Tab.III and Tab.IV respectively.

Tab. III – Exposed group: summary sheet	
Subjects number	85
“Significant” differences number	58 (68,2%)
“No Significant” differences number	27 (31,8%)

Tab. IV – Control group: summary sheet	
Subjects number	45
“Significant” differences number	25 (55,6%)
“No Significant” differences number	20 (44,4%)

Analysing the above results an greater cases number with TEOAE response alterations in the exposed group (68%) respect to control group (55,6%) it has been obtained. Besides in the control group, in absence of EMF, more than 50% presents a “Significant difference” probably due to the random noise overlapped to the TEOAE signal.

Statistical analysis

The results do not clear up if the TEOAE alterations founded in the exposed group was really in correlation to the typical GSM electromagnetic field, so a statistical comparison of the results obtained in the two group it is necessary.

In our case the Chi square test is indicated. Chi square is a non-parametric test of statistical significance for bivariate tabular analysis. Any appropriately performed test of statistical significance lets us know the degree of confidence we can have in accepting or rejecting an hypothesis. Typically, the hypothesis tested with Chi square is the null hypothesis [7]. In our case it establish that the two groups (exposed and control groups) are not different enough respect to their behaviour in presence of EMF.

The first step in the building the Chi square test is the data summary in a table (as shown in Tab.V) where in the rows the independent variables and in the columns the dependent variables are reported. In this analysis the two groups are considered the independent variables while the results of the computation analysis on the TEOAE responses are considered the dependent variables

Tab.V – Data summary of the experimental results			
	“Significant” differences	No “Significant” differences	Total
Exposed group	58	27	85
Control group	25	20	45
Total	83	47	130

The expected frequencies for the above data are calculated multiplying the total number of each row for the total number of each column and dividing the result by the subjects total number. The results are shown in Tab. VI.

Tab.VI – Data summary of the experimental results			
	“Significant” differences	No “Significant” differences	Total
Exposed group (observed)	58	27	85
Exposed group (expected)	54,26	30,73	
Control group (observed)	25	20	45
Control group (expected)	28,73	16,26	
Total	83	47	130

Before to calculate the Chi square value it is necessary to determine the threshold of tolerance for error. For our purposes we set a probability of error threshold of 1 on 20, or $p < 0.05$. Applying the following formula (4) the Chi square value has been computed:

$$\chi^2 = \sum_{i=1}^4 \frac{(O_i - E_i)^2}{E_i} \quad (4)$$

where O_i represent the observed values while E_i the expected values. On the basis of the data reported in Tab.VI the Chi square value is:

$$\chi^2 = 0,257 + 0,452 + 0,484 + 0,86 = 2,05$$

For significance at the 0,05 level and degree of freedom equal to one, the Chi square should be greater than or equal to 3,84.

Therefore the distribution is not significant and the null hypothesis is not rejected. In other words, the difference between the two groups is not statistically significant respect to their TEOAE responses in presence or not of EMF, so the variations are not ascribable at the electromagnetic fields emitted by the GSM cellular phones but probably to the random noise overlapped to the TEOAE signals.

Summary

A study of the GSM 915 MHz electromagnetic fields effects on the auditory system has been carried out. For the first time the subjects number that taken part in a study of this matter has been statistically significant. 130 healthy young adults volunteers randomly divided into two groups have been considered: group (X) exposed to EMF consisting of 85 people and group (Y), control, consisting of 45 people.

All the subjects have been underwent TEOAEs measurements two times. In particular for the group (X) the TEOAEs were recorded before and throughout 6 minutes EMF exposition (average power irradiated: 1Watt), while for the group (Y) the TEOAEs were recorded for two consecutive intervals of six minutes without EMF.

The TEOAEs measured are composed by two slightly different signals in the time domain. The difference is due at the randomly overlapped noise to the signal. The analysis of the signals have been carried out by the density power spectrum estimate related to each waveform using the Welch periodogram method.

The results shown an greater cases number with TEOAE response alterations in the exposed group (68%) respect to control group (55,6%). Besides in the control group, in absence of EMF, more than 50% of the subjects present TEOAE response alterations probably due to the random noise overlapped at the TEOAE signal

Therefore a statistic analysis has been conducted in order to establish whether the alterations found in the exposed group are correlated with the EMF exposition. Applying the Chi square test the null hypothesis has been tested: the two groups, exposed and control, are not different in their behaviour in presence of EMF.

The test result indicates that the distribution is not significant and the null hypothesis is not rejected. In other words, the difference between the two groups is not statistically significant respect to their TEOAE responses in presence or not of EMF, so the variations are not ascribable at the electromagnetic fields emitted by the GSM cellular phones but probably to the random noise overlapped to the TEOAE signals

Abstract

Modernization has led to increased proliferation of various electronic and electrical equipment in all fields of human life including domestic, industrial, the fast expanding information technology sector and above all wireless telecommunication. The increasing use of mobile telephony in our society has brought focus and great concern on the health effects of EMFs. A number of epidemiological, *in vitro*, *in vivo* studies have shown conflicting, inconclusive and controversial reports. Considering the scientific evidence from the current scenario, the objective of this epidemiological study was planned to assess the genotoxic potential of RF-EMF exposure from mobile telephony (800-900MHz). 100 subjects using mobile telephones for more than three years, were compared with 80 age and sex matched controls. The statistical data indicated in our study, involving Comet assay showed a lesser significance in exposed subjects compared to controls. The hormonal profile of melatonin is supportive to our study, possibly envisaging the role of the hormone in EMFs stress. Lipid Peroxidation assay also substantiated the DNA damage via oxidative stress. The comparatively lesser significance reported from our findings may have large implications with chronic exposure, emphasising the need for health concern, amidst the environmental hazard of this invisible electromagnetic pollution.

Introduction

The radiofrequency (RF) signals emitted from mobile phones are considered as a type of non-ionizing electromagnetic radiation and are perceived as health risk. More focus has been brought on the potential effect of RF-EMFs to elicit biological response, in association with its detrimental effects on widespread application and long-term induction. The biological effects as a result of RF exposure include changes in cell membrane function, metabolism, cellular signal communication, activation of protooncogenes and cell death. There are scientific evidences on the health hazards due to RF-EMFs, like neurodegenerative disorders, brain tumors and cancer. Most of these reports are inconclusive and no convincing data has been established on causal relation between RF and health risk.

Mobile phone has become the fastest selling consumer product with about 1.6 billion users worldwide and 76 million users in India, contributing to 8% of the population. To date, few epidemiological studies have directly examined the relationship of mobile phones to genomic instability. With a need to arrive at a scientific consensus, an attempt has been made to study the genomic instability on human subjects exposed to mobile phones operating at 800-900MHz. The subjects using mobile phones for more than 2 years were screened with age and sex matched controls with similar socioeconomic status (non-smokers, non-alcoholics). The frequency and duration of mobile phone use along with the model and type of phone with specific absorption rate (SAR) were taken into account.

The whole body exposure of mobile phone radiation is hypothesized to result in structural rearrangement of DNA and increase in number of single-strand and double strand DNA breaks. The DNA damage was observed using

single cell gel electrophoresis SCGE (comet assay) in which the leukocytes were isolated, placed on a microscope slide, lysed, eventually electrophoresed and silver stained. The DNA fragmentation was assessed from the DNA migration path length or comet tail length.

The potentially hazardous effects of electromagnetic fields on melatonin rhythm disturbances remain to be elucidated. The physiological relevance of melatonin could be important in the explanation of the RF-EMFs effect via oxidative stress. The RF fields may induce oxidative stress that has been implicated with increase in free radicals, which mainly enhance lipid peroxidation. To substantiate lipid peroxidation, the level of malonyl dialdehyde (MDA) in plasma and RBCs was measured.

Methodology

DNA Integrity

Single cell gel electrophoresis or Comet assay (Singh *et al*, 1998) was used to study DNA damage. Leukocytes suspended in low-melting agarose were embedded on to a pre-coated layer of normal melting agarose and layered again with low-melting agarose. The cells were treated in lysing solution for overnight and then incubated in alkaline electrophoresis buffer for 20 minutes to facilitate DNA unwinding and expression of alkali labile sites. Electrophoresis was carried out for 30 minutes at 300mA at 0.67V/cm and then neutralized using Tris buffer. Silver stain technique was followed to visualize and measure migration path length. 200 cells per treatment was measured in duplicates. Mean \pm SD of DNA damage was calculated.

Melatonin Levels

Competitive enzyme immunoassay was performed for the quantitative determination of melatonin in plasma (IBL kit, Germany). The sealed ELISA plate consisting of equal proportion of sample (standard, subject and controls), melatonin-biotin and antiserum was incubated overnight at 2-8°C. The plates washed thrice with assay buffer and enzyme conjugate was added (1:5) and incubated for 2 hours at room temperature. After incubation, washing step was repeated and substrate p-nitrophenyl phosphate (PNPP) added to incubate for 20 minutes. Stopping solution was then added to end the substrate reaction. Optical density was read at 405nm.

Lipid peroxidation assay

Lipid peroxidation was estimated by measuring the stable end product, malondialdehyde(MDA) in plasma (Lef'evre *et al*, 1998) and RBCs (Armstrong and Browne, 1994). The protein free plasma was treated with thiobarbituric acid that forms a 1:2 adduct measured at 535nm with spectrophotometer. Mean and \pm SD or SE was established for the samples. The concentration of MDA equivalents in nmol/ml in samples were interpolated from the standard curve.

Results & Discussion

The findings from our epidemiological study show, some statistical significance in the DNA migration path lengths, of the exposed subjects when compared with the controls. The SCGE (Comet assay) demonstrated a mean of comet tail length for control group as 6.63 ± 0.120 and for the subjects as 8.26 ± 0.092 . Phillips (1998) reported, DNA single strand breaks exposed to cellular telephone frequency at 813.5 MHz and 836.5 MHz. The protocol and findings for evaluating the DNA breaks is similar and supportive to the present study. Similarly, Gandhi and Anita (2005) employed SCGE assay for assessing genetic damage in mobile phone users being exposed to 800-2000 MHz and reported a significant increase in DNA tail length and micronuclei. The Swedish-Norwegian epidemiological study concluded a statistical significance between mobile phone users and prevalence of certain bioeffects (Mild *et al* 1998). The *in vitro* study performed by Diem *et al* 2006 indicated a stronger non-thermal DNA breakage effect, in intermittent exposure by mobile phone radiation at 1800MHz. A dose dependent increase in DNA strand breaks from microwave RF at low intensity levels as evaluated by Lai and Singh (1995, 1996) indicate a casual relationship between RF exposure and genetic damage. Many controversial findings report on non-cooperative action between the RF-EMF exposure and induced DNA damage (Annemarie *et al* 2006).

Few epidemiological studies reported an increased risk of brain tumors among analogue cellular phone users (Hardell *et al* 2003). Repacholi *et al* (1997), conducted mice studies using 900 MHz mobile phone frequency radiation and found a statistically significant 2.4 fold increase in lymphoma. On the contrary, Heynick's (2003) report on epidemiological studies showed no indication of *in vivo* and *in vitro* exposure of RF field and cancer.

MOBILE TELEPHONY AND RISK ASSESSMENT

Currently, there is insufficient evidence to assess an association between RF exposure and brain cancer, leukaemia, or lymphoma (ICNIRP, 2004).

The sleep disruption related to radiofrequency radiation hypothesized from our findings for melatonin relevance has been reported in several scientific studies (Lai and Singh 1998, Burch *et al* 2002). Mann *et al* (1996) and Loughran *et al* (2005) observed that a radiofrequency radiation, similar to digital mobile phones reduced sleep in humans altering the EEG (brain wave) signals.

The increase in free radical production for LPO activity shows a statistical significance (Table 1) in the exposed population compared to those unexposed. This observation is similar to the data published by Stopczyk *et al* 2005.

Despite both negative and positive findings about the biological effects of radiofrequencies, certain more long term studies, better conceived and supported by, *in vitro* experimentations would envisage the possible cumulative effects on general health. Further, the lag periods that have been examined are short, where if a longer lag period of about 10 years is required for a health effect to occur, it would not be possible in short exposures and the results will be difficult to interpret.

Table 1: RBC and Plasma markers of Oxidative stress for Lipid Peroxidation (MDA)

MDA (nm/mL)	Control Group	Exposed Population
RBC	0.20 \pm 0.07	0.28 \pm 0.10
Plasma	0.21 \pm 0.1	0.42 \pm 0.2

Data in terms of Mean \pm SD; Significant * P<0.001

Summary

Mobile telephony, the integral unit of modern telecommunication and third generation wireless technology, relays information with RF signals. The extensive use of mobile telephones has given rise to public concern about the possible health effects that the whole-body exposure to RF signals may have. There is a wide spread conviction that electromagnetic emissions from mobile phones were capable of significant biological tissue interactions. The temperature increase is insignificant to cause direct effect but certain scientific reports document increase in DNA strand breaks and chromosomal damage in cells. The non-thermal resultant effects do include increased free radical production, cell stress and premature aging, changing in brain function, neurodegenerative conditions, reduction in melatonin secretion and cancer.

This epidemiological study, assesses the long-term human health risk from RF-EMF exposure for genomic instability. Some individuals have reported to experience certain non-specific symptoms such as sleeplessness, fatigue and headache. The levels of melatonin and the oxidative stress marker, MDA could substantiate in hypothesizing the correlation of non-specific symptoms and whole body exposure to mobile phones. The effects of the RF-EMFs on genomic instability determined by SCGE assay in our study showed lesser statistical significance from the control population. The results are expressed in terms of an estimate of relative risk, ie the multiplier by which risk is higher in people exposed to the RF-EMF of mobile telephony than in unexposed group. However, the findings and scientific interpretations drawn from this epidemiological study about the potential risk from mobile telephony might not be sufficient to arrive at a consensus. But possible implications on long term and chronic exposure to mobile phone use could be made.

Abstract

The effects of exposure to radiofrequency fields on germination and seedlings growth were investigated in lettuce (*Lactuca sativa* L.), tomato (*Lycopersicum esculentum* L.) and onion (*Allium cepa* L.). Seeds were exposed to continuous EMF (23 V m⁻¹) at 400 and 900 MHz for 2 and 4 h as well as to modulated field (80% AM 1 kHz sinus) for 2 h in GTEM-cell. At 400 MHz, inhibition of lettuce germination was noticed after 2 h of exposure to continuous RF-EMF while the growth of lettuce and tomato was decreased after 4 and 2 h of exposure, respectively. Contrary, the growth of onion was increased after 2 h of exposure to continuous RF-EMF. At 900 MHz, increased germination of tomato was observed after exposure to modulated field. At this frequency, the growth of lettuce increased after 4 h of exposure to continuous RF-EMF while the growth of onion increased also after exposure to modulated field. On the other hand, the growth of tomato decreased after 2 and 4 h of exposure to continuous RF-EMF. Results indicate that seedlings growth was more sensitive to RF-EMF exposure than germination and that the effects depended on field and exposure characteristics as well as plant species.

INTRODUCTION

Various kinds of radiofrequency electromagnetic fields (RF-EMF) from 30 kHz to 300 GHz are used to transmit information (TV, radio, mobile phones and satellite communications). Although classified as nonionizing, these fields can have various biological effects including changes in the cell membrane's permeability and interferences with ions and molecules like DNA and proteins (Kwee & Raskmark 1998, Kwee *et al.* 2001, Banik *et al.* 2003).

Germinating seeds and seedlings subjected to environmental stresses could failure to cope with the adverse effects which results in poor germination, disturbed seedling development, and eventually reduced crop yields. Only few investigations about effects of RF-EMF exposure on seed germination and early plant growth have been reported so far with various results (Jonas 1952, Nelson & Walker 1961).

In this work the effects of exposure to EMF at 400 and 900 MHz on germination of lettuce (*Lactuca sativa*), tomato (*Lycopersicum esculentum*) and onion (*Allium cepa*) seeds as well as some parameters of seedlings early growth were investigated.

Determination of germination and early growth

Seeds of *Lactuca sativa* L. ("Unicum"), *Lycopersicum esculentum* L. ("Marglobe") and *Allium cepa* L. ("Srebrnjak") were placed in plastic Petri dish on filter paper wetted with distilled water. The Petri dishes were maintained for 12 h at 24 ± 2 °C in the darkness and then subjected to EMF. During exposure control was kept in the same growth conditions (24 ± 2 °C, darkness) as seeds exposed to EMF but in the field-free environment. Three replicates of 15 seeds were used in each treatment. Protrusion of the radicle was the criterion used for germinated seed. After germination seedlings were watered every day and their root and shoot length as well as fresh weight was measured after four days (lettuce) or seven days (tomato and onion). All results were expressed as means followed by the

corresponding standard errors. Significant differences between means ($P \leq 0.05$) were established by one-way ANOVA followed by Duncan's multiple range test (STATISTICA 6.0) and presented in the Figures with asterisks (*).

Exposure to radiofrequencies fields

For generation of RF-EMFs Gigahertz Transversal Electromagnetic (GTEM) cell (Fig. 1.) was used (Tkalec *et al.* 2005). In GTEM-cell, electric and magnetic field exist at the same time and they are perpendicular to the wave propagation direction. Besides the GTEM-cell, a signal generator with continuous wave and an amplifier was also needed.

Seeds in plastic Petri dishes were exposed in GTEM cell to the continuous EMFs of 400 and 900 MHz at field strengths of 23 V m^{-1} for 2 and 4 hours as well as modulated EMF (80% AM 1 kHz sinus) for 2 h. Petri dishes were placed in parallel, perpendicular to the electric field, in the area where field was uniform with required field levels (Fig. 2).

Figure 1. Instruments used for the exposure to RF-EMF: GTEM-cell, HP 8657A signal generator and 5 W MiniCircuits amplifier.

Figure 2. Position of Petri dishes ($d=9 \text{ cm}$, $h=1.5 \text{ cm}$) in GTEM-cell: below the septum (A), in respect to the direction of wave propagation, z (B).

RESULTS

Seed germination

The exposure of seeds to continuous EMF at field frequency of 400 MHz and strength of 23 V m^{-1} for 4 h as well as to modulated field at the same frequency and strength for 2 h did not have significant effect on germination of lettuce (*Lactuca sativa*), tomato (*Lycopersicum esculentum*) and onion (*Allium cepa*) seeds in comparison with non-exposed seeds. On the other hand, exposure to continuous field at 400 MHz and 23 V m^{-1} for 2 h inhibited lettuce germination (Figure 3A).

The exposure of seeds to continuous EMF at field frequency of 900 MHz and strength of 23 V m^{-1} for 4 h as well as to modulated field at the same frequency and strength for 2 h also did not have significant effect on germination of seeds. The exception was stimulation of tomato germination noticed after exposure to modulated field at 23 V m^{-1} for 2 h (Figure 3B).

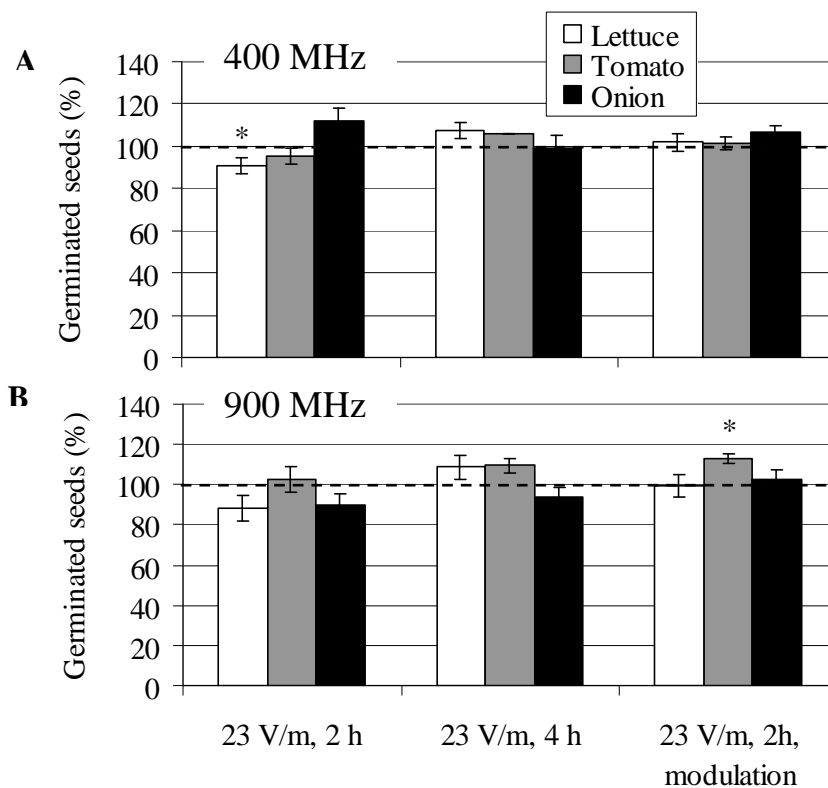

Figure 3. Germinated seeds (%) of lettuce (*Lactuca sativa*), tomato (*Lycopersicum esculentum*) and onion (*Allium cepa*) seeds after exposure at 400 and 900 MHz to continuous field at 23 V m^{-1} for 2 and 4 h and to modulated field for 2 h. Data represent means \pm SE ($n = 45$). Control (non-exposed seeds) is expressed as 100 %. Significant differences between exposed and non-exposed seeds at $P \leq 0.05$ are marked with asterisk (*).

Early growth of seedlings

The growth of lettuce seedlings measured as root and shoots length and seedling fresh weight was neither affected by exposure for 2 h to continuous nor modulated EMF at 400 MHz and 23 V m^{-1} . But, lettuce root length and fresh weight decreased after exposure for 4 h to continuous EMF at the same frequency and strength (Fig 4A).

Root and shoot length and fresh weight of tomato seedlings decreased after exposure for 2 h to the continuous field at 400 MHz and 23 V m^{-1} while exposure to the modulated field and longer exposure to the continuous field at the same frequency and strength did not affect tomato growth significantly (Fig. 4B).

The growth of onion seedlings was not significantly impaired after exposure to EMFs at 400 MHz except increase of shoot length noticed after exposure for 2 h to the continuous field at 23 V m^{-1} (Fig. 4C).

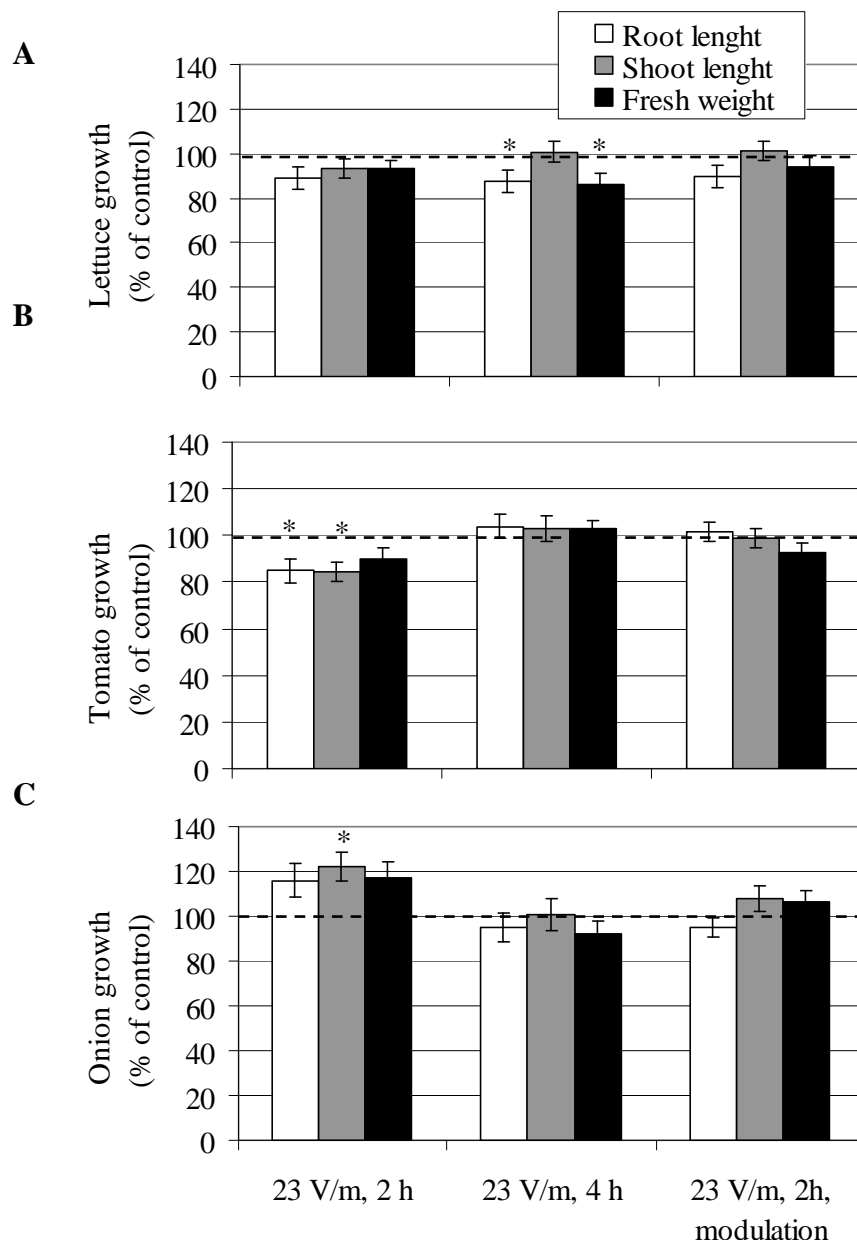

Figure 4. Root and shoot length as well as fresh weight of lettuce (A), tomato (B) and onion (C) seedlings after exposure at 400 MHz to continuous field at 23 V m^{-1} for 2 and 4 h and to modulated field for 2 h. Data represent means \pm SE ($n = 45$). Control (non-exposed seeds) is expressed as 100 %. Significant differences between exposed and non-exposed seeds at $P \leq 0.05$ are marked with asterisk (*).

EFFECT OF RF ON PLANT GERMINATION AND GROWTH

At 900 MHz the early growth of lettuce seedlings, similarly as at 400 MHz, was neither affected by exposure to continuous nor modulated field at 23 V m^{-1} for 2 h. However, at this frequency, lettuce shoot length and fresh weight significantly increased after exposure for 4 h to continuous EMF (Fig. 5A).

The growth of tomato seedlings measured as fresh weight significantly decreased after exposure for 2 h to continuous field at 900 MHz and 23 V m^{-1} , similarly as after exposure at 400 MHz, but at this frequency longer exposure to the field had the same effect (Fig. 5B).

The growth of onion seedlings at 900 MHz, like lettuce growth, significantly increased after exposure for 4 h to the continuous field at 23 V m^{-1} as well as after exposure to modulated field (Fig. 5C).

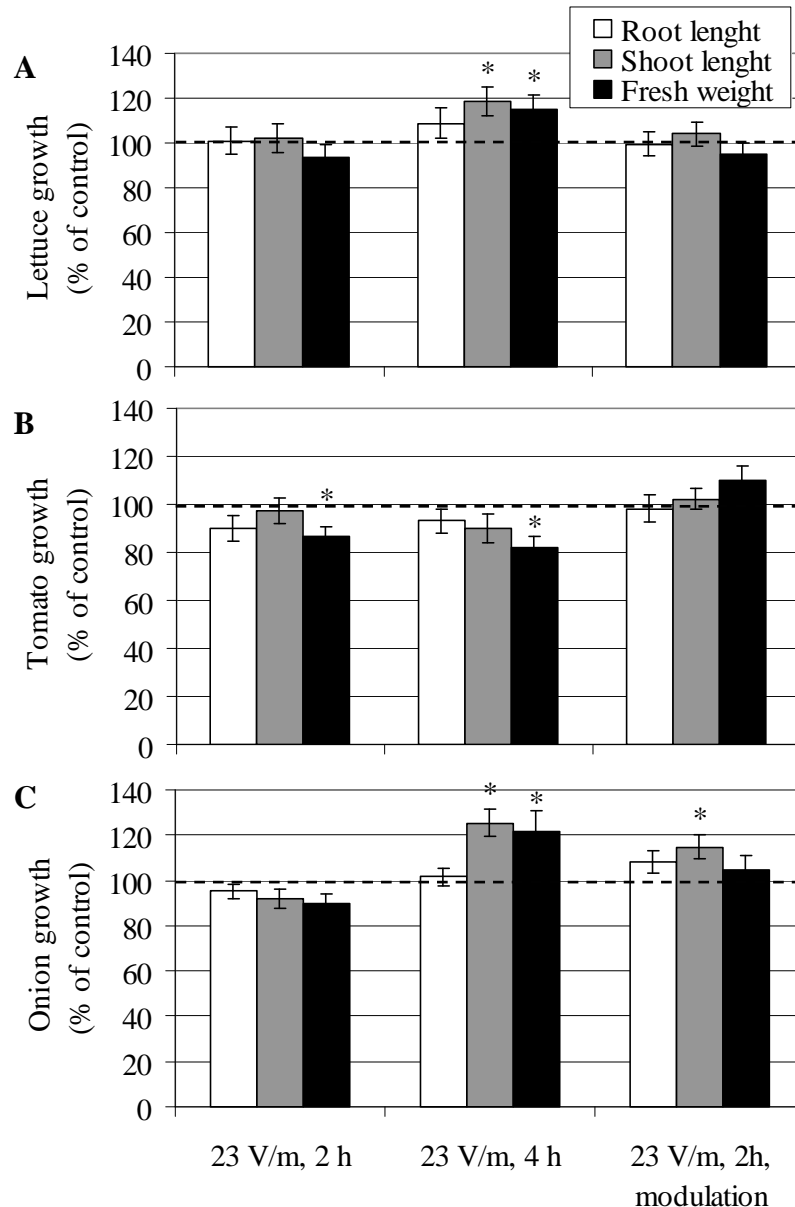

Figure 5. Root and shoot length as well as fresh weight of lettuce (A), tomato (B) and onion (C) seedlings after exposure at 900 MHz to continuous field at 23 V m^{-1} for 2 and 4 h and to modulated field for 2 h. Data represent means \pm SE ($n = 45$). Control (non-exposed seeds) is expressed as 100 %. Significant differences between exposed and non-exposed seeds at $P \leq 0.05$ are marked with asterisk (*).

Summary

The effect of radiofrequency electromagnetic fields (RF-EMF) on seeds germination and early plant growth has been investigated. At 400 MHz, the exposure to continuous field at 23 V m^{-1} for 2 h inhibited the lettuce germination while longer exposure decreased the growth of lettuce seedlings. At this frequency after 2 h of exposure to the continuous field growth of tomato seedlings was decreased, but the growth of onion seedlings significantly increased. At 900 MHz, germination of tomato seeds was increased after exposure to modulated field at 23 V m^{-1} as well as the growth of onion seedlings. The growth of lettuce and onion seedlings significantly increased after 4 h of exposure to continuous field at this frequency while, on the other hand, the tomato growth decreased after 2 and 4 h of exposure. Obtained results indicated that seedlings growth was more sensitive to RF-EMF exposure than germination and that the effects of RF exposure on plant germination and growth could be positive as well as negative depending not only on field and exposure characteristics but on plant species as well.

Abstract

Over the past 3 decades the actions of Radio-frequency EMF (RF) on biological systems have been examined extensively, concurrently with investigations into the generation of free radicals and reactive oxygen species under stress conditions. Biological systems endure complex environments where countless interactions among myriad different factors are important to our understanding the pathophysiological mechanisms and events by which RF may induce the activation or suppression of natural occurring antioxidant systems.

A total of 75 rats were exposed to 2 frequencies of RF (SAR=0.5 W/kg): (n=25, sham exposure; n=25, 900 MHz; n=25, 1800 MHz). After a 30 min exposure period, blood plasma levels showed increased levels of both catalase (CAT) and superoxide dismutase (SOD) and total glutathione peroxidase (GSH-Px). After initiating RF exposures at 900 MHz and 1800 MHz, animals at each 5 min interval (5min (n=5); 10min (n=5); 15min(n=5); 20min (n=5); 25min (n=5)), showed increasing levels of malondialdehyde (MDA) (lipid peroxidation product). After 10-th minute from the beginning of exposure simultaneous increasing of SOD, CAT and GSH-Px concentrations in rat blood plasma appear. No statistically significant differences in these blood plasma products were observed between the 2 RF exposures used. Our results are in good agreement with previous investigations examining free radical generation in the early stages of EMF exposure. Radio-frequency EMF may affect biological systems by increasing the lifespan of reactive oxygen species.

Introduction

Studies of electromagnetic field promotion of free radical formation are provided widely and significant effects are obtained in low frequencies of electromagnetic field spectrum, which are predominant. According Bordiushkov,IuN, et al. 2000 low frequency EMF, increase 2 fold SOD activity. Katsir,G. and Parola,A.H. 2002 showed indirectly changes of catalase activity by low frequency EMF.

High frequency EMF may affect biological systems by increasing free radicals, which appear mainly to enhance lipid peroxidation, and by changing the antioxidase activities of human blood which leading to oxidative stress.

ACUTE EFFECTS ON OXIDATIVE STRESS MARKERS OF HIGH FREQUENCY ELECTROMAGNETIC FIELD 900 AND 1800 MHz IN RATS- PRELIMINARY EXPERIMENTS

Influence of high frequency EMF on Antioxidant enzymes activity at model systems in vitro correlative analysis of SOD activity and MDA concentration in human blood platelets at 900 MHz exposure for different time intervals have been investigated by Stopczyk,D. [Stopczyk,D. et al 2002; Stopczyk,D. et al. 2005], they obtained significant increase of both levels of MDA and SOD after 7 min exposure.

Again at in vitro experiments Hook,G.J et al. 2004 find out that the levels of activities of superoxide dismutase (SOD), total glutathione peroxidase (GSH-Px) are increased by 847.74 MHz (CDMA) RF EMF.

Other investigations of RF EMF action at systems in vivo with healthy volunteers showed that, after RF EMF exposure lipid peroxide and the activities of superoxide dismutase (SOD), total glutathione peroxidase (GSH-Px) and catalase levels are measured. The results obtained showed that the plasma level of lipid peroxide was significantly increased after 1, 2 and 4 h of exposure to RF EMF. Moreover, the activities of SOD and GSH-Px in human erythrocytes showed significant reduction while the activity of catalase in human erythrocytes did not decrease significantly. These results indicate that acute exposure to RF EMF of commercially available cellular phones may modulate the oxidative stress of free radicals by enhancing lipid peroxidation and reducing the activation of SOD and GSH-Px, which are free radical scavengers. Therefore, these results support the interaction of radiofrequency fields of cellular phones with biological systems [Moustafa,Y.M. et al 2001]

Free radical processes in living organism could be impact by exogenic way as follow:

- direct reducing of abnormal production of ROS by means of antioxidant molecules;
- by inactivation of already formed prooxidants;
- by means of phagocyte inhibitors or by COX inhibitors.

In our experiments we divided experimental animals by groups according time intervals each interval has a 5 min by three investigated groups (Sham, Exposed 900, Exposed 1800 MHz) and estimate four parameters MDA concentration and SOD, CAT, and GSH-Px enzyme activity.

Exposure	Sham exposed	900 [MHz]	1800 [MHz]
Mean Enzyme activity Rel.U.			
SOD	2.31±0.201	2.66±0.495	3.56±0.172
CAT	2.03±0.201	2.49±0.436	2.56±0.432
GSH-Px	2.42±0.201	2.19±0.695	2.48±0.373

Anti-oxidative activity

Fluorescent analysis were applied for investigation of concentrations of antioxidant enzymes (SOD, CAT, and total GSH) when their concentration where measured we calculated their activity per protein concentration and velocity of substrate catalysis.

TBARS-test (Thiobarbituric Acid Reactive Substances) was applied for in vivo registration of MDA derivates. The influence on the ROS formation in liposome suspensions was investigated by measurement of MDA (malondialdehyde), which is the final product of lipid peroxidation in the same model systems. The sensitivity of TBARS has made this assay the method of choice for screening and monitoring lipid peroxidation, a major indicator of oxidative stress [Armstrong, D. and Browne, R. 1994; Yagi, K, 1998]. Some modifications made possible the application of this rapid procedure at animal biological tissues [Janero, D. 1998]. Despite of some controversy regarding the specificity of TBARS toward compounds other than MDA, the test remains the most widely employed assay used to determine lipid peroxidation [Armstrong, D. and Browne, R. 1994].

According to TBARS-test, MDA is captured by thiobarbituric acid in a colored product comprising 532 nm chromophore by means of condensation presented in Figure 3:

Figure 3. Condensation of TBA with MDA and creation of 532 nm chromophore

The concentration of MDA as a product of lipid peroxidation is calculated from the molar extinction coefficient (E) as specified below.

The samples were centrifuged at 3000 rpm for 10 min, the supernatant was taken off and 1.8 ml of 0.5% thiobarbituric acid was added to 2 ml of supernatant. The resulted solution was incubated at 90°C for 40 min to obtain pink color with $\lambda_{\max} = 532$ nm [Asakawa, T. and Matsushita, S. 1980]. The molar extinction coefficient (E) was measured at 532 nm with spectrophotometer (Cecile-3000) with polystyrene quvettes.

ANOVA statistical method for evaluation of significance of the present results were applied, Bonferoni test for statistical significance in the range $P > 0.05$ were applied and results are presented as \pm S.D.

Results

We obtained time dependence of high frequency EMF action at in vivo systems by means consequence measurements of concentration of oxidative stress marker (MDA) and antioxidant enzymes activity

For 900 MHz exposure we obtained significant changes at MDA concentration at 15 min. after beginning of exposure and for 25-th minutes we obtained maximum of SOD concentration.

ACUTE EFFECTS ON OXIDATIVE STRESS MARKERS OF HIGH FREQUENCY ELECTROMAGNETIC FIELD 900 AND 1800 MHz IN RATS- PRELIMINARY EXPERIMENTS

For 1800 MHz exposure we obtained significant changes at MDA concentration at 10 min. after beginning of exposure and for 25-th minutes we obtained maximum of SOD concentration. Other enzymes CAT and GSH-Px, have smaller but also significant increase of their concentrations in comparison with sham exposed group. Between two exposed groups have no significant differences therefore we can claim for any frequency dependence of RF EMF action.

It have been measured tendency for increasing of life span of ROS formation and in parallel with that increasing of concentration of anti-oxidant enzymes, but with significant time-delay.

Summary

On the base of our results we can conclude that oxidative stress after exposure to RF EMF may be the reason for many adverse changes in cells and may cause a number of systemic disturbances in the human body

Abstract

Aim of this study was to examine whether 2.45 GHz irradiation has effects on rats' nocturnal urinary 6-sulfatoxymelatonin (6SM) excretion. Urinalysis parameters after whole-body exposure of two hours per day, five days a week, throughout fifteen days lasting experiment was followed-up. The average specific absorption rate (SAR) was calculated to 1.25 (± 0.36) W/kg. The concentration of 6SM in urine samples was determined by direct radioimmunoassay kit (Stockgrand Ltd., Guildford, UK). Urinary glucose, bilirubin, ketones, specific gravity, blood, pH, protein, urobilinogen, nitrite and leukocytes appearance has been accomplished by means of multiple reagent strips (N-Multistix® Bayer Diagnostic, UK). In comparison to the sham-exposed group, no significant changes in body temperature or food and water intake were observed. Delayed significant decline in 6SM of irradiated rats has been obtained between days eight and eleven. Until the end of experiment 6SM level remained low. The results of urinary pH, glucose, bilirubin, ketones, specific gravity, blood, protein, urobilinogen, nitrite, leukocyte appearance in the urine indicated no significant differences between treated and control group. In conclusion: it is likely that applied microwave field poses capacity to affect the hormone melatonin balance in rats after repeated exposure.

Introduction

Current scientific effort is based on the growing recognition that low-intensity radiofrequency microwave (RF/MW) exposure can be detected in living tissues and result in well-defined bioeffects. Because mechanisms involved into the complexity of RF/MW biological activity are multiple, animal studies play an important role in evaluating the complex reactions of various body systems. Systems like nervous, haematopoietic or immune are largely responsible for homeostasis – the essential maintenance of the internal environment. Co-coordinated, interdependent response of these systems when challenged by potentially damaging stimuli could be easier reproduced in contrast to a human study [1, 2]. One of straightforward approach with comprehensive output of possible elucidation how RF/MW affects living organisms, certainly could be covered by melatonin hypothesis [3]. Hypothesis that melatonin as oncostatic, or inhibitor of cancer cell growth or it is effect on immune system, along with the report that EMF could alter its oncostatic properties [4]. There are three postulates how EMF could be acting through the melatonin pathway. EMF could lower melatonin concentration, resulting in increased estrogen and prolactin levels, and consequently increase hormonally-mediated cancers. Further, lower melatonin levels, with melatonin acting as an antioxidant, could result in increased susceptibility to DNA damage. This may result in a general increase in risk for a variety of cancers. Finally, EMF may affect the effectiveness of melatonin for inhibiting cell proliferation. This mechanism could be relevant to cancer in general [3]. Several studies show that EMF across the spectrum from extremely low

frequencies (ELF) to RF/MW reduces melatonin in animals and people [5]. Light going through our eyes passes a message to the pineal glands in the brain which slows down the production of melatonin during the day time. At night the production of melatonin is speeded up. Melatonin is considered to scavenge cancer cells and impurities in our bodies and boost the immune system. Non-ionizing radiation is supposed to act on the pineal gland and suppress the night-time melatonin to daytime levels; hence the good work of the melatonin at night will be restricted leading to suppression of the immune system [6]. Otherwise, melatonin circadian profile was not been disrupted in 37 young male volunteers submitted to the EMFs of 900 and 1800 MHz frequency field [7]. Additionally, both continuous and/or pulsed 900 MHz field exposure for 15 min to 6 hours at day or night had no notable effect on pineal melatonin synthesis in rodents [8].

There has been insufficient research on the effects of RF/MW on melatonin excretion level, and the few existing studies do not provide clear information about such effects. As urinary 6-sulfatoxymelatonin (6SM) appears to be the main metabolic end product of pineal melatonin hormone, the aim of this investigation was to examine whether 2.45 GHz exposure has effects on rats' nocturnal urinary 6SM along with. Urinalysis parameters after exposure were also studied.

Materials and Methods

Male Wistar rats (13 week old, approximate body weight 450 g) had passed through a week accommodation period. Both sham-exposed control (n=10) and exposed animal group (n=10) were kept in steady-state microenvironment conditions ($22^{\circ}\text{C} \pm 1^{\circ}\text{C}$), receiving standard laboratory food and water from 7:00 AM till 7:00 PM, with alternating 12-hours light and dark cycles. The animals were exposed to 2.45 GHz continuous waves two hours daily, five days a week every day between 8:00 AM and 10:00 AM. The animals were exposed to RF/MW source (modified Micro-Chef Moulinex generator, 900 W, 2.45 GHz) in individual Plexiglas cages. Rats were irradiated separately at the same time. The field power density within the cages was measured by EM Radiation Monitor, EMR-20 and 8.2, Wandel & Goltermann GmbH & Co. Germany, at "average mode". The exposures were conducted with a field power density of 5-10 mW/cm². Specific absorption rate (SAR) was estimated according to radiation dosimetry handbook [9]. The average whole-body SAR value was calculated to be 1.25 (± 0.36 SE) W/kg. According to recent literature calculated SAR of this range excludes thermal stress in rats [10]. The animals did not receive food or water during exposure sessions. The experiment lasted fifteen days. The rectal body temperature was measured by Thermo Scan thermometer (Braun GmbH, Germany) before and after the treatment. No significant changes in body temperature were observed. Control animals were handled as the treated ones, but without RF irradiation. In order to collect nocturnal urine, both, control and exposed animals were held individually in metabolic cages every night, from 7:00 PM till 7:00 AM next day. The volume of collected urine was measured. The concentration of 6SM in rat urine samples was determined by direct radioimmunoassay kit (Stockgrand Ltd., Guildford, UK). To get a quick overview into the urinary biochemical parameters, a rapid screening test has been performed. Nocturnal urinary glucose, bilirubin, ketones, specific gravity, blood, pH, protein, urobilinogen, nitrite and leucocyte manifestation has been accomplished by multiple reagent strips (N-Multistix® Bayer Diagnostic, UK). During or after exposure procedure no changes were observed neither in food/water intake or behavioral pattern. The results were statistically evaluated using Mann-Whitney and Kruskal-Wallis tests [11].

Results

When we conducted the 6SM test after 2.45 GHz rats' whole-body microwave irradiation, samples of urine were collected every morning at the same time during the fifteen days lasted experiment. The time-course of nocturnal 6SM in rat urine samples during the 2.45 GHz exposure of 2 hours a day, 5 days a week is presented at Figure 1. In comparison with sham-control animal group the significant decline in 6SM of irradiated rats has been obtained between experimental days eight and eleven ($p < 0.05$). Reduced metabolic end product of melatonin appears to be consequence of cumulative RF/MW irradiation. The 6SM level in urine of exposed animal group remained low until the end of the experiment, but it has not significantly differed in comparison with the sham-control ones.

The semi-quantitative biochemical findings in nocturnal urine samples during the 2.45 GHz exposure of 2 hours a day, 5 days a week is presented at Figure 2. The results of urinary pH, glucose, bilirubin, ketones, specific gravity, blood, protein, urobilinogen, nitrite, leukocyte appearance in the nocturnal urine indicated no significant differences between treated and control animal group.

6-SULFATOXYMELATONIN EXCRETION IN IRRADIATED RATS

Discussion

Interest in melatonin is that it could help explain results of some studies on unsafe EMF biological potency across the spectrum from ELF to RF/ MW by means of the reasonable underlying mechanisms of action. Melatonin has been reported to block RF/EM radiation-induced DNA strand breaks in rat brain cells and slow the growth of some preneoplastic lesions in rats in relation to the influence of EM exposure [12, 13]. Studies on small animals provide the strongest data supporting the hypothesis that EM field suppresses melatonin. It gives the impression that EMF suppresses different elements of melatonin biosynthesis, specifically secretion and metabolism [4, 14, 15, 16]. On the other hand, chronic exposure of lambs to the environmental electric and magnetic fields revealed that EMF does not affect the mechanism underlying the generation of the circadian pattern of melatonin secretion [17]. Additionally, Stärk et al., call attention to the absence of chronic RF exposure effect on salivary melatonin concentrations in cattle, along with Vollrath's group who found no short-term effect of high frequency RF exposure on the mammalian pineal gland and melatonin synthesis [18, 8]. Recent investigations suggest that short term exposure to 1439 MHz field does not alter melatonin synthesis in rats, and two hours daily exposure to the 900 and 1800 MHz during 14 day period achieve no effect on 6SM excretion in rats [19, 20]. We studied whether 2.45 GHz frequency field has demonstrable effects on nocturnal urinary 6SM level and urinalysis parameters in rats after exposure of two hours a day, five days a week exposure. The animals were not irradiated for two days on weekends. Major decline in 6SM excretion in microwave exposed rats has been obtained between experimental days eight and eleven ($p < 0.05$). Reduction in melatonin metabolite levels seems to be consequence of increasing RF/MW irradiation over the time. Obtained effects appeared after repeated exposure, but apparently not leading into the irreparable damage. Recovery of 6SM urinary excretion is likely related to absence of irradiation on experimental day thirteen and fourteen. The findings reveal that urinary melatonin metabolite could be a sensitive marker of RF/MW biological potency (Figure 1). Accordingly, it is in agreement with Lai's statement that: "Existing results indicate changes in the response characteristics of the nervous system with repeated exposure suggesting that the effects are not "forgotten" after each episode of exposure" [21]. The semi-quantitative biochemical findings in nocturnal urine indicated that applied 2.45 GHz exposure does not influence glucose, bilirubin, ketones, blood, protein, urobilinogen, nitrite, leukocyte appearance as well as urinary pH and specific gravity (Figure 2). The behavioral pattern of the animals was not altered during the course of the experiment. It can be concluded that 2.45 GHz microwave field has a capacity to affect the hormone melatonin balance in rats after repeated exposure.

Abstract

Probable alterations of human cognitive functions, caused by electromagnetic fields (EMF) emitted by cellular phones, are still under investigation. The present study focused on the effect of a 900MHz signal on the early components of event related potentials (ERPs) recorded during an auditory memory task.

Nineteen normal subjects (10 women and 9 men) were examined with and without radiation in a random order. Measurements included the recording at 16 scalp electrodes of the P50 and N100 components which were evoked by two warning stimuli which differed in frequency (low=500 Hz, high=3000Hz).

Results showed that for the low frequency stimulus radiation caused a statistically significant positive shift on the waveform of the early components while for the high frequency stimulus there was a significant negative shift at the Fp1 electrode. The affected area of the left prefrontal cortex (Fp1 electrode site) plays a key role in working memory operation.

These findings provide further evidence that both the P50 and N100 components of the ERPs, which reflect pre-attentive and attentive information processing respectively, are modality specific. Furthermore the amplitudes of the two components for the two modalities are influenced by EMF in opposite ways.

Introduction

Cellular (GSM) telephones are widely used throughout the world. Although there is no clear evidence of possible effects of the electromagnetic field (EMF) on brain physiology, there is common concern about this matter. In this context, some reports suggested that the exposure to mobile phone (MP) EMF exerts facilitating effects on these brain operations [1, 2, 3, 4] while other studies did not find any changes in these functions in relation to the applied MP-EMF [5, 6]. Thus, it has been proposed that ‘the inability to replicate previous findings could have been caused by lack of actual EMF effects or the magnitude of effects being at the sensitivity threshold of the test used. [5].

Event related potentials (ERPs) due to their high resolution properties can be of significant use in studying EMF effects on brain activity [7]. It should be noted that the earlier components of the ERPs are thought to represent the activity of the sensory pathways that transmit the signal generated at peripheral receptors to central processing systems. These components are ‘modality specific’, that is they are influenced primarily by the stimulus parameters such as intensity and frequency. In this respect, given that both attention and WM are associated with the P50 and N100 components of ERPs [8, 9, 10] it seems reasonable to review the effects of MP-EMF on these components taking also into account the kind of stimulus that provokes them.

The analysis of the patterns of N100 waveforms of ERPs during MP-EMF exposure revealed conflicting results. Urban et al., [11] did not find changes to the visual evoked N100 components of ERPs (amplitude and latency) following 5 min exposure to EMFs. A recent study by Maby et al. [12], based on the investigation of auditory evoked potentials recorded from healthy volunteers and epileptic patients revealed that the exposure to MP-EMF induced decreased N100 amplitude in both assessed groups, and decreased N100 latency for the healthy subjects. The authors drew the conclusion that these effects are attributable to the ‘mild, localized heating’ evoked by MP-EMF. It is possible that some of the inconsistencies just mentioned may be related to the different modalities involved (i.e. auditory versus visual) and complexity of the tasks employed.

Taking into account the above considerations, we hypothesized that the electrophysiological brain activity as indexed by P50 and N100, in relation to WM operation, could be of value in detecting possible psychophysiological mechanisms underlying alterations evoked by MP-EMF. Thus, the present study was designed to assess the effect of the exposure of MP-EMF on the patterns of P50 and N100 ERP components elicited during a WMtest.

Methods

Participants

Nineteen healthy individuals (9 men and 10 women, mean age = 23.3 ± 2.23 years, mean education = 16.9 ± 1.82 years) participated in the experiment. The male and female subgroups were homogeneous with regards to age and educational level. All participants were right-handed and had no history of any hearing problem. Informed consent was obtained from all subjects.

Stimuli and procedure

The subjects were evaluated with the digit span Wechsler Auditory test [13, 14]. A warning stimulus of either high (3000 Hz) or low frequency (500 Hz) was presented through earphones to the subjects, who were asked to memorize the numbers that followed. The warning stimulus lasted 100msec. A one second interval followed the onset of the warning stimulus and then the numbers to be memorized were presented by a male voice. At the end of the number sequence presentation, the same signal tone was repeated. If the frequency of the signal tone was low the subjects had to recall the numbers in the same order with that presented, else, if the frequency was high, the subjects had to recall the numbers in the opposite order.

Before any ERPs’ recording, practice trials were administered until the subjects could clearly discriminate the warning stimuli (tones). After completion of the above-mentioned process, a rest period of five minutes followed, before the recording of the ERPs.

The experimental setup included a Faraday room, which screened any electromagnetic interference that could affect the measurements. The subjects sat in an anatomical chair and a certified dipole antenna was fixed near their right ear. Care was taken so that the distance between telephone and ear (about 20 cm) was constant during the whole session. The antenna was driven by a signal generator, which could be switched on or off. In the on mode the antenna emitted a 900 MHz electromagnetic field with mean power at 64 mWatt [13].

ERPs were recorded during 1 sec between the onset of the warning stimulus and the onset of the first

administered number. The electrophysiological signals were recorded with Ag/AgCl electrodes. Electrode resistance was kept constantly below 5 k Ω . EEG activity was recorded from 15 scalp electrodes based on the International 10-20 system of Electroencephalography [15], referred to both earlobes. An electrode placed on the subject's forehead served as ground. The bandwidth of the amplifiers was set at 0.05 Hz to 35Hz. During the administration of stimuli, the subjects had their eyes closed in order to minimize eye movements and blinks. Eye movements were recorded through electro-oculogram (EOG) and recordings with EEG higher than 75mV were rejected. Warning stimuli, as well as learning material, i.e. the numbers to recall, were presented binaurally via earphones at an intensity of 65dB sound pressure level. The evoked biopotential signal was submitted to an analogue-to-digital conversion, at a sampling rate of 1 KHz, and was averaged by a computerized system. Each recording session consisted of 52 repetitions of the trial.

Because the P50 and N100 components are included in the array of early-endogenous ERPs components, which normally are modality specific, the ERPs induced by the two modal stimuli were averaged separately [7]. In particular, two varieties of waveforms for each component were obtained, one (low P50 and low N100) evoked by the low frequency modality (26 trials) for each lead in all subjects and another (high P50 and high N100) evoked by the high frequency modality (26 trials) for each lead in all subjects .

The following parameters were calculated. ERPs were recorded for each subject at EEG leads Fp1, Fp2, F3, F4, C3, C4, C5, C6, P3, P4, O1, O2, Pz, Cz, and Fz. Recordings with acceptable EEG level were averaged for each lead by a computerized system. An algorithm was used, which identified the P50 as the most positive peak in each averaged lead curve, between 30 and 80 msec and the N100 as the most negative peak in each averaged lead curve, between 70 and 150 msec, after the onset of the warning stimulus. Peak amplitudes were measured relative to the mean amplitude of the 100-msec prestimulus baseline period and latency measurements were computed relative to stimulus onset.

Statistical analysis

The values of the P50 and N100 amplitudes and latencies at the fifteen leads were subjected to multivariate analysis of variance with the two frequency tones and the two radiation conditions as the between subjects factors. The frequency X radiation interaction was also taken into consideration. Post-hoc pairwise comparisons (with the necessary corrections for multiple comparisons) were carried out between the two frequencies in the absence and presence of radiation, as well as between the two radiation conditions at the low and high frequencies for both components. Statistical significance was set at 0.05.

Results

The multivariate analysis revealed that neither frequency, nor radiation by themselves had any significant effect on P50 and N100 amplitudes of the entire group of subjects taken as a whole. There was, however, a significant frequency X radiation interaction effect (p value of Pillai's trace=0.013).

Figure 1 and figure 2 are quite helpful in explaining this interaction effect. In the absence of radiation the following findings were observed: The low frequency tone induces higher negative peak amplitude values of the N100 component than the high frequency one at all the fifteen leads under consideration. This difference achieves statistical significance at nine leads (Fp1, C3, Fp2, C6, O1, O2, P3, Pz, Fz). The high frequency tone induces higher positive peak amplitude values of the P50 component than the low frequency one at all the fifteen leads under consideration. This difference achieves statistical significance at eleven leads (Fp1, C5, C3, Fp2, C6, C4, O1, O2, P3, Pz, Fz).

The application of EMF radiation demotes these differences, since in the case of this application statistically significant differences of the P50 amplitudes for the two frequency tones are observed only in three leads while no statistically significant differences of the N100 amplitudes for the two frequency tones are observed.

This is accomplished by a slight increase of the negative values of the N100 amplitudes together with a slight decrease of the positive values of the P50 amplitudes at the high frequencies. These differences achieve statistical significance at lead Fp1 for both N100 and P50. Also a slight decrease of the N100 amplitudes together with a slight increase of the P50 amplitudes was observed at the low frequencies. In P50 the increase achieves statistical significance at two leads (Fp1 and O1) while in N100 the decrease achieves statistical significance at lead Fp1

Figure1: P50 amplitudes at 15 leads for high and low frequency stimuli, with and without EMF exposure.

THE EFFECT OF EMF ON THE EARLY COMPONENTS OF ERPS

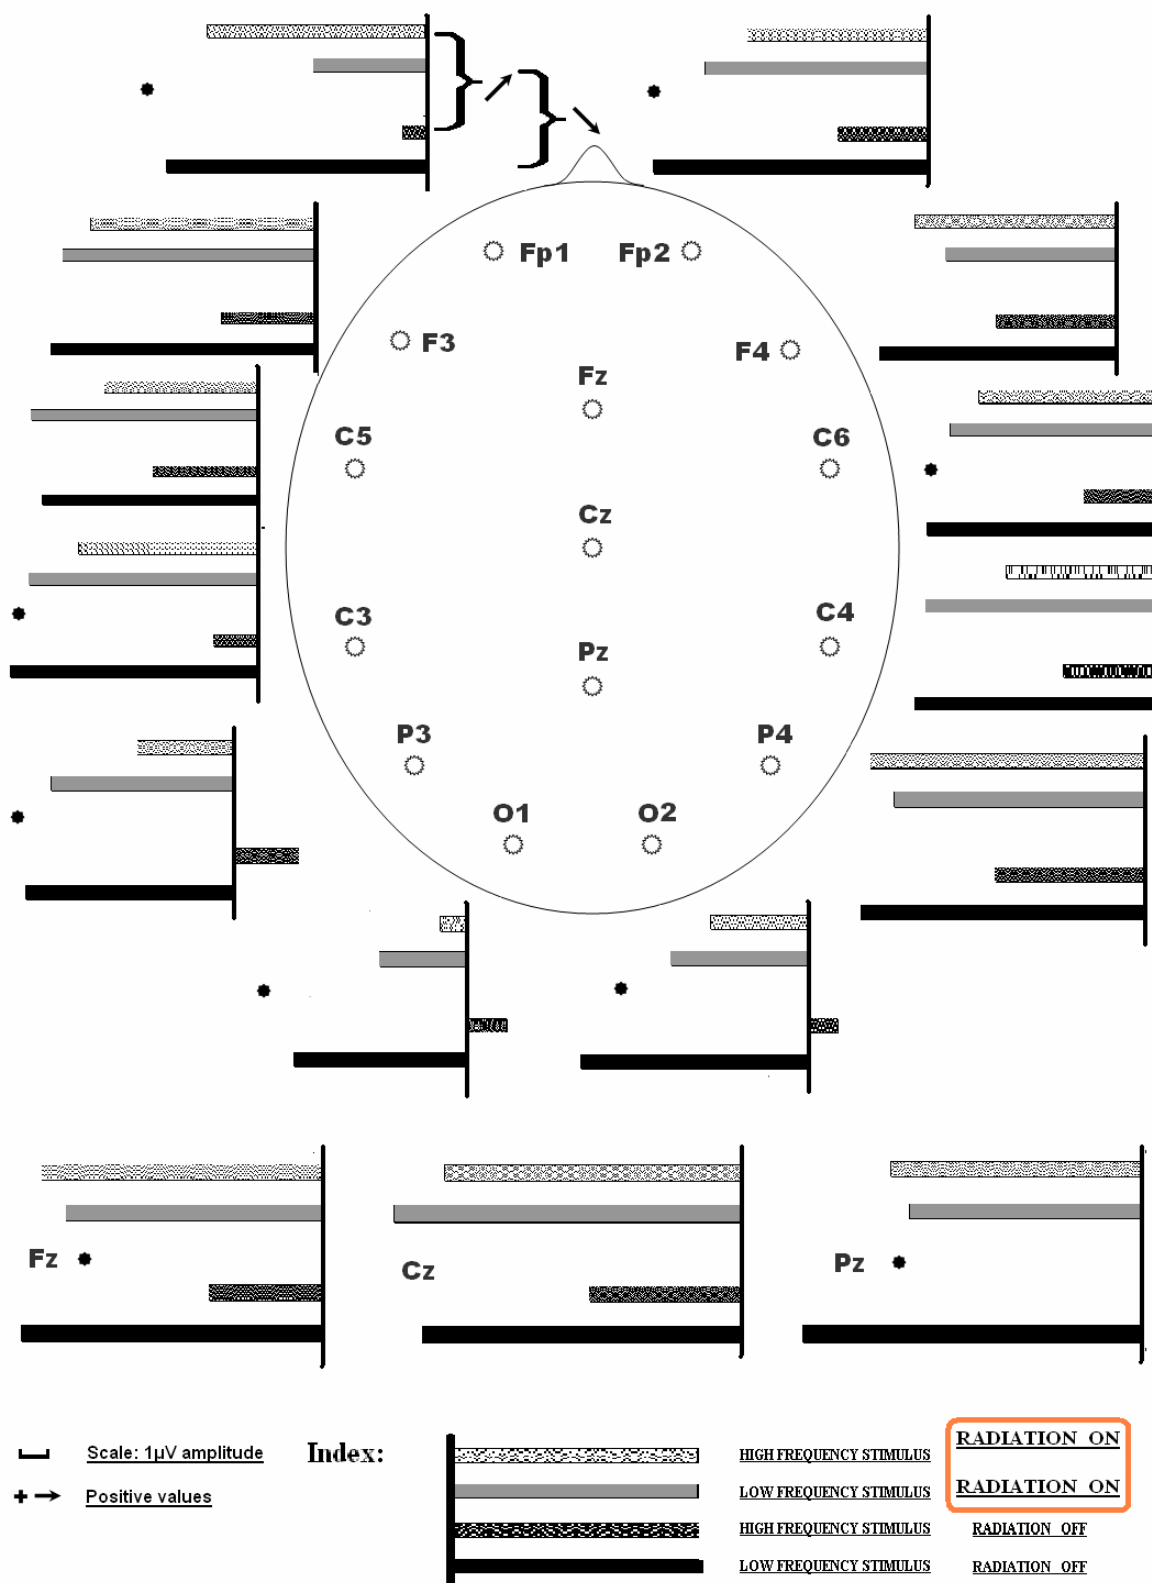

Figure2: N100 amplitudes at 15 lead for high and low frequency stimuli, with and without EMF exposure

The crossover effect of these changes results in the fact that Fp1 stands as the only lead, at which in the presence of radiation the N100 amplitudes are lower at the low frequency than at the high frequency tone while the P50 amplitudes are higher at the low frequency than at the high frequency tone. This is the main reason for the appearance of a significant overall frequency X radiation interaction effect.

Neither radiation, nor frequency, nor their interaction had any significant effect on the N100 and P50 latencies. Memory performance did not differ, in both cases, between the two frequency modalities (58.4 ± 26.5 for the low frequency tone, and 54.9 ± 24.6 for the high frequency tone, *t*-test, $p=0.552$). It also did not seem to depend on radiation, and sex.

Discussion

The findings of the present study indicate that MP-EMF may alter the patterns of the auditory P50 and N100 components of ERPs elicited in a working memory task. More precisely, the results showed that the presence of MP-EMFs, when high frequency stimulus was applied, induced statistically significant decrease in the amplitude of P50, while there was a statistically significant increase in the amplitude of N100 at Fp1 electrode site, as compared to themselves without MP-EMF exposure. In contrast, the exposure to EMF when low frequency stimulus was applied, revealed statistically significant increase of the amplitude of P50 at Fp1 and O1 electrode site while there was a statistically significant decrease of the amplitude of N100 at Fp1 only electrode site, as compared to themselves without EMF exposure. Also the amplitude of P50 without radiation appeared significantly higher in the high frequency warning stimulation as compared with those of low frequency stimulation while the opposite situation appeared for the N100 (smaller values of N100 for the high than these for low frequency stimulus)

The observed differences of the amplitudes of P50 and N100 without radiation may be explained considering the fact that these components belong to the earlier components of ERPs which are sensitive to physical parameters of the stimuli [7]. The dissociation observed for the P50 and N100 potentials with reference to the modality of the warning stimuli just mentioned, suggests that an alternative explanation must be considered in connection with the effects of EMF upon these peaks evoked by high frequency and the peaks evoked by low frequency warning stimuli.

In line with this point of view, the obtained changes concerning N100 waveforms evoked by low frequency warning stimuli seem to be in accordance with those reported by Maby et al.[12] and Hamblin et al.[11], as mentioned earlier. On the other hand, the patterns of results concerning the N100 evoked by the high frequency warning stimuli appears to be consistent to those reported by Koivisto et al.[3] who reported that the exposure to the EMF has a facilitating effect of attentive processing involving left frontal area during the manipulation of information in WM.

Taken together, the obtained results provide evidence that the EMF emitted by mobile phone affect differentially the attentive information processing, as it is reflected by the N100 component of ERPs. This differential effect might be explained considering that the N100 arises from multiple sources [17, 18]. An alternative explanation can be conceived in terms of attentional demands: Eulitz et al. [19] reported that 30 min EMF exposure altered the beta frequency band of the brain electrical response to acoustic stimuli in an oddball paradigm. More precisely, this effect appeared when subjects processed task-relevant target stimuli but it was not present for irrelevant standard stimuli. Another group of investigators observed reduced slow brain potentials as an effect of exposure to EMF during a demanding experimental condition, whereas they did not observe any alteration when the exposure occurred during a not demanding experimental condition [20]. Thus, a possible explanation of the finding concerning the N100 evoked by the high frequency warning stimuli may be due to the fact that in this condition the subjects had to recall the administered numbers in the opposite order (see experimental procedure), consequently, the subjects faced a rather demanding experimental condition.

The findings of P50 amplitudes in relation to the MP-EMF radiation cannot be compared with those of other studies, because to our knowledge there are no previous reports assessing this ERP component in relation to MP-EMF radiation. An exception appears to be the study by Arai et al. [21], which reported no effects on mid latency evoked brain potentials in 15 healthy controls using the Japanese mobile phone emitting 800MHz. But there are important differences in methodology that make a direct comparison difficult, for instance, in the present study the obtained findings would likely have occurred immediately upon presentation of the MP-EMF and lasted throughout its presence, whereas, in the study by Arai et al., [21] the reported effects referred to evoked brain response before and after using a mobile phone for 30 min. The main difference is that in the present study the evoked potentials were recorded during the presence of the radiation and without the presence of the radiation, while in the study of Arai the ERPs were studied before and after the expose to the MP-EMF. However, it may be easier to understand the importance of the patters in P50 amplitude during MP-EMF radiation reported here in the light of psychophysiological indices concerning the meaning of the P50 potential on the one hand, and on the other considering the proposed influence of MP-EMF on brain function. The P50 potential is a subcomponent of the γ EEG activity reflecting the transient synchronization of thalamocortical

activity in response to sensory stimulation [22, 23]. In keeping with this suggestion, concerning the low frequency amplitude of P50 waveforms, the present findings, seem to be compatible with a recent study by Croft et al.,[24] focusing on the effects of mobile phone on EEG as a function of time, which show ‘an increase in the γ response at midline frontal and lateral posterior sites’. Further, since the MP-EMF is observed to enhance the enzymatic activity of the cholinergic system [25, 26, 27], and on the other hand the augmentation in P50 amplitude is thought to reflect increased cholinergic activation during arousal [28, 29], thus it is reasonable to suppose that this mechanism could account for the observed increase in the amplitude of P50 evoked by the low frequency stimuli, in association with MP-EMF radiation. The obtained results provide evidence that the MP-EMF emitted by mobile phone affect pre-attentive information processing; however, the underlying mechanisms of such influence are still unclear, although several possibilities exist, calling for potential directions of future research. These highly complex physical and biological phenomena necessitate the development of new experimental, measuring and observation procedures.

A further point for discussion is the location of the observed changes with regard to the N100 amplitude. The affected area of the left prefrontal cortex (Fp1 electrode site) plays a key role in working memory operation [30, 31]. Moreover, comparable effects on this brain area after PM-EMF exposure has been reported by other researchers. Specifically, Huber et al. [32] using positron emission tomography scans showed that exposure to MP-EMF alters the cerebral blood flow of 12 healthy young men in the left dorsolateral brain region. In line with this, it is noteworthy that brain imaging studies suggest that attention and working memory generally engage left frontal areas of the brain cortex [33, 34].

In conclusion, the findings of the present study support the view that MP-EMF during the performance of a WM task, affect pre-attentive and attentive operation, possibly mediated by the left frontal brain networks. However, before drawing any final conclusions, the present results advocate the need for more follow-up studies in order to evaluate not only the short-term but also the long-term effects of MP-EMF use in pre-attentive, attentive and WM operation.

The findings of the present study indicate that MP-EMF may alter the patterns of the auditory P50 and N100 of ERPs elicited during a working memory task. More precisely, the results showed that the presence of MP-EMFs, when high frequency stimulus was applied, induced statistically significant decrease in the amplitude of P50, while there was a statistically significant increase in the amplitude of N100 at Fp1 electrode site, as compared to themselves without MP-EMF exposure. In contrast, the exposure to EMF when high frequency stimulus was applied, revealed statistically significant increase of the amplitude of P50 at Fp1 and O1 electrode site while there was a statistically significant decrease of the amplitude of N100 at Fp1 only electrode site, as compared to themselves without EMF exposure.

Abstract:

P-selectin plays roles mainly in the initial process of tumor cell adhesion to platelets. The object of present work was to determine the expression level of P-selectin in a colon tumor model that was affected by sinusoidal electromagnetic fields (SMF).

We used male Wistar albino rats 2-2.5 months age. Animals were divided into 4 groups: I (MNU), II (SMF+MNU), III (SMF) and IV (CONTROL). Rats were housed five per polycarbonate cage. 60 mg MNU was dissolved in 6 ml sterile 0.9% NaCl. Prepared solutions were given i.r. to the 1st and 3rd groups as 0.2 ml /per animal. The same procedure was applied to the 2nd and 4th groups but 0.2 ml /per animal sterile isotonic solution was administrated instead. This procedure was repeated once a week for 10 weeks. After administered at MNU, 2nd and 3rd groups were exposed to a sinusoidal magnetic field (SMF, 50 Hz, 5mT) for 6 hours/day for 8 months. The expression of P-Selectin in four groups of rat colon tissues by immunohistochemistry on paraffin sections. The labeled streptavidin biotin method was performed.

Fisher's exact test was used for differences between proportions. There was no statistically significant ($p>0.05$) change in expression level of P-selectin.

P-SELECTIN EXPRESSION IN A COLON TUMOR MODEL EXPOSED BY SINUSOIDAL ELECTROMAGNETIC FIELDS

Introduction:

One of the major man-induced environmental changes, which occurred in the last century, is the continued use of oscillating electromagnetic fields (EMF). These fields are generated for communication (*via* radio, television, cellular telephones), as by products of the technology set up for the visualizing on computer and television screens, or from power lines. It has been long believed that electromagnetic radiation in this wavelength range were harmless, and for sure, their inconvenience as pollutants were extremely small when compared to the health dangers associated with, for instance, smog-generating fuel. Yet, now that the major sources of environmental pollution have been identified and are being taken care of, the question about the biological effects of these electromagnetic fields becomes relevant (1).

In fact, some investigators have seen variations in cell proliferation and apoptosis after exposure to ELF fields (2), while others have not observed such changes. Thus, from a careful examination of the literature in this field, it is apparent that further studies examining the role of ELF fields in cancer are necessary. Cancer cell proliferation, apoptosis, invasion, and metastasis are complex phenomena controlled by an even more complex series of pathways, which communicate with each other through a myriad of signaling cascades. In this scenario, a pivotal role is played by cell adhesion molecules (CAMs). CAMs and their receptors mediate cell-cell and cell-matrix interactions and also play a fundamental role in tumor growth, death, metastasis, and invasion. The CAMs principally involved in these processes are those directed against important components of the extracellularmatrix (ECM) such as fibronectin, collagen, laminin, hyaluronan, heparan sulfate, and elastin. Although the number of studies examining the effects of magnetic fields on cell adhesion is rather limited, nonetheless, several studies have provided important insights into this important question (3).

Stimulated endothelial cells and activated platelets express P-selectin (CD62P), a member of the selectin family of cell adhesion molecules, which interacts with P-selectin glycoprotein ligand-1 (PSGL-1, CD162) for leukocyte rolling on stimulated endothelial cells and heterotypic aggregation of activated platelets onto leukocytes. Cross-linking of PSGL-1 by P-selectin also primes leukocytes intracellularly for cytokine and chemoattractant-induced integrin activation for firm adhesion of leukocytes. Furthermore, P-selectin mediates heterotypic aggregation of activated platelets to cancer cells and adhesion of cancer cells to stimulated endothelial cells. There is an increasing body of *in vivo* experimental evidence indicating that P-selectin can play important roles in the growth and metastasis of cancers. In this regard, the elucidation of the molecular mechanisms responsible for the regulation of the expressions of these different P-selectin ligand molecules in various human cancer cells will be an important and very interesting future task (4).

The object of present work was to determine the expression level of P-selectin in a colon tumor model that was affected by sinusoidal electromagnetic fields (SMF).

Material and Methods:

Animals

Healthy male Wistar albino rats, 2-2.5 months age, were employed in the present study. A duration of one week before the experimental period was held for the compliance and controls of experimental animals. Animals were divided into 4 groups as shown in Table 1.

TABLE 1.

Experimental groups with number of animals.

1-MNU 7

2-SMF+MNU 7

3-SMF 9

4-Control 5

Rats were housed five per polycarbonate cage (cages standard for all groups were cleaned twice a week). Water and pelleted diet were available *ad libitum*. The animal room was checked for temperature, humidity and light status (12:12 light-dark cycle). Temperature was maintained between 23 and 25 °C and relative humidity between 35 and 65 %.

Carcinogen administration

60 mg MNU (N-Methyl-N-Nitrosurea) (Sigma Chemical Co., Dorset, England) was dissolved in 6 ml sterile isotonic solution (0.9% NaCl). Prepared solutions were given *i.r.* (intra-rectal) to the MNU and SMF+MNU

groups as 0.2 ml /per animal. In the procedure a number 8 feeding tube was inserted 6 cm into the rectum and solution was administered. The same procedure was applied to the SMF and Control groups but 0.2 ml /per animal sterile isotonic solution was administrated instead. This procedure was repeated once a week for 10 weeks.

Application of magnetic field

12 serially connected copper solenoid coils generated the magnetic fields, each having 560 turns. The cores of the coils were filled with soft iron rods and they were tightened to increase the magnetic flux intensity. Plastic cages were used so that the magnetic field strength and distribution would not be affected. The coils were placed vertically and the cages were held 1.2 cm above the coils to hinder them from probable vibration. To protect the cages from heat of the coils, 1 cm thick wooden plates were placed between the coils and the cages. The coils were connected to the 220 V 50 Hz sinusoidal city electric systems. When current passed through the coils, the magnetic flux intensities were measured at five different places inside the cages to be 5 mT. For measurement, we used a Leybold Heraeus 54050 model Hall effect teslameter.

Histological processing

The animals from all groups were killed 8 months after the first i.r. injections of MNU. Immediately after the sacrifice, colons were removed, cut open along its longitudinal axis, and fixed flat in 10% buffered formalin for 24 hours at room temperature. We photographed and/or checked the aberration of the surface of colon mucosa.

Immunohistochemistry and evaluation

For immunohistochemical analysis, the labeled streptavidin biotin method was performed using a Vectastain Universal Quick Kit (Vector Laboratories, Burlingame, CA, USA) with microwave accentuation. The paraffin-embedded sections were heated for 30 minutes at 65°C, deparaffinized in xylene, and rehydrated through graded alcohols at room temperature. A 0.05 M Tris-HCl buffer (pH 7.6) was used to prepare solutions and for washes between various steps. Incubations were performed in a humidified chamber. Four- μ m-thick sections were treated for 20 minutes at room temperature with 5% BSA and incubated overnight at 4°C with primary antibodies against P-selectin (BD PharMingen, San Diego, CA, USA). For each case, negative controls were performed on serial sections. On the control section, incubation with the primary antibody was omitted. Horseradish peroxidase activity was visualized by treatment with H₂O₂ and diaminobenzidine for 5 minutes. At the last step, the sections were weakly counterstained with hematoxylin.

A semiquantitative analysis of the immunohistochemistry was performed to determine the approximate percentage of cells expressing P-selectin as follows: absent (-), 0% expression; slight (+), up to 20% of cells positive; moderate (++), 21% to 50% of cells positive; and strong (+++), more than 50% of cells positive.

Histopathological examination

Histological evaluation was performed by routine procedures with H&E staining. The stained sections were examined for grade of histological abnormality.

Results

No appreciable change in food consumption was observed among different groups of rats. Fisher's exact test was used for differences between proportions. There was no statistically significant ($p>0.05$) change in expression level of P-selectin.

Discussion:

Electric and magnetic fields associated with the production, transmission, and use of electricity are ubiquitous in industrialized society. These electric and magnetic fields are predominantly of low frequency (60 Hz in the US, 50 Hz in Europe and Japan) and generally of low intensity. Electric fields exist when there is electric potential in a line, while magnetic fields exist only when there is current flow (5). Since both electric and magnetic fields often occur together and are interactive, these fields have often been referred to as electric and magnetic fields or EMFs.

More recent research has focused on potential adverse biological effects of exposure to magnetic fields. The residential exposures in most homes are to magnetic field intensities of <2 milligauss (mG), which is equivalent to 0.2 microtesla (μ T) although some areas in homes may exceed this field intensity. In certain industrial settings, mean workplace magnetic field exposure may exceed 10 mG (6).

Metastasis is a cascade of cellular events by which cancer cells establish new colonies at distant sites in the

P-SELECTIN EXPRESSION IN A COLON TUMOR MODEL EXPOSED BY SINUSOIDAL ELECTROMAGNETIC FIELDS

body (7,8). It comprises multiple, consecutive steps. Several cell adhesion molecules are involved in the various stages of cancer metastasis (9). P-selectin has been shown to bind to several human cancers and human cancer-derived cell lines, such as colon cancer, lung cancer including small-cell lung cancer, breast cancer, malignant melanoma, gastric cancer, neuroblastoma, and adenoid cystic carcinoma of the salivary gland. There is an increasing body of *in vivo* experimental evidence indicating that P-selectin can play important roles in the growth and metastasis of cancers. In this regard, the elucidation of the molecular mechanisms responsible for the regulation of the expressions of these different P-selectin ligand molecules in various human cancer cells will be an important and very interesting future task (10,11,12).

The expression of P-selectin is regulated at both the transcriptional and cellular levels. At the transcriptional level, tumor necrosis factor- α induces P-selectin expression in mouse and bovine endothelial cells (13,14) whereas interleukin-4 and oncostatin M induce P-selectin expression in human umbilical vein endothelial cells, which can last up to 72 h (15). There is still a long way to go to elucidate the details regarding this pathway (12). Immunohistochemical studies of P-selectin expression in this model demonstrated no statistically significant ($p > 0.05$) differences between the groups. Our results suggest that this study needs confirmation by repetitive experiments, including new methods for P-selectin detection *in-vivo* and *in-vitro*. Further work is required to determine the relative effect of the magnetic fields on this molecule and relation with metastasis phenomena.

Abstract

In this study, we explored the subchronic effect of RF-EMF on blood-cerebrospinal fluid barrier (BCB) function, which defined as one of the blood-brain barrier functions. To attain the purpose, we used the micro-perfusion method, which makes it possible to quantify BCB function in vivo with high sensitivity, and evaluate the effect on barrier function during RF-EMF exposure to rat. Using a custom-made “8”-shaped loop antenna, which optimized for RF-EMF exposure to rat's head locally, we exposed 1.5 GHz RF-EMF with PDC modulation to the head of juvenile rats. A 30 minutes exposure was repeated everyday for 6 successive days, and on the 6th day, BCB function was quantified by using micro-perfusion method. The fluorescence intensity in collected cerebrospinal fluid did not increase indicating BCB did not affected by RF exposure at the brain average SARs of 0.5, 2.0 and 10 W/kg. These results suggest that the daily exposure of 1.5 GHz RF-EMF did not affect the BCB function in juvenile rats under our experimental conditions.

Introduction

Possible health effects of weak RF-EMF have been discussed worldwide. However, further scientific evidences are needed for better health risk assessment, particularly; the effects on the blood-brain barrier (BBB) which are still not clear due to the variety of experimental designs. One of the main problems on BBB study is that there are few methods which are able to monitor the barrier function on real time in vivo. In this study, we developed a real-time measuring system for blood-cerebrospinal fluid barrier (BCB) function which defined same as BBB in a broad sense. To collect CSF continuously, we employed micro-perfusion method to the measuring system. By using this method, we explored the subchronic effects on the BCB when RF-EMF was exposed to the head of animal.

Animals and surgical procedure We used male Sprague-Dawley rats (Tokyo Laboratory Animals Science Co., Japan) aged 5 weeks. Rats were anesthetized by i.m. injection of a cocktail of ketamine hydrochloride (90 mg/kg body weight, Sigma Chemical Co., St. Louis, MO) and xylazine hydrochloride (10 mg/kg body weight, Sigma Chemical Co.), and a guide cannula (Eicom Co., Kyoto, Japan) was introduced to one of the lateral ventricles through the hole and secured to the skull with dental cement. Assembly of push-pull cannula including guide cannula was shown in Fig 1.

Exposure conditions Rats for exposure groups were divided into three groups. Each exposure condition was at 0.5, 2.0, 10W/kg (brain averaged SAR) for 30 minutes per day for 6 consecutive days. We applied RF-EMF (1,439 MHz) with PDC modulation which generated by an 8-shaped loop antenna (Fig.2). During exposure, the antenna was located at 4 mm above the rat head by using the stereotaxic apparatus. In the sham exposure group, rats were also anesthetized and kept on the stereotaxic apparatus without RF-EMF exposure. On the 6th day of exposure, a push pull cannula (Fig.1) was inserted into a guide cannula. The inlet and the outlet of the cannula

were connected to the push-pull micro perfusion pump unit (EP-70, Eicom Co.) which enabled the collection of CSF continuously. At the beginning of RF-EMF exposure, FITC-labeled albumin (FITC-albumin) was injected into caudal vein and CSF perfusion was started at a rate of 1 μ l/min. Fluorescence intensity of FITC-albumin in perfusate was monitored by using spectrofluorometry under the condition of excitation /emission wave length at 490/515nm .Fluorescence intensity in perfusate was monitored for 180 minutes from the beginning of the exposure. Experimental setup was summarized in Fig. 3.

All experimental procedures are approved by the animal experiment committee in National Institute of Public Health.

Results No statistical difference on BCB function was detected among each exposure condition (Fig.4).

Fig 1 Assembly of push-pull cannula for rat
Upper is an inner cannula which includes in/out route and lower is a guide cannula

Fig 2 Overview of an "8-shaped" loop antenna for RF-EMF exposure

Fig.3 Schematic diagram of developed system for real- time monitoring of blood barrier function

Artificial CSF flow into the lateral ventricle via inlet of cannula (red arrow) and perfusate flow out via outlet of cannula (blue arrow).

Fig.4 Fluorescent profiles of sham and RF-EMF exposed group

Fluorescence intensity was emitted by fluoro-spectrometer which connected to the outlet of the push-pull cannula. Due to the dead-volume of the connection tubes, changes of fluorescence intensity in cerebrospinal fluid were reflected to this profile with some time delay. There is no statistical difference among each group.

Summary

In the previous studies, we have already reported that acute exposure to RF-EMF does not induce the effect on the blood-cerebrospinal fluid barrier (BCB) [1, 2]. In this study, we explored the subchronic effect on BCB by RF-EMF exposure. To attain the purpose, we used the micro-perfusion method, which makes us possible to quantify the barrier function in vivo with high sensitivity, and can be applied during exposure. After 6 consecutive days exposure for 30 minutes/day to 1.5GHz RF-EMF using an “8”-shaped loop antenna, the fluorescence intensity in collected fluid did not increase in any group. These results indicate blood-cerebrospinal fluid barrier did not affected by the RF exposure. As a conclusion, sub-chronic RF-EMF exposure under this experimental condition was not affect blood-cerebrospinal fluid barrier function in rats.

Abstract

The effect of long-term exposure to high frequency electromagnetic field (HF EMF) on some somatic and neural characteristics was studied in neurodefective Lurcher mutant (+/Lc) and normal wild type mice (+/+). Both newborn and young adult (3 months) animals derived from two strains (C3H, C57Bl/7) were exposed to HF EMF (870 MHz) from 1st to 21st day or from 91st to 120th day respectively. In animals of both groups and controls we observed the development of body weight. Moreover, in the HF EMF exposed adult C57Bl/7 animals we studied spatial learning ability, motor functions and the CNS excitability. To investigate specific energy absorption rate (SAR) in experimental animals we have done the basic 3D calculations of the electromagnetic energy distribution in the simplified model of the mouse. The HF EMF exposed animals exhibited a mild increase of body weight with small strain differences. The long-term exposure to HF EMF did not significantly influence the ability to learn in the Morris water maze. However, lower swimming speed was found in the irradiated +/Lc as well as lower motor activity of +/+ in the open field when compared to controls. No significant differences were found between HF EMF irradiated animals and controls in examination of the CNS excitability and motor functions.

Introduction

Increasing use of different devices (mobile phones) and other ones (radars, radio transmitters) that emit potentially harmful radiofrequency (RF) radiation is the reason why the effect of high frequency electromagnetic field (HF EMF) on human (and/or animal) body and especially on the brain, is subjected to a concentrated research. Despite this effort there is e.g. no unambiguous evidence about broadly discussed promoting effect of RF EMF on the brain cancer growth. Some results have indicated increased risk (Repacholi et al., 1997; Hardell et al., 2002) while other studies have shown no effect (Salford et al., 1997a) or even decreased risk (Adey et al., 1999). On the other hand, the clear effect of RF radiation - including that from global system for mobile communication (GSM) microwaves (MWs) - increase in blood-brain barrier (BBB) permeability in rats for their own albumin has been found (Persson and Salford, 1996; Fritze et al., 1997; Persson et al., 1997; Malmgren, 1998; Salford et al., 2001; Töre et al., 2001). Furthermore, it was observed, that the albumin leakage over the BBB caused neuronal damage in both the cortex, the hippocampus and the basal ganglia in the brains of rats exposed acutely two hours to GSM mobile phone EMF of different strengths (Salford et al., 2003). Recently, rats exposed also for 2h to GSM MWs (915 MHz, SAR 0.4 mW/g) exhibited affected expression of genes in cerebellar cells (Belyaev 2006).

Behavioral experiments in animals showed performance deficits in spatial learning in rats (Lai, 1996; Lai et al., 1998) and in mice (Sienkiewicz et al., 1998) exposed to low-frequency EMF (50 and 60 Hz). Affected learning process was also described in rats exposed to HF EMF (2450 Hz) and examined in the radial and the

Morris water maze (Lai et al., 1994; Wang et al., 2000). On the contrary, no significant effect on spatial learning was described in rats influenced by head only exposure system emitting a 900-MHz GSM EMF (Dubreuil et al., 2002).

In human, changes of working memory and evoked potentials were found as a consequence of mobile phone use (Koivisto et al., 2000; Jech et al., 2001). Except for influence of EMF on membrane ion transport (Bawin, Adey, 1976; Blackman et al., 1982; Dutta et al., 1989; Liu et al., 1990; Cleary 1990a,b, 1995) and neurotransmitter system (Merritt et al., 1977; Modak, et al., 1981; Inaba et al., 1992) the reason of the effect can be also, that mobile phones broadcast specifically at frequencies at which the head serves as an antenna and brain tissue serves as a demodulating radio receiver (Weinberger and Richter, 2002).

In previous works we described the results of our research dealing with some functional and morphological characteristics of the brain in normal and neurodefective mice exposed to both acute and chronic influence of HF EMF (Vožeh et al. 2004, Cendelín et al. 2004). The aim of this work was to survey further results of experiments concentrated on somatic and neurobehavioral characteristic in the same types of mice chronically influenced by HF EMF in two phases of their life.

Animals and methods

Experimental animals we used were Lurcher mutant and wild type mice of both sexes derived from two strains (C3H, C57B1/7). Mice were kept on a 12:12 hour light:dark cycle with constant temperature ($21 \pm 1^\circ$ C) and humidity ($60 \pm 10\%$). Water and food were available ad libitum. All these experiments have been done in full agreement with the law of the Czech Republic dealing with the right treatment of experimental animals.

The mutants suffer from genetically determined olivocerebellar degeneration due to mutation of the $\delta 2$ glutamate receptor gene. The $\delta 2$ glutamate receptor is especially expressed by cerebellar Purkinje cells (Zuo et al., 1997) and this is a reason why Lurcher mutants (heterozygotes, +/Lc) are characterized by complete progressive extinction (a type of excitotoxic apoptosis) of Purkinje cells and by a substantial decrease in number of cerebellar granule cells and inferior olive neurons (Caddy and Biscoe, 1979). The mutants exhibit signs of cerebellar ataxia, deterioration of cognitive function and higher sensitivity to some neurotoxic agents (Caddy and Vožeh, 1997; Vožeh et al., 1999). Their littermates - wild-type mice (homozygotes +/+) are healthy. One half of experimental animals (+/Lc and +/+) was subjected to chronic exposure to HF EMF, the unexposed animals of the second half were controls. The whole body exposition was performed using HF generator with HF amplifier and antenna. Frequency of HF EMF was 870 MHz (close to mobile phones frequency) and power output of the apparatus was 10 W. The radiation was directed by a wave guide to a plastic box with the animals placed just in front of it (Fig.1).

Fig. 1: Scheme of HF EMF exposure

The animals of two developmental periods were exposed to HF EMF:

- 1) newborns (irradiated from 1st to 21st day of life, 2.5 h daily, together 162 animals of both strains),
- 2) young adults (irradiated from 91st to 120^{ies} day of life, 3 h daily, together 94 animals of both strains).

To estimate SAR in experimental animals we have done basic 3D calculation of electromagnetic energy distribution in a simplified dielectric model of an adult mouse. The model consists of a homogenous lossy dielectric material mimicking muscle tissue and has shape of a cylinder (radius 3 cm and high 9 cm terminated to cone) with dielectric properties $\epsilon_r = 54$, conductivity $s = 0.8 \text{ S/m}$, density $\rho = 1000 \text{ kg/m}^3$ (Fig. 2).

Fig. 2: Scheme of the simplified dielectric model of an adult mouse during SAR measurement (bird's-eye view).

The calculations were done with the aid of 3D electromagnetic field simulator SEMCAD which used FDTD (Finite Different Time Domain). The method is based on the fact that original continuous function is replaced by the set of discrete function's values. Maxwell's equations are discretized using a 2nd order finite-difference approximation both in space and in time in an equidistantly spaced mesh. Several simulations for different positions of mice were done. Input power during simulations was normalized to 1 watt.

Both HF EMF exposed and unexposed animals (C3H and C57B1/7 newborns and young adults) were subjected to examination of the body weight development during the irradiation periods. Spatial learning ability, passive avoidance learning, CNS excitability and behavioral activity as well as topical motor skills were tested in young adult C57B1/7 mice only.

The topical body weight in individual animals was investigated every day during the irradiation period. Data obtained in individual days we used for calculation of the relative body weight increase which represented the ratio of the values in individual days to the value received on the first day of the HF EMF exposure.

Spatial learning was tested using Morris water maze. It consists of round plastic pool with a small round platform hidden under the water surface, permanently at the same place. The mouse had to locate the platform only by its relationship to distant landmarks (window, laboratory furniture, tube lights). Four swimming trials daily were performed during 6 days long examination period (D1 – D5 and D8). If the mouse did not find platform within 60 s, it was placed there. The mouse stayed on the platform always for 30 s. Mean latencies of reaching platform, swimming speed and the length of trajectory were compared in HF EMF exposed animals and controls.

For examination of discriminative learning we used "step down" method of the passive avoidance inhibitory reaction. In this test the mouse is positioned on a small platform (bench), the size of which is dependent on the age of the animal, 5 mm above an electrified grid floor of the plastic box (200 x 250 x 200 mm high). The animal is trained until the chosen criterion (100 s on the bench without descent) is met. Four parameters are measured: latency to the first descent, number of descents, time to criterion and time of stay on the grid. The same procedure is repeated 24 hours later and evaluation of each parameter is obtained by dividing the values of the retention test by those obtained in the learning (1st day) test.

CNS excitability was tested with the audiogenic epilepsy method. The mouse was placed into a plastic box covered with a transparent lid. Inside the box was an electric doorbell which served as a source of a sound stimulus of intensity of 90 dB. The sound was switched on for 60 s and the reaction of the animal was observed. The reactions were divided into 5 degrees: 1. no reaction, or exploration, 2. running, 3. fast running and

jumping, 4. convulsions, 5. death of the animal as a consequence of the convulsions. Mean reaction degree was compared.

Behavioral and spontaneous motor activity were studied using the open-field test. The open-field chamber was rectangular plastic box (400 x 400 x 450 mm high), open at the top. The box was cleaned using dilute alcohol before each trial to eliminate odorous cues. Behavior of mice and their activity were coded by a simple computer program and time spent in the central zone or in individual corners of the box as well as the length of locomotion trajectory were evaluated.

The topical complex motor skills were tested using four methods:

- 1) Fall - releasing the mouse (the right hand grips the mouse tail, the left hand the skinfold behind) from the height of 30 cm and evaluation of the drop to the cushioned table either to four extremities or to the flank.
- 2) Wire suspension - evaluation of the mouse ability to hang on a horizontal wire (diameter 1 mm, 40 cm above a cushioned table) after its front paws were placed on it. The criterion for success: 1 min.
- 3) Slanting ladder - evaluation of the mouse ability to stay on or climb up the ladder (length 35cm, width 4 cm, distance of 1 cm, inclination from horizontal 60°) after being positioned in the middle of it with head upwards.
- 4) Rotating cylinder - evaluation of the mouse ability to stay on a slowly rotating cylinder (diameter 15 cm, length 20 cm, after being positioned there with its head in the direction of the rotation. The criterion for success: 1 min.

Results

The animals exposed to HF EMF from 1st to 21st day exhibited body weight differences between them and controls only in C3H wild type mice females. They revealed statistically significant body weight increase mainly between 7th and 18th day of irradiation (Fig. 3).

Fig. 3: Relative body weight (b.w.) increase (in grams) in C3H wild type HF EMF irradiated females and controls during the postnatal period 1 - 21 days.

The animals exposed to HF EMF between days 91 and 120 of their life exhibited most significant body weight differences also in females but in some cases in males too. In C3H neurodefective females the significant body weight increase was found 7 times during the 30 days irradiation period (Fig. 4).

Fig. 4: Relative body weight (b.w.) increase (in grams) in C3H Lurcher mutant HF EMF irradiated females and controls during the postnatal period 91- 120 days.

In C57Bl/7 neurodefective females were no significant differences between HF EMF exposed animals and controls while the HM EMF irradiated neurodefective males revealed significant body weight increase 3 times during the first half of the irradiation period (Fig. 5).

Fig. 5: Relative body weight (b.w.) increase (in grams) in C57Bl/7 Lurcher mutant HF EMF irradiated males and controls during the postnatal period 91- 120 days.

Investigation of spatial learning ability showed no statistically significant differences in latencies of climbing the platform and the lengths of trajectories between HF EMF exposed animals and unexposed controls of both types (+/+, +/Lc). However, HF EMF exposed Lurcher mutant mice revealed significantly lower swimming speed (in D1 and D2, $p < 0.01$ and $p < 0.02$ respectively) in comparison with controls (Fig. 6).

Fig. 6: Average swimming speed in C57Bl/7 HF EMF irradiated Lurcher mutants and controls in individual days of the spatial learning process examination.

Results of inhibitory reaction of passive avoidance learning showed no significant differences between HF EMF exposed animals and unexposed controls of both types (+/+, +/Lc). Any significant differences were found between experimental (irradiated) animals and controls neither in investigation of open field activity nor in the examination of CNS excitability by the method of audiogenic epilepsy. Nevertheless, HF EMF irradiated wild type mice exhibited mildly lower motor activity (on the margin of statistical significance) in the open field testing when compared to controls.

Also tests of complex topical motor skills did not show any statistically significant differences between animals exposed to HF EMF and unexposed controls. On the other hand there are visible clear differences in the graphs between performances of healthy wild type mice and neurodefective Lurcher mutants (Figs. 7A, B).

Fig. 7A: Meeting criteria in individual topical motor skills tests and in total expressed as percentage in C57Bl/7 HF EMF irradiated wild type mice and controls.

Fig. 7B: Meeting criteria in individual topical motor skills tests and in total expressed as percentage in C57Bl/7 HF EMF irradiated Lurcher mutant mice and controls.

Calculations of SAR performed in connection with the simulation of absorption electromagnetic energy by experimental animals using the artificial dielectric model showed the dependence of the absorption on the real topical position of the mouse against the waveguide and was in the range of 0.05 to 1.44 mW/g (Fig. 8).

Fig. 8: SAR value (in mW/g) expressed as different hues in dependence on position of the dielectric mouse model.

Summary

Similarly as in our previous works the results were obtained in healthy and partly neurodefective mice in two developmental periods chronically exposed to HF EMF which corresponded to that used in GSM mobile phones.

Both healthy and partly neurodefective animals were used and some of experiments were realized in both types of mice derived from two different strains. The fact that the chronical exposure of mice to HF EMF was performed in their early ontogeny (during the first 3 weeks of life) which involved "the brain growth spurt" period and later (from 3 to 4 month of life) enabled us to investigate the effect of HF EMF in complex and more detailed way.

First of all, the results of our experiments showed the positive effect of chronic HF EMF exposure on gentle but in some cases significant body weight increase mainly in females of both strains. In addition, on days (D1, D2) HF EMF irradiated C57Bl/7 Lurcher mutants exhibited significantly lower swimming speed in the Morris water maze when compared with HF EMF unexposed animals.

Despite other examinations didn't show any further significant differences between HF EMF irradiated animals and HF EMF unexposed controls it is possible to say: in agreement with our previous results the HF EMF revealed the indubitable effect on some somatic and neuro-behavioral characteristics in newborn and young adult animals. This is the reason why the problem of the biological effect of HF EMF on living beings needs to be further studied.

FAST MICRODOSIMETRY

Z. WANG, Y. ALFADHL, X. CHEN

*DEPARTMENT OF ELECTRONIC ENGINEERING, QUEEN MARY, UNIVERSITY
OF LONDON,
MILE END ROAD, LONDON, E1 4NS, UK*

Abstract

Microdosimetry has emerged as an interesting area in the electromagnetic studies at cellular level. However, it is confronted with the difficulty of the treatment of the thin cell membrane, which often leads to extremely large memory usage and long running time in simulation. In this paper, we have introduced a technique for fast microdosimetry in the RF band. A simple double layer spherical cell model has been set up with given dielectric properties. Under the quasi-static approximation, the E field of the cell model can be evaluated by solving Laplace's equation. This simple cell model was solved by using Finite Element Method (FEM), verified with analytical solution and MIE theory. Next, the FEM with quasi-static approximation has been applied to evaluate the EM field interaction with the cells in various shapes, such as ellipsoidal, cylindrical and erythrocyte. It is demonstrated that, under the same meshing scheme, the FEM with quasi-static approximation runs much faster than the FEM solving full-wave Maxwell's equations.

I. Introduction

Recently, microdosimetry, i.e. the numerical study of EM fields interacting with the cellular and sub-cellular substances has received considerable interest. However, microdosimetry is confronted with a major difficulty, that is, the treatment of the thin cell membrane, which quite often leads to extremely large memory usage and long running time in simulation. In the previous work [1], FEM (Finite Element Method) with adaptive meshing has been used to solve the Maxwell's equations to evaluate the electric field distribution within cells. In the literature [2], quasi-static approximation was introduced to simplify the problem, i.e., the electric field distribution being approximately evaluated by solving Laplace's equation.

In this paper, a quantitative evaluation of the quasi-static approximation has been performed on a simple double layer spherical cell model at first. It is demonstrated that, under the same meshing scheme, the FEM with quasi-static approximation runs much faster than the FEM solving full-wave Maxwell's equations. The FEM with quasi-static approximation has been applied to evaluate the EM field interaction with the cells in various shapes, such as ellipsoid, cylinder and erythrocyte.

II. The models

The initial cell model in this study is a rigid particle rounded by a thin shell, representing a cell with membrane, with homogeneous, lossy and dispersive dielectric properties for each layer, as shown in figure 1. The cell radius is normally 10 μm and membrane thickness is 10 nm. The cell is exposed to a linear polarized plane wave with the electric field E_0 of 1V/m in the external medium. Due to the axial symmetry; a 2D model is adopted to evaluate the electric field distribution within the cell.

The frequency-dependent dielectric properties of the cytoplasm, membrane and external medium vary according to the Debye 1st order relaxation model, which will be further discussed in section 3.1. The values at 2.45GHz are listed in table 1.

	Cytoplasm (Ω_1)	Membrane (Ω_2)	External (Ω_3)
Permittivity (ϵ)	55.6	11.3	75.3
Conductivity (σ)	1.43	0	2.04

Table 1 Dielectric properties of cell compartments at 2.45 GHz

Fig. 1 Double layer cell model with cell radius 10 μm and membrane thickness 10 nm.

2.1 Quasi-static analysis by solving Laplace's equation

The wavelength at the studying frequency band (100MHz ~ 100GHz) is much larger than the cell dimension, so the quasi-static approximation applies in this study. Therefore, Laplace's equation together with the boundary conditions on the interfaces is sufficient to define the problem.

$$\begin{aligned} \nabla^2 \Phi &= 0 & \text{In } \Omega_1 \ \Omega_2 \ \Omega_3 & \quad (1) \\ (\varepsilon_2 \bar{E}_2 - \varepsilon_1 \bar{E}_1) \cdot \hat{n} &= 0 & \text{On } \Gamma_1 & \\ (\varepsilon_3 \bar{E}_3 - \varepsilon_2 \bar{E}_2) \cdot \hat{n} &= 0 & \text{On } \Gamma_2 & \end{aligned}$$

The analytical solutions of the Laplace's equation in a spherical cell model can be solved as follows.

$$E_{1n} = \frac{3\varepsilon_2\varepsilon_3}{\varepsilon_2(\varepsilon_1 + 2\varepsilon_3) + 2\alpha(\varepsilon_1 - \varepsilon_2)(\varepsilon_3 - \varepsilon_2)} E_0 \quad \text{In } \Omega_1 \quad (2a)$$

$$\begin{aligned} E_{2n} &= \frac{\varepsilon_3(\varepsilon_1 + 2\varepsilon_2)}{\varepsilon_2(\varepsilon_1 + 2\varepsilon_3) + 2\alpha(\varepsilon_1 - \varepsilon_2)(\varepsilon_3 - \varepsilon_2)} E_0 \\ &+ \frac{(1 + \cos^2 \theta) r_1^3}{r^3} \frac{\varepsilon_3(\varepsilon_1 - \varepsilon_2)}{\varepsilon_2(\varepsilon_1 + 2\varepsilon_3) + 2\alpha(\varepsilon_1 - \varepsilon_2)(\varepsilon_3 - \varepsilon_2)} E_0 \quad \text{In } \Omega_2 \quad (2b) \end{aligned}$$

$$E_{3n} = E_0 + \frac{(1 + \cos^2 \theta) r_1^3}{r^3} \frac{\varepsilon_2(\varepsilon_1 - \varepsilon_3) - \alpha(\varepsilon_1 - \varepsilon_2)(\varepsilon_3 - \varepsilon_2)}{\varepsilon_2(\varepsilon_1 + 2\varepsilon_3) + 2\alpha(\varepsilon_1 - \varepsilon_2)(\varepsilon_3 - \varepsilon_2)} E_0 \quad \text{In } \Omega_3 \quad (2c)$$

$$\text{where } \alpha = \frac{1 - \left(\frac{r_1}{r_2}\right)^3}{3}.$$

In addition to the analytical solution, the Laplace's equation (Equation 1) can also be solved numerically. The numerical solution was performed in the trial version v3.2b of Comsol Multiphysics (FEMLAB) based on FEM (Finite Element Method). Meshing scheme of a quarter of the cell model and the zoom-in view of mesh on the membrane are shown in figure 2.

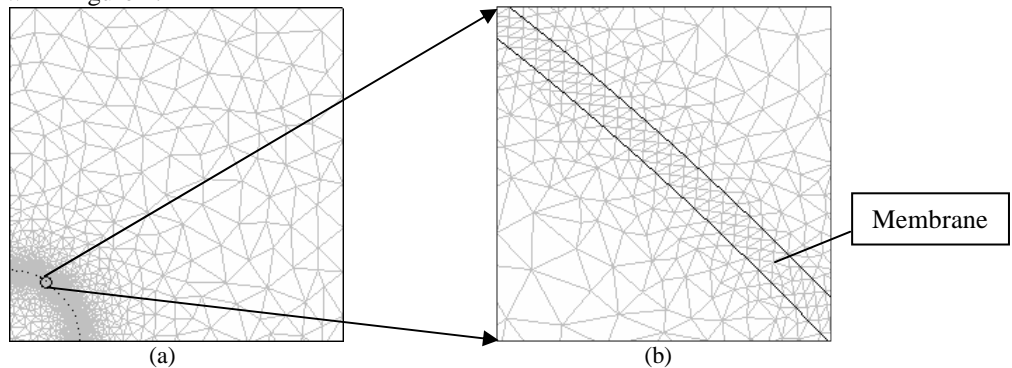

Figure 2 Meshing schemes of the cell model: (a) mesh on a quarter of a cell; (b) the zoom-in view of mesh on the membrane

2.2 Full-wave analysis by solving Maxwell's equations

On the other hand, the full wave equation, i.e. Maxwell's equations is a complete description of the problem. The theoretical solution of Maxwell's equations is obtained based on the Mie theory, which solves the Helmholtz's equations in the studying regions. Boundary conditions at the interfaces Γ_1 and Γ_2 are involved with the electric and magnetic fields of the incident wave.

$$\nabla^2 \bar{E} + k^2 \bar{E} = 0 \quad (3a)$$

$$\nabla^2 \bar{H} + k^2 \bar{H} = 0 \quad \text{In } \Omega_1 \Omega_2 \Omega_3 \quad (3b)$$

$$(\bar{E}_2 - \bar{E}_1) \times \hat{e}_r = 0; \quad (\bar{H}_2 - \bar{H}_1) \times \hat{e}_r = 0; \quad \text{On } \Gamma_1$$

$$(\bar{E}_i + \bar{E}_3 - \bar{E}_2) \times \hat{e}_r = 0; \quad (\bar{H}_i + \bar{H}_3 - \bar{H}_2) \times \hat{e}_r = 0; \quad \text{On } \Gamma_2$$

The calculated electric and magnetic fields are expressed by the vector harmonics M_{oln} , M_{eln} , N_{oln} , N_{eln} (products of cosine, Legendre and Bessel functions of corresponding parameters in spherical coordinate system) in equation 4. The coefficients a_n , b_n , c_n , d_n , f_n , g_n , v_n and w_n are solved by the wave expressions together with the boundary conditions. The summation of infinite elements in the following equations provides the accurate result, which is not applicable in practical calculation, so the element-summation truncation number N is selected as 12 to balance the accuracy and computation overheads.

$$\bar{E}_1 = E_0 \sum_{n=1}^N i^n \frac{2n+1}{n(n+1)} (c_n \bar{M}_{oln}^{(1)} - i d_n \bar{N}_{eln}^{(1)}) \quad (4a)$$

$$\bar{H}_1 = \frac{-k_1}{\omega \mu_1} E_0 \sum_{n=1}^N i^n \frac{2n+1}{n(n+1)} (d_n \bar{M}_{eln}^{(1)} + i c_n \bar{N}_{oln}^{(1)}) \quad (4b)$$

$$\bar{E}_2 = E_0 \sum_{n=1}^N i^n \frac{2n+1}{n(n+1)} (f_n \bar{M}_{oln}^{(1)} - i g_n \bar{N}_{eln}^{(1)} + v_n \bar{M}_{oln}^{(2)} - i w_n \bar{N}_{eln}^{(2)}) \quad (4c)$$

$$\bar{H}_2 = \frac{-k_2}{\omega \mu_2} E_0 \sum_{n=1}^N i^n \frac{2n+1}{n(n+1)} (g_n \bar{M}_{eln}^{(1)} + i f_n \bar{N}_{oln}^{(1)} + w_n \bar{M}_{eln}^{(2)} + i v_n \bar{N}_{oln}^{(2)}) \quad (4d)$$

$$\bar{E}_3 = E_0 \sum_{n=1}^N i^n \frac{2n+1}{n(n+1)} (-b_n \bar{M}_{oln}^{(3)} + i a_n \bar{N}_{eln}^{(3)}) \quad (4e)$$

$$\bar{H}_3 = \frac{k}{\omega \mu} E_0 \sum_{n=1}^N i^n \frac{2n+1}{n(n+1)} (a_n \bar{M}_{eln}^{(3)} + i b_n \bar{N}_{oln}^{(3)}) \quad (4f)$$

The Maxwell's equations are also solved by FEM in the Comsol Multiphysics (FEMLAB) as the full-wave analysis, using the same meshing scheme as the quasi-static method, as shown in figure 2. The scattering boundary conditions are used assuming the boundary is transparent for the scattered wave.

2.3 Results

Figure 3 shows the calculated E-fields by using Mie theory (red dotted line) and the Laplace's solution (red solid line), compared with the numerical calculated results of full-wave (blue dotted line) and quasi-static FEM (blue solid line). It is observed that the two dotted lines (Mie theory and FEM with full-wave) agree with each other quite well, presenting a more accurate evaluation than the other two methods based on the quasi-static approximation (Laplace's solution and FEM with quasi-static). However, the largest discrepancy between them is no more than 5%, which is acceptable in the estimation of the field distribution in cell modelling.

The left part of the separator symbol ('//') on figure 3 shown the electric field distribution near the membrane of the cell. The field inside the cell is slightly higher than the external field strength (1V/m), and the field outside the cell is lower than the external field. The right part (right of '//') showed that the electric field increases while leaving the edge of the cell, and approaches the external field strength gradually.

Figure 3 Electric field distributions along the axis parallel to the external field (analytical and numerical)

Solving the 2D cell model with quasi-static approximation took 2 minutes 27 seconds in the simulation software FEMLAB, whereas the full-wave analysis of the same cell model and meshing scheme took 26 hours 48 minutes, both on a 2.80GHz PC with 512M memory. Therefore, the fast microdosimetry based on quasi-static approximation is much more efficient than the traditional full-wave analysis while maintaining acceptable accuracy (<5% error). All the simulations in next two sections use the models based on the quasi-static approximation.

III. Analyses

3.1 Influences of dielectric properties

The cytoplasm was modelled as physiological saline (0.07N) containing a protein volume fraction of 0.262, so the relative permittivity and the conductivity were obtained in literature [3]. As a protein solution, the major dispersion at microwave frequencies is dominated by the water relaxation near 20GHz, and diminished a little due to the proteins' displacement of a corresponding volume of water. The membrane, as a phospholipid bilayer, has a frequency-independent relative permittivity of 11.3 (membrane capacity $1.0\mu\text{F}/\text{cm}^2$) and conductivity of 0 [4]. The external medium is assumed to have the frequency-dependent dielectric properties of physiological saline (0.15N) [4] with a static and infinite frequency permittivity values of 76 and 5, respectively. There is no apparent difference between the relaxation frequency of the medium and that of the pure water, which is 20GHz at room temperature. The characteristic values of the dielectric properties on the three sub-domains are listed in table 2.

	Cytoplasm (Ω_1)	Membrane (Ω_2)	External (Ω_3)
ϵ_s	57	11.3	76
ϵ_{in}	5	0	5
f_c (Hz)	15e9	-	20e9
σ_s (S/m)	0.3	0	1.1

Table 2 Dielectric properties of double layer cell model

The parameters illustrated in table 2 are static relative permittivity, infinite frequency relative permittivity, relaxation frequency and static conductivity, respectively. The frequency dependent permittivities are plotted in figure 4. The electric fields inside and outside the cell are almost uniform, whereas the field concentrated on the membrane varies according to the theta angle in the polar coordinate. The maximum value of the field intensity happens at the zenith angle (90°), and depends on the frequency, as plotted in figure 5.

Figure 4 Debye 1st order relaxation properties of cell model (Relative permittivity)

Figure 5 Maximum E fields on the membrane of the spherical cell model

Figure 5 displays the electric field simulated by FEM with quasi-static approximation and calculated by directly solving Laplace's equation. The two curves agree with each other very well. With the logarithm scaled axes, figure 5 illustrates that at the lower frequency band, the E-fields are not significantly dependent on the dielectric model. While at the higher frequency range the maximum electric field is strongly dependent on the frequency, which agrees well with the trends shown in figure 4 of the dielectric properties.

3.2 Elliptical cells

One of the most common cells shapes is ellipsoid, which has one more dimensional variable than the spherical model, axial ratio (the ratio between major and minor axes). When the cell is exposed to the plane wave illumination, the electric field also concentrates on the membrane and the maximum electric field appears at the zenith angle of the cell. The dielectric properties used in the simulations in this section are the same values as listed in table 1. Amplitudes of the maximum electric fields of the cell model with different axial ratios are plotted in figure 6.

Figure 6 Maximum E fields on the membrane of the ellipsoidal cell (according to different axial ratio)

Figure 6 presents that the maximum electric field is higher when the major axis of the ellipsoidal cell is perpendicular to the external field, and the value decreases while the minor axis increasing. When the major axis is parallel to the external field, the E field value increases with the increasing of the minor axis. Plotting the E field amplitude according to the axial ratio in logarithm scale, this relationship is approximately linear.

The ellipsoid exposed to external electric fields with different polarisations as illustrated in Figure 7 has also been investigated. The maximum value of electric field presents at the frontier of the structure. Figure 8 shows the maximum electric field on the membrane decreasing when the external electric field polarisation changing from 0 degree to 90 degree.

Figure 7 Ellipsoidal cell exposed to electric field with different polarisation

Figure 8 Maximum electric fields on the membrane of the ellipsoidal cell (according to different polarisation of external electric field)

3.3 Other shapes of models

The geometric shape of the structure also influences the maximum electric field on the membrane. For a cell model with length 10 microns and width 5 microns, the maximum E fields of the ellipsoids, rods and erythrocytes are compared in Table 3. The “vertical ($\uparrow 0^\circ$)” and “horizontal ($\rightarrow 90^\circ$)” in Table 3 indicates the directions of external electric field as shown in Figure 4. The location of maximum electric field is labelled by the red circles in Table 3.

		E field (external E_0 : horizontal $\rightarrow 90^\circ$)		E field (external E_0 : vertical $\uparrow 0^\circ$)	
Ellipsoid		4.776		5.415	
Rod		4.762		5.492	
Erythrocyte		4.779		5.780	

Table 3 E fields on the membrane (according to different cell shapes)

IV. Summaries

In this paper, a fast microdosimetry technique based on the quasi-static approximation has been studied. It is demonstrated that the fast microdosimetry technique runs much faster than the one working with full-wave analysis, while maintaining acceptable accuracy. The following analyses of frequency-dependent dielectric properties of the simple cell model have revealed their influences on the electric field concentration on the membrane. In addition, the effects of the various shapes of cell models have been also been investigated. In the future, the fast microdosimetry can be performed on more realistic cell models, in order to study the field distribution and transmembrane potential of the cell.

Abstract

The effect of the spatial magnetic gradient in static magnetic field (SMF) exposure on the velocity of chemical wave in Belousov-Zhabotinsky (BZ) reaction was examined. The BZ medium was exposed to SMF of maximum magnetic flux density 210 mT and maximum spatial gradient 37 mT/mm for a period of up to 20 min at room temperature. The SMF was generated by a parallel pair of attracting rectangular NdFeB magnets positioned opposite to each other. The results suggested three characteristics for the alternation of BZ chemical wave formation: (1) the magnetic gradient could be the dominant factor for the alternation of the chemical wave; (2) the direction of accelerated velocity of chemical wave was vertical to the direction of magnetic gradient; (3) the effect was symmetry to the gradient direction and our experiments demonstrate clearly that The effect of SMF on the chemical wave propagation was affected by the thickness of the BZ medium.

1. Introduction

It has been reported that static magnetic field (SMF) can influence physicochemical reactions [Boga et al., 1990; He et al., 1994] and biochemical reactions [Harkins and Grissom, 1994], and therefore it has been predicted that SMF might affect auto-oscillations in the nonequilibrium system. We used the Belousov-Zhabotinsky (BZ) reaction known as nonequilibrium system and one of the simplest chemical oscillators in order to test this hypothesis. The steady oscillations of BZ reaction can be easily observed for a long period. The present study shows that the spatial magnetic gradient in the SMF exposure affects the velocity of chemical wave propagation. This phenomenon could be attributed primarily to the magnetic force acting the iron ion complexes in the BZ solution.

2. Experiment

The BZ medium of 20 ml contains the following solutions: (1) 7 ml H₂O, (2) 3 ml NaBrO₃ (1 M), (3) 2 ml H₂SO₄ (3 M), (4) 2 ml CH₂(COOH)₂ (1 M), (5) 2 ml NaBr (3 M), and (6) 4 ml Fe[(phen)₃]²⁺ (20 mM). Every solution from (1) to (5) was added in number order. After these 5 solutions were mixed in a glass vessel, the solution turned yellowish, started to fade and became colorless in some minutes. In the end, solution (6) ferroin was added into the previous solution.

The magnetic device is constructed using a pair of rectangular neodymium magnets (Fig.1). The opposite magnets attracting each other through a 26 mm air gap are fixed parallel to both sides of the stainless frame. The maximum magnetic flux density was measured to be approximately 210 mT at the bottom center of the Petri dish by using a gaussmeter (Model 4048, Hall probe A-4048-002; Bell Technologies, Orlando, FL, USA).

(1) The BZ medium was put into a petri dish with a diameter 140 mm (3030-150; Iwaki Glass Co, Japan), which was put on a magnetic device (Fig.1). BZ reaction was initiated at the center of the Petri dish using a silver wire. The images were taken by a digital video camera (DIGICAM, NV-GS250-S, Panasonic, Japan) from above. The pictures were quantified by using Scion software (Scion Image; Scion, Frederick, MD, USA). All the experiments were carried out at a room temperature. Four independent experiments were averaged per data point. All values are expressed as mean \pm SD.

(2) To examine the effect of the thickness of BZ medium on the chemical wave propagation, the thickness of BZ medium was controlled from 0.5 to 0.9 mm at 0.2 mm intervals by slipping some cover glasses with a thickness 0.1 mm in between two square plates. These plates were put on one side of the magnetic device with the edges of the plates parallel to the inner line of the magnet. The BZ medium was poured in between two plates. BZ reaction was initiated from the edge of plates using a silver wire to observe chemical wave propagation from the center of the device. The images were taken by a digital video camera in the same way as

the previous experiment.

Fig.1. Experimental device

A Petri dish with a diameter 140 mm was put on the magnetic table where, two parallel rectangular magnets (NdFeB, L. $80 \times$ W. $18 \times$ H. 55 mm, TDK Corporation, Japan) attract each other.

3. Results and discussions

The concentric propagation of chemical wave was observed in the BZ medium when sham exposure was performed without magnet (the background geomagnetic field intensity at our laboratory is $\sim 50 \mu\text{T}$) (Fig.2A). On the other hand, the different propagation from concentric pattern of chemical wave was observed when the BZ medium was exposed to SMF (Fig.2B). The thickness of BZ medium in the petri dish was 1.3 mm.

These results suggested three characteristics for the alternation of BZ chemical wave formation: (1) the magnetic gradient could be the dominant factor for the alternation of the chemical wave; (2) the direction of accelerated velocity of chemical wave was vertical to the direction of magnetic gradient; (3) the effect was symmetry to the gradient direction.

The velocity of chemical wave of BZ reaction to Y direction was accelerated on the inner line of the magnet where the magnetic gradient to X direction was maximum (Fig.2). This result indicates that the BZ chemical reaction was accelerated to one direction by the magnetic gradient, and that the direction was perpendicular to the gradient. The chemical wave can be visualized by the oxidation-reduction reaction of ferroin. However, BZ reaction is induced by the complicated combination of several chemical reaction steps. Ions produced in the chemical reaction could be affected by the inhomogeneous magnetic field. The alternation of the chemical wave propagation in BZ reaction could be caused by the different orientation of iron ions under SMF exposure from that of sham exposure (no magnet).

In order to quantify the alternation of chemical wave, the angles θ of tangent line of the chemical wave front to the inner line of the magnet defined in Fig.3 were measured under the both conditions of sham exposure (no magnet) and SMF exposure (Fig.4). The deformation rates of chemical wave in SMF exposure were significantly larger and reached their maximum levels earlier than those in sham exposure.

Fig.2. (A) Chemical wave not exposed to magnets (sham exposure) (B) Chemical wave exposed to magnets (SMF exposure; white dashed lines correspond to the position of magnets)

Fig.3. Angle θ of tangent line of the chemical-wave front to an inner line of the magnet (dashed line corresponds to the position of magnet)

Fig.4. Angles defined in Fig.3 measured per data point in the case of no magnet and SMF exposure

Fig.5. Angles defined in the same way as Fig.3 per data point of BZ reaction of several thickness 0.5, 0.7, 0.9 mm of BZ medium

The effect of SMF on the chemical wave propagation was affected by the thickness of the BZ medium as shown in Fig.5. When the thickness of BZ medium was different, the velocity of reaction front varied. Therefore, the forms of chemical wave propagation were different among three conditions. The thicker the BZ medium was, the larger the deformation rate of chemical wave was. However, there was no significant difference per data point between the thickness 0.7 and 0.9 mm. It is conceivable that the degree of the chemical wave propagation would not change in the case of both more than constant thickness and less than the threshold of thinner thickness. This means that there is a window effect of SMF on the deformation rate of chemical wave depending on the thickness of the BZ medium. The result given in Fig.5 includes the factor of the velocity of the reaction front on the inner line of the magnet. The elements of the distance of reaction front should be taken into account in order to quantify the anomalous propagation in detail.

Abstract

The hydrogen peroxide (H_2O_2) which is formed in cell bathing aqueous solution upon Electromagnetic Fields (EMF) exposure is very often considered as the most reliable messenger through which the biological effect of EMF is realized. To check this hypothesis the comparative study of the effects of 4Hz EMF-treated and H_2O_2 - containing physiological solutions (PS) on Ach sensitivity of snail neuron as well as on the nerve tissue hydration were studied. The 4 Hz EMF-treated and H_2O_2 -containing PS at room temperature ($23^{\circ}C$) had depressing effects on Ach-induced current, while in cold medium ($12^{\circ}C$) these effects disappeared. The EMF-treated ouabain-containing and K-free PS elevated the amplitude of Ach-induced current, while the H_2O_2 – containing PS has inhibitory effect on it. The both, EMF-treated and H_2O_2 -containing PS have dehydration effects on cell hydration in nerve ganglia. It is suggested that the ELF EMF-induced H_2O_2 formation could serve as one of the metabolic pathways through which the depressing effect of ELF EMF on membrane chemosensitivity is realized.

Key words: EMF, H_2O_2 , neuron, acetylcholin -sensitivity, membrane, cell volume.

Introduction

Although, the abundance of experimental data on the biological effect of magnetized water and water solutions on different cells and organisms are available (Klassen, 1982; Ayrapetyan et al., 1994a; Ayrapetyan, 2006), the nature of the messenger transferring the signal of magnetic and electromagnetic fields-induced water structural changes to cell metabolic cascade is not clear yet. As the water molecule dissociation is the most variable water property, it is suggested that the EMF-induced vibration of water dipoles could change water dissociation and its products could serve as possible messengers through which the biological effect of EMF is realized (Ayrapetyan 1994). By privies our work the depressing effect of extremely low frequency (ELF) EMF on specific electrical conductivity (SEC) of water and water solutions (which is marker for its dissociation) was documented (Ayrapetyan et al., 1994). It was also shown that the depressing effect of LF EMF on water SEC as well as its biological effects on various cells are most pronounced at frequency of 4 Hz (Stepanian et al. 1999; Ayrapetyan 2006).

The fact that the vibration of water dipoles in presence of oxygen could generate the H_2O_2 , which could initiate the modulation of a number of metabolic pathways in the cell, makes it as one of the most reliable candidates for the messenger able to transfer the ELF EMF-induced water structure changes to cell metabolic cascades (Klassen, 1982). As the acetylcholine (Ach) sensitivity of neuronal membrane is sensitive to the effect of magnetized physiological solutions (MPS) (Ayrapetyan et al., 1994a; Ayrapetyan et al., 2004), it was chosen as an experimental model for testing the above-mentioned hypothesis.

The overall aim of the present review is to present the results of the comparative study of 4 Hz EMF-treated and H_2O_2 –containing PS on snail neuromembrane chemosensitivity, as well as on the nerve tissue hydration which has a crucial role in metabolic regulation of membrane chemosensitivity (Ayrapetyan & Arvanov, 1979).

Method

The experiments were carried out on non-selected giant neurons of the right parietal ganglion of *Helix pomatia*. The standard Voltage-Clamp method was used to record the Ach-induced current through the neuronal membrane (Ayrapetyan and Arvanov, 1988). The normal physiological solution contains (in mM): NaCl-80,

KCl-4, CaCl₂-7, MgCl₂-13, Tris-HCl (pH 7.8)-10, glucose-10. In K-free solution 4mM KCl was replaced by 4mM NaCl. Different concentrations of acetylcholine (10^{-4} - 10^{-6} M) and H₂O₂ (10^{-4} - 10^{-11} M) were prepared from Ach and H₂O₂ stock solution (10^{-2} M) before the experiments. The transient application (less than 30 sec) of Ach was performed by thin (diameter ~1mm) polyethylene tube placed near the investigated neuron. The H₂O₂ was added to the perfusion solution to a final concentration from 10^{-4} to 10^{-11} M and applied to the cells at a rate of 2-3 ml/min. The time of pre-incubation of neurons in tested physiological solution before the Ach application was 3 min.

The tested physiological solution was preliminary exposed to 4Hz EMF with the intensity of 2,5 mT for 30 minutes. The experimental setup consisted of a glass test tube with diameter of 10 mm and volume of 10 ml., EMF generator with low-noise amplifier and a coil. The coil has the cylindrical form with diameter of 154 mm. and height of 106 mm. The coil consists of Helmholtz rings that generate the homogeneous magnetic field. Rings of Helmholtz are formed by two equal ring coils located coaxially and in a parallel way. The distance between ring coils is equal to their radius of 77 mm. The magnetic field created by these rings has high homogeneity. For example, on distance of 0.25R from the center of an axis strength differs from computed by

formula only on 0.5 % $H = 71.6 \cdot \omega \cdot \frac{I}{R}$. Herewith, the intensity of generated EMF is equal to 2.5 mT and 4 Hz

frequencies. The instrument used for measurement of magnetic field intensity was a Teslometer W1-8 (Armenian Radiophysical Institute). This instrument measures magnetic fields in the range 10^{-3} to 1.6 T ($\pm 5\%$). The magnetic induction converter was a crystal, type X511-1, 1.5 X 0.2 mm² and was fixed on non-magnetized material (PX13-1). During the experiment the neurons were perfused with normal and 4Hz EMF treated solutions. The physiological solution treated by 4Hz EMF for 30min. and immediately (interval from the end of the treatment and till the beginning of perfusion was no longer than 1-2 min.) used for perfusion of neuronal ganglia. The control (unexposed) PS taken from the same reservoir of PS (Vol: 1-2 l) also was placed in the same test tube for 30min in an inactive coil system, i.e. the background field was the same for the control (sham exposed) and tested PS. The background of magnetic field in the area of experimental setup in the laboratory, supplied by 60 Hz electricity, was less than 0,001 mT. The holder of the exposure tube and the coil holder were placed in two neighboring tables to excluded the vibration during the exposure.

For determination of tissue hydration, the wet samples of the nerve ganglia were weighted and dried in thermostat at 105°C, during 24 hours. After determination of dry weight the quantity of water on 1 g. of dry weight was determined by the equation: $(A - B) / B$, where A- wet weight of the tissue, B- weight of the tissue after drying.

The procedure of measuring a single cell volume has been previously described in Ayrapetyan et al., 1994a. Briefly, single neurons were dissected and isolated from the ganglion under a dissecting microscope (Lomo, B-14, Russian production) on which was mounted a digital video camera (WPI, USA) connected to PC. The system had the sensitivity such that changes of $\pm 0.1 \mu\text{m}$ could be detected. These neurons had diameters of 50-100 μm .

The mean value, standard deviations, and the statistical probability, determined by Student Test were calculated with the help of computer program Sigma Plot (Version 8.02A).

Results

It is known that three types of neurons can be distinguished according their sensitivity to Ach: (a) insensitive, (b) depolarizing (D), and (c) hyperpolarizing (H) (Shakarov et al., 1969). The present experiments were carried on 22 neurons having D-responses and 20 neurons having H-responses. The membrane potential (MP) of neurons was clamped on the level of resting potential (-40 to -60 mV). After recording the control Ach-induced currents in normal physiological solution (control) the cells were perfused with magnetized PS (MPS) or by different concentrations of hydrogen peroxide- containing PS during 7 minutes and the end of 7-th minutes the application of Ach was performed.

By previous our work was shown that the normal MPS has a reversible depressing effect on Ach-induced membrane current and this effect of MPS was absent in cold (12°C) medium. The typical record of such responses presented on Figure 1. (Ayrapetyan et al., 2004).

Figure 1. The effect of magnetized physiological solution (MPS) on ACh-induced current in D type neuron in voltage-clamp experiments, where the clamping potential (E_c) was equal to the resting membrane potential ($E_r = -50$ mV).

A- at room temperature (23°C), B- in cold medium (12°C).

The rows show the transit (30 msec) application of 10^{-4} M ACh containing PS. The time of pre-incubation of neurons in tested physiological solution (PS and MPS), before the application of ACh was 3 min. The intervals between ACh applications was 5 min.

Figure 2. The typical record of dose-dependent effect of H₂O₂ on ACh-induced current in D-type neuron in voltage-clamp experiments, where the clamping potential (E_c) was equal to the resting membrane potential ($E_r = -60$ mV). ACh concentration was 10^{-4} M. The time of pre-incubation of neurons in H₂O₂ containing physiological solution (PS) was 7 min. All presented data were taken from one neuron. The intervals between ACh application was 5 min.

As shown in Figure 2, the H₂O₂ at concentrations of 10^{-11} - 10^{-4} M also has a depressing effect on ACh (10^{-4} M)-induced ionic currents in D-type neurons. After removing of H₂O₂ from extracellular medium the amplitudes of ACh-induced currents were recovered to their initial level within 5 minutes. The maximum depressing effect of H₂O₂ on ACh-induced current appeared at concentration of 10^{-4} M ($75 \pm 1.2\%$), while the threshold of H₂O₂ concentration, unable to change the amplitude of ACh-responses of the membrane during 7 min. pre-incubation, was 10^{-12} M. The character of H₂O₂-induced inhibition of ACh-responses in both, H- and D- types neurons was the same (Figure 3, $n=5$), which could serve as indicator of potential independence of inhibitory effect of H₂O₂ on ACh responses.

Figure 3. The dose-dependent effect of H_2O_2 on Ach-induced current in H-type neurons in PS (A) and in K-free solution (B), where the clamping potential (E_c) was equal to the resting membrane potential ($E_r = -52mV$). 1- Ach $5 \times 10^{-4} M$; 2- Ach $10^{-4} M$; 3- H_2O_2 , Ach $5 \times 10^{-4} M$; 4- H_2O_2 , Ach $10^{-4} M$; 5- Ach $10^{-5} M$; 6- H_2O_2 , Ach $10^{-5} M$; 7- Ach $10^{-6} M$; 8- H_2O_2 , Ach $10^{-6} M$.

The data are taken from one neuron. The presented data are typical for all 10 studied neurons. The H_2O_2 concentration was $10^{-6} M$. The time of pre-incubation of neurons in H_2O_2 containing PS was 7 min.

This suggestion was confirmed by studying the potential-dependency of inhibitory effect of H_2O_2 on Ach responses, by clamping MP at different levels (Figure 4).

Figure 4. The Ach-responses (nA) in D-type neuron in voltage-clamp experiments in normal (circles) and $10^{-6} M$ H_2O_2 -containing (triangles) PS, when the membrane potential was clamped on different levels ($n=5$).

The study of the potential-dependence of Ach-induced outward currents in normal and H_2O_2 ($10^{-6} M$) containing solution showed that the Ach-induced currents in presence of H_2O_2 became potential independent in the range of MP= - 50 – - 80 mV (Figure 4, $n=5$). These data could serve as additional evidence that H_2O_2 – induced depression of Ach-responses could not be explained by modulation of ionic channel activity, determining the Ach-responses. As shown in Figure 5, the depressing effect of H_2O_2 on Ach-responses as in case of MPS (Figure 1B), disappeared in cold medium ($5^{\circ}C$) (Figure 5, $n=5$), which could be considered as an evidence on the metabolic nature of H_2O_2 -induced depression of Ach-responses of the membrane. The low temperature ($12^{\circ}C$) -induced slight elevation of Ach-induced current (Figure 1B) could be interpreted as the increase of the lifetime of agonist-activated ionic channels (Bregetovski et al., 1979).

Figure 5. The absence of depressing effect of H₂O₂ on Ach (10⁻⁴ M)-induced ionic currents in cold medium (5°C). H₂O₂ concentration was 10⁻⁴ M, (n=5).

The data on temperature sensitivity of the EMF-treated and H₂O₂-containing PS-induced depressing effects on Ach membrane responses allow us to speculate on their metabolic nature. As shown in our early works the electrogenic Na⁺-K⁺ pump serves as one of the powerful metabolic mechanism through which the metabolic regulation of membrane chemosensitivity is realized (Ayraperyan and Arvanov, 1988). As shown by the obtained data, these factors have opposite effects on Ach-induced membrane currents in K-free medium, when Na⁺-K⁺ pump was in inactive state (Thomas 1972): the K-free -induced pump inactivation reversed the effect of EMF-treated PS on Ach-induced membrane current (Figure 6), while the H₂O₂ had more pronounced inhibitory effect in K-free medium than in normal K-containing PS.

Figure 6. The depressing effect of 10⁻¹¹ M H₂O₂ in K-free solution on Ach-induced current in D-type neuron in voltage-clamp experiments. Neuron was clamped $E_c = -55$ mV. The data are taken from one neuron. The presented data are typical for all 5 studied neurons.

As shown in Figure 6, the H₂O₂ at 10⁻¹¹ M in K-free solution has strong (reversible) depressing effect on Ach-induced current amplitude (80±2.5%, n=5) in D-type neurons. No significant differences were observed between H₂O₂-sensitivity of Ach-responses in D and H-type neurons. These data allow us to conclude that from one side, the both MPS and H₂O₂-induced modulations of Ach-responses could not be explained by the activation of Na⁺-K⁺ pump, and from another side, the nature of metabolic pathways through which they modulate the membrane chemosensitivity in K-free medium is different. Therefore, the elucidation of the nature of mechanism of H₂O₂ effect on membrane chemosensitivity would be the subject for the next series of experiments.

It is known that the agonist-induced membrane current changes could be the result of modification of ionic channel properties or the process of interaction between receptors and agonists. As the above-mentioned data on potential independence of the H₂O₂ effect on membrane chemo-sensitivity excluded the role of channel mechanism in this process, the main reliable mechanism through which the H₂O₂-induced depression of Ach-responses is realized is the process of modification of interaction between Ach and its receptors: the changes of the number of functionally active receptors or their affinity to agonist. Therefore, the effect of H₂O₂ on kinetic curve of dose-dependent Ach-induced membrane response was studied.

Figure 7. The effect of 10^{-6} M H_2O_2 on dose-dependent curve of Ach-response in K-containing (A) and K-free (B) mediums in H-type neuron. Circles show the control, the triangles - in the presence of H_2O_2 , ($n=10$).

As shown in Figure 7A, in H_2O_2 -containing solutions the Ach-induced responses reached of their maximum values at 10^{-4} M concentration, while in normal physiological solution the curve wasn't saturated even at 10^{-3} M Ach concentration. Such pronounced depressing effect of H_2O_2 on "maximums" of the dose-dependent curves of Ach could serve as evidence on the decreasing effect of H_2O_2 on the number of functionally active Ach-receptors in the membrane. It is worth to note that, although, in K-free solution the H_2O_2 also has depressing effect on number of receptors involving in generation of Ach-responses, there are significant differences between the kinetics of dose-dependent curves of Ach-responses in K-free and K-containing solutions (Figure 7B), which could be the subject for more detailed investigation.

Thus, it is important to clarify, which metabolic pathways could be responsible for H_2O_2 -induced decrease of number of functionally active receptors interacting with the agonists. It is suggested that the actinlike protein phosphorylation-induced contraction of cytoskeleton could serve as one of such mechanism through which the H_2O_2 could decrease the number of membrane receptors. As the cytoskeleton (cell) shrinkage is accompanied by the increase of membrane electrical resistance (Carpenter et al., 1992), for testing the above-mentioned suggestion the effect of H_2O_2 on I-V characteristics of membrane was studied (Figure 8).

Figure 8. The effect of H_2O_2 on current-voltage (I-V) characteristic of D-type neurons. The I-V curves in normal and 10^{-4} M H_2O_2 -containing solutions were obtained by changing the holding potential from -20 to -80mV. Pre-incubation time in H_2O_2 -containing solution was 7min. ($n=5$).

As shown in Figure 8 there are significant increase of membrane resistance upon the effect of H_2O_2 and this effect has pronounced elevation tendency by increasing the cell membrane polarization. If the H_2O_2 -induced increase of membrane resistance could be explained by the possible decrease of cell volume, the mechanism responsible for potential-dependence of such effect of H_2O_2 is not clear and needs more detailed investigation.

Figure 9. The effect of 10^{-9} M H_2O_2 on neuronal volume. Scale bar $10\mu m$. ($n=5$)

For testing the above mentioned conclusion on H_2O_2 -induced cell volume (shrinkage), which leads to the decrease of membrane active surface (number of receptors in the membrane), in the next series of experiments the effect of H_2O_2 on cell volume was studied by means of light microscopy. Figure 9 shows that H_2O_2 in nM concentrations has shrinking effect on the cell.

Discussion

Although the hypothesis on the role of H₂O₂ as a possible messenger through which the biological effect of magnetized aqueous solutions is realized has long history (Klassen, 1982), its role in biological effect of SMF and ELF EMF is not elaborated yet. This difficulty is due to the absence of reliable theory explaining the cellular and molecular mechanisms of biological effects of ELF EMF from one side, and multisided metabolic effect of the H₂O₂ from the other side. Previous works of our laboratory have shown a crucial role of intracellular messenger-dependent Na⁺/Ca²⁺ exchanger in realization of biological effect of magnetized solution (Ayrapetyan et al., 1994b, 2005). As the Na⁺/Ca²⁺ exchanger serves as one of powerful mechanisms regulating the intracellular Ca²⁺ homeostasis (Dipolo and Beauge, 2006), which determines the membrane chemo-sensitivity (Bregestovski et al., 1979), the latter could serve as a convenient experimental model for studying the role of H₂O₂ as a potential messenger in realization of biological effect of magnetized solution on cell membrane.

The presented data on similar inhibitory effect of MPS (Figure 1) and H₂O₂ (Figure 2) on Ach-induced current and their temperature dependence, from the first face could be considered as an evidence of their synergic influences on membrane chemosensitivity. In previous our works the following metabolic cascade through which ELF EMF-treated PS can modulate the membrane chemosensitivity was suggested: the MPS-induced activation of cGMP-dependant Na⁺/Ca²⁺ exchanger leads to the removal of the intracellular Ca-induced inhibition of Na⁺-K⁺ ATPase as a result of reactivation of Na⁺-K⁺ pump, which causes the decrease of a number of receptors in the membrane due to the pump-induced cell shrinkage. While the pump is in inactive state (when the pump-induced cell volume changes are excluded), the ELF EMF-induced elevating effect can be explained by the decrease of intracellular Ca concentration (Ayrapetyan et al., 2004). The fact that in K-free solution the H₂O₂ has more pronounced inhibitory effect on Ach-induced current compared to its effect in normal PS could not be explained from the point of the mentioned metabolic cascades and serves as evidence on different nature of metabolic pathways through which the inhibitory effects of MPS and H₂O₂ are realized.

It is known that the agonist-induced membrane responses could be changed as a result of modification of ionic channel properties and (or) interaction processes between membrane receptors and agonists. The obtained data on potential independence of H₂O₂-induced inhibition of Ach-responses (Figure 4) allow us to exclude the role of ionic channels in this inhibition and it could be explained by the depression of the process of interaction between receptors and agonists. The H₂O₂-induced depression of the “maximum” in Ach dose-dependent curve serves as evidence on the changes of number of functionally active receptors in the membrane interacting with the agonist molecules (Figure 7). Early our works showed that the Na⁺-K⁺ pump-induced activation caused the similar inhibition of membrane Ach-sensitivity in result of cell shrinkage (Ayrapetyan and Arvanov, 1979), however the data obtained in present experiments on elevation of H₂O₂-induced depression on Ach-responses in K-free solution (when Na⁺-K⁺ pump is inactive) (Figures 3B, 7B), excludes the role of Na⁺-K⁺ pump in this process. The disappearance of such inhibitory effect of H₂O₂ on membrane chemo-sensitivity in cold (5°C) medium (Figure 5) indicates its metabolic nature. Therefore, it is suggested that the H₂O₂ leads to the decrease of the number of functionally active receptors in the membrane by unknown metabolic mechanisms (not by Na⁺-K⁺ pump). Previous our works showed the close correlation between membrane active surface (cell volume) and number of functioning chemo-receptors in the membrane (Ayrapetyan and Arvanov, 1979). It is predicted that the H₂O₂-induced depression of membrane Ach-sensitivity could be the result of cell shrinkage. The microscopic study of the H₂O₂ effect on cell volume (Figure 9) proved this suggestion.

Summary

The data obtained in the present work clearly showed that the H₂O₂ in nM concentrations depressed the membrane chemosensitivity by decreasing the number of functioning receptors in the membrane as a result of cell shrinkage (probably by cytoskeleton phosphorylation). We came to the same conclusions in previous our work on studying the effect of magnetized solutions on Ach-induced responses of the membrane (Ayrapetyan et al., 2004). It was shown that the MPS caused the depression of membrane Ach-responses at room temperature (23 °C), while in cold medium (5 °C) it had no effect (Ayrapetyan et al., 2004, Figure 1). These effects were explained by MPS-induced cell dehydration which led to the decrease the number of chemo-receptors in the membrane (Danielyan et al., 1999).

Thus, the comparison of the physiological data obtained in the present work on the influences of H₂O₂ with the previous results on the effects of magnetized solution on membrane sensitivity to Ach demonstrates the close synergism between the effects of these two factors on Ach responses in normal PS which are the result of cell dehydration. However, opposite dependence of their effects on Na⁺-K⁺ pump activity allow us to suggest that H₂O₂-dependent metabolic pathway could serve as one of the metabolic pathways through which the biological effect of ELF EMF is realized.

Simulations of ELF Magnetic Shields

Josef Pekar Moshe Netzer Yekutiel Pekar
EMC Engineering & Safety
Haifa, Israel

Abstract

This paper describes a multi-stage algorithm for efficient calculation of magnetic flux contours, for optimizing the design of structural magnetic shielding. The multi-stage algorithm enables albeit medium-power computer system to calculate the effect of shielding materials with a given geometry, in a reasonable timeframe without compromising precision. The outcome results are a large number of electrical utility models and the best cost-effective shielding materials and geometries for ELF magnetic flux reduction per Authority regulations and requirements.

This paper attempts to review methods and principles for calculation of an extremely low frequency (50/60 Hz) electromagnetic field originating from power utilities and power lines, for the purpose of constructing efficient magnetic shielding. The paper points out difficulties in existing methods and proposes a new algorithm for analysis and construction of magnetic shielding.

Introduction

Magnetic field of extremely low frequency (ELF) is produced by utility and industrial electric lines, machines and cables, and various electrical fixtures, devices, and apparatuses all of which are surrounding us and deployed everywhere. Often, the level of the magnetic fields exceed the permissible exposure limits setup by international¹ and national agencies for non-ionizing radiation protection, thus need to be reduce at locations where people dwell. It can be achieved by several cost effective methods, such as: relocation of strong magnetic field emitters; reduction of electrical current; reconstruction of the electrical circuits to reduce the loop areas generating magnetic fields. If any of the above outlined relative simple solutions do not provide the desired results, it might be necessary to install structural magnetic shielding made of various metal types some of which might be very expensive such as μ -metal, co-netic and other metals with great permeability.

Before the actual building of structural magnetic shielding starts, one needs to determinate the magnitude of the magnetic field exposure problem. It can be performed by actual field measurements, or if the electrical utilities are still unavailable or none operational it entails modeling the utilities and solving electro-magnetic equations³, all of which enables the prediction of magnetic flux contours with and without magnetic shielding buriers.

To determine the best engineering solutions for structural shielding, one needs to employ very complex analysis. The analog approach is impractical because of the uniqueness of each problem and the associated difficult level. Also, the digital approach is still too difficult for the most of today's personal computer systems. Subsequently, the calculation is less accurate and time-consuming. It can take from tens to hundreds of man-hours to prepare models and to solve a single problem.

Strategies and Stages in Planning Magnetic Field Reduction

To first stage in planning the shielding effectiveness required for magnetic field reduction is to obtain the overall worst-case intensity of the ELF magnetic flux in locations where people may reside. This can be doe using two methods – the analytical method (also good for the design stage), and/or field measurements when construction is completed and populated). These two strategies to determine the magnetic field is summarized as follows:

1. **Analytical Prediction:** given the geometry of the structure and the current sources producing the ELF magnetic fields, including the geometry of these magnetic sources, the integrated cumulated field levels in every relevant place (places where there may be people residing) can be predicted.
2. **Measurements:** conducting field level measurements where people work and reside could provide a general picture of the magnetic field including evaluation of maximal loads in maximal power consumption, hence, worst-case magnetic flux contours.
The decision for the need for magnetic shielding is best taken based on results obtained by strategy 2 – measurements. However, the structural shielding design must use strategy 1 – analytical prediction. It facilitates cost-effective shielding design, placement, barrier dimensions, shielding materials, and installation methods. It enables theoretical examination of the shielding effectiveness elsewhere in the facility. If shielding is insufficient based on phase I of the analytical design effort, it is modified by reselecting of:
 - ☐ shielding materials;
 - ☐ barrier dimensions;
 - ☐ placement

Phase II of the shielding design commences to obtain the shielding effectiveness of the modified design. Phase II might yield an insufficient engineering solution and go into Phase III, etc., until a best engineering solution is obtained.

Simulations of ELF Magnetic Shields

Availability of Analytical Methods

The analysis methods available for determining the electromagnetic field levels are many and vary in complexity, accuracy and easiness of pre and post processing. Some of the most known numerical methods are:

- Finite Difference Methods
- Variation Methods
- The Methods of Moments (MoM)
- Finite Element Method^{4,5}
- Transmission-line-matrix Method
- Monte Carlo Methods
- Method of Lines

The **Finite Difference Method** requires the performance of the following steps:

1. Divide the region of interest into a grid of nodes (common rectangular, skew, triangular or circular type of grids)
2. Approximate the given differential equation by finite difference. (To relate the dependent variable at a point in the region of interest to its values at the neighboring points)
3. Solve the difference equations subject to the boundary and initial condition.

This method is very intuitive and fairly easy for numeric realization. It is not clear which grid is preferable in every case. A problem arises in cases where the point for which the value is calculated is not exactly on the grid. The ease or programming “balances” in extensive calculation time.

For simple enough problems, when one arrives at a collection of equations (both integral and differential), the problem can be solved by finding functions that give the integrals a minimum value⁶. Problems of this type are called *variational problems*.

This method is limited to theoretical problems, requires a high level of mathematics and seldom used to solve practical problems.

The **MoM** requires the performance of the following steps:

1. Derivation of the appropriate integral equation.
2. Conversion this set of equation into a matrix equation (the process called discretization that is based on using basic functions (kernels) and weighting (or testing) functions.
3. Evaluation of the matrix elements.
4. Solving the matrix equation and obtaining the parameters of interest.

This is a sturdy method that turns problems containing integral equations into matrix equations (of course, accurate calculation requires an extensive calculation power and a large amount of memory). Many of today’s solutions are based on this method.

The **Finite Element Method** comes from the area of materials strengthening and has been used for calculating electromagnetic fields since the 1970s.

The **Finite Element Method** requires the performance of the following steps:

1. Discretizing the solution region into a finite number of subregions (called elements). These elements may be one, two or three-dimensional.
2. Deriving governing equations for a typical element.
3. Assembling all elements in the solution region.
4. Solving the system of equations obtained.

Among the method’s advantages, it can be used with almost no changes for different areas of problems. The most accepted areas are mechanics and electricity, but lately it has also been used for image processing. It is difficult to match an appropriate element for every problem, and the method required extensive calculation time.

Other methods are more theoretical or methods suitable for solving specific problem types not related to our goals.

It is customary to imagine shielding as an infinite surface or a closed sphere. Only in these cases may accurate analytic methods be obtained. All analysis of other models is semi- empirical. The accuracy of the results decreases as we increase the practical details of the shielding. The analytical solution for calculating shielding cannot take the form of a method as we must solve a different problem each time (this includes building a new model with range, limit conditions, sources, new geometry etc.).

Solving the problem using a computer somewhat reduces the complexity of the mathematical solution, but adds the problem of a model that is very resource consuming for most existing computers. The problem lies in both memory size and calculation power.

As a result, any calculation (construction of a mathematical or digital model, inputting the problem's data, calculation and examination of probability of the received results) requires hundreds of man hours and dozens of computer hours. It is clear that under these limitations it is impossible to perform a large number of attempts (analysis phases as described above) in order to reach an appropriate solution. The desire to examine a single problem for several shielding solutions, in order to select the best one, often seems as "mission impossible".

Practical Methods Combined with Analysis

The problem we face is: to calculate the electromagnetic field in defined areas generated by known sources with the presence of a given specific shielding burrier design to reduce the EM fields.

There are no analytical systems and algorithms that we know for writing a program that enables inputting of entry data (such as range, sources, shielding location, shielding materials etc.), followed by the required targeted field level in a certain area, let one or more parameters acting as the unknown ones and perform calculations (assuming convergence) that solve the unknown parameters.

Presently, all we can do is as follows: place shielding (using previous practical experience) in places that seems most logical using materials that were suitable in similar cases, calculating the field levels in questioned areas, comparing the results to the values we aim for, and if the results are unsatisfactory, slightly change the shielding size, geometry, location and/or materials.

The form of shielding accepted today is a rectangular plate, inserted between the source and the area in which field level should be reduced. Magnetic shielding includes 3 different effects: reflection, absorption, and fringe radiation (that usually reduces the shielding effectiveness).

The theoretical basis for high frequency (radiofrequency) shielding for distant EM field is relatively well developed and has accelerated in recent years. In the case of ELF fields and for an adjacent source – these theories cannot be straightforward adopted. In the case of high impedance, the source if electric field is dominant; in the case of low impedance – the source is a magnetic field is dominant. In this case a separate approach for shielding against the magnetic part and from the electric part of the EM field is the correct approach.

An alternating electromagnetic field, originating from 50 Hz electrical facilities is an "adjacent source" field. The characteristic impedance of the magnetic component is very low while the characteristic impedance of the electric component is high. Therefore, currents in low voltage electric facilities generate dominant magnetic field components; the associated electric field component is negligible. A source of a solely magnetic field does not cause electromagnetic waves. Therefore a 50Hz magnetic field is quasi- static in nature. This field is "static" because it acts as a static field, but is called "quasi" as it is not completely static due its source (alternating field).

Two phenomena exist in magnetic shielding for a quasi- static field – static shielding and dynamic shielding.

Static shielding is independent of the field frequency and works in the same way for both the earth's static magnetic field and for sources of 50 Hz or more. The shielding quality depends on the material's relative permeability (μ) and its geometrical dimensions. The higher the permeability (μ) and the thicker the plate, the more effective is the shielding.

Dynamic shielding depends on the frequency of the primary field and the shielding material's electric conductivity. At 50 Hz the effect is well pronounced. The phenomenon is based on Foucault currents (eddy currents) and Lentz laws. The higher the conductivity and the higher the frequency – the more effective is the shielding.

There are no materials that combine both phenomena well, and so it is customary to use two plates or more for constructing shielding to reduce quasi- static magnetic field. In many cases shielding construction is attempted using no analysis, based only on instinct, experience or luck. In many cases this might not only not decrease field levels, but even raise its intensity in undesirable locations.

The principle of magnetic shielding is based on two phenomena of decrease of the electromagnetic field intensity in different materials: absorption of a magnetic field (absorption loss) and reflection of the field back to the source (reflection loss).

The above discussion is highlighted with a real problem description and shielding planning demonstration.

The field level in an area adjacent to a transformation substation inside a residential building is analyzed.

The area of interest is only the residential area as shown in Figure 1. Analysis show that the level is higher than desirable and shielding must be constructed.

A simplistic calculation with substitution of a plate of finite dimensions with an infinite surface does not give correct results. In this case substitution of the plate creates distortions in the plate ends, and as a result the field level would not only decrease, but may increase. It is clear that in this case the attempt to build magnetic shielding without proper planning might causes more damage than benefit.

Three dimensional shielding against the magnetic field from the transformation substation could be done by covering parts of the walls, ceiling and floor adjacent to the location of the transformers. Walls, ceiling and floor covering is obtained by using special materials that decrease the magnetic flux density caused by the transformer's secondary terminal (low voltage) phase lines and neutral line loops.

Field sources are often having a complex geometry which makes it analysis difficult to solve. It is much more difficult to solve the problem of the shielding effect on the magnetic source flux lines as it is in our example. It is important to note that for our specific problem, the source is 3 currents in the same frequency and different phases, and at every point the field vector is a complex vector value (as are all the matrix analysis).

"Absorption" of a static magnetic field can be done using magnetic materials with a high magnetic permeability. Plates of this material are used for construction of static shielding. The efficiency of the static shielding depends on several factors, as follows:

- Relative magnetic permeability (μ_r) of the plate material.
- Plate width.
- Angle between the direction of the magnetic flux vector and the plane of the plate.

Simulations of ELF Magnetic Shields

Figure 1: Primary Magnetic Flux Analysis near an Internal Transformation Station

There is no “reflection” phenomenon of a static magnetic field. The reflection phenomenon exists only in an alternating electromagnetic field. The flux of an alternating magnetic field that permeates plates made of a material with electric conductivity creates induced currents known as eddy currents. These currents create a secondary magnetic flux at a direction opposed to the direction of the original magnetic field flux and thus reduce the magnetic field flux. This is known as Lenz’s law.

Plates made of metals with high electric conductivity are used for building dynamic shielding. The efficiency of the dynamic shielding depends on several factors, as follows:

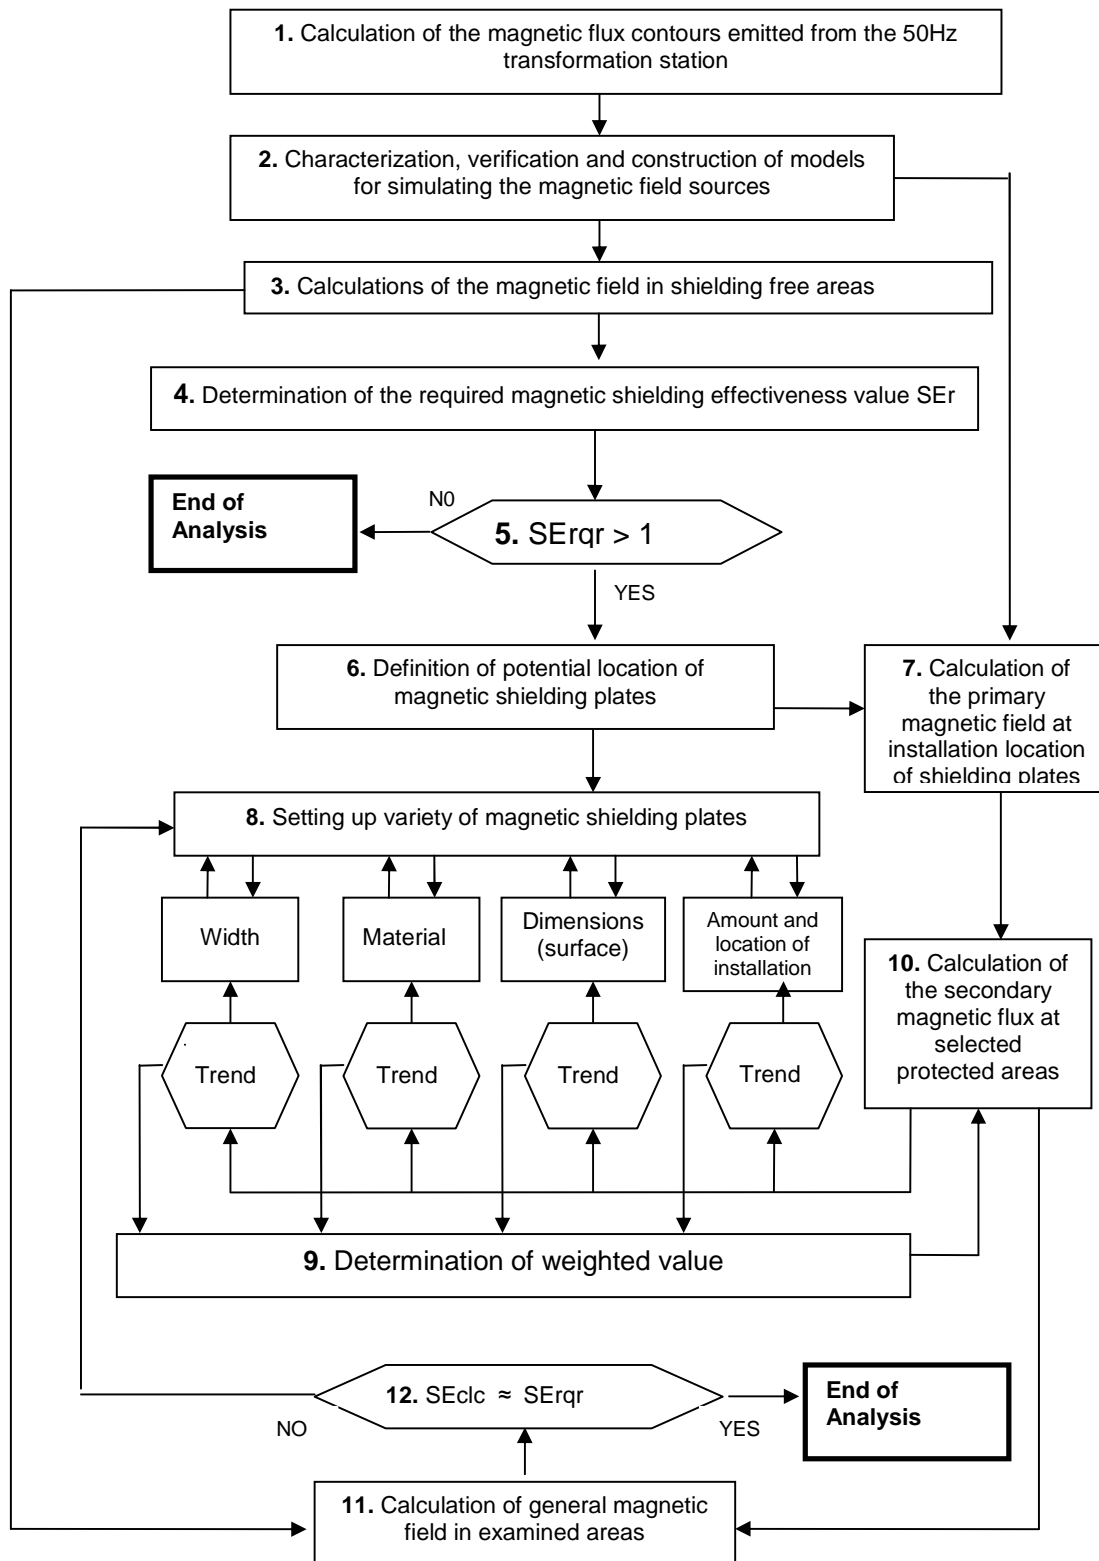

- The plate material’s electric conductivity σ .
- Frequency of the alternating magnetic field.
- Plate width (up to a certain width).
- Angle between the direction of the magnetic flux vector and the plate’s perpendicular.

The efficiency of static and dynamic shielding, as a rule, is a different and non linear dependence on the parameters outlined above. The main difference, in terms of shielding efficiency, is in the inverse effect on efficiency of the incident angle of the magnetic flux lines on the shielding plate:

- When the direction of the magnetic flux vector is closer to that of the shielding plate’s normal direction, the efficiency of dynamic shielding increases while that of static shielding decreases.
- When the direction of the magnetic flux vector is closer to that of the tangent to the shielding plate, the efficiency of dynamic shielding decreases while that of static shielding increases.

As the magnetic flux adjacent to electric facilities is not uniform in size and direction, the highest efficiency in reducing the magnetic flux density in the entire shielded space is accomplished by a combination of static and dynamic shielding.

New Algorithm for Shielding Analysis

Simulations of ELF Magnetic Shields

The first step is the calculation of the magnetic flux density in the entire space, especially the area we wish to protect and the space in which we wish to introduce the shielding barrier. Analysis of the **primary field** is done using the laws of Faraday and Ampere. This analysis affords a comprehensive picture of the entire area, and a decision on whether shielding is in fact necessary or can be substituted by simpler less-costly measures, such as relocation of power utilities or personnel.

There are many analysis methods, most popular of which is the finite elements method discussed above. Using this method, the shielding barrier is divided into subcomponents so that lack of uniformity can be neglected and the field is perceived as uniform. This is the second step of the analysis.

In the third step, each point in the shielded area is analyzed as a sum of the effects of each shielding element. This is the **secondary field** reduced from the primary field by the shielding.

Now, as a picture of the effect of the shielding is formed, one can decide on the continuation (or termination) of the process.

Using this method there is no need for difficult neither complex analysis for the entire problem, only for the shielding effect on the secondary field intensity in the examined area. This analysis method greatly reduces analysis complexity, gives accurate results and reduces calculation time by an order of magnitude. The finite elements method enables to perform sufficient iterations in order to obtain the best results among several different shielding barriers from different materials and dimensions and compare the outcome results to select the best solution. The time required for the entire process is equal to the time it would have taken to calculate a single iteration using one of the old methods.

The course of the analysis is presented in the algorithm flow chart.

1. Analysis of 50 Hz magnetic field contours caused by the transformation substation – step 1 of this project is defining the problem and possible solution subset.
2. Construction, verification and determination of models for simulating the magnetic field source. These models can be used to calculate magnetic flux densities in all areas adjacent to the field source.
3. Analysis of the magnetic field in the areas that are examined without any shielding. Analysis is carried out using a computer program based on integrals of complex magnetic moment methods.
4. Determination of the required magnetic shielding effectiveness value SE_{rq} . This action is taken and is presented in table 3 of step 1 of the project (reference 2). The SE_{rq} value is determined by comparing the results of the analysis to the exposure threshold recommended by the Ministry of the Environment or other requirements of the client, using the following formula:

$$SE_{rq} = B_{max} / B_{crm}$$

Where:

- B_{max} – the maximal value of the magnetic flux density analyzed in the examined area based on a model of magnetic field source simulation at its typical current, as coordinated with the client.
 - B_{crm} – the value of magnetic flux density coordinated with and determined by the client based on recommendations set by the Ministry of the Environment for general public magnetic field exposure at 50/60 Hz.
5. Existence of a condition $SE_{rq} > 1$ (YES) causes the continuation of the project for design and magnetic shielding barrier required, while the (NO) response ends the analysis and the project.
 6. Selection of potential locations for installation of magnetic shielding plates. As a rule, it is accepted to cover walls and/or ceilings and/or floors within the area in which the magnetic field source is located. In transformation substation with two transformers, these areas are: the TR01 and TR02 transformer cells and/or the entire transformer room.

The possibility to install shielding around a whole transformer cell is not feasible, as complete and continuous shielding in the cell might hinder the maintenance and natural ventilation of the transformers. Opening ventilation hatches and/or installation of forced ventilation might reduce shielding effectiveness to below requirements.

The feasible shielding practice is to cover all or part of the walls, ceiling and floor of the transformer room.

7. Analysis of the magnetic field in some locations of the shielding plates. As an auxiliary action for calculating shielding effectiveness, the complex vector of the magnetic flux density in the walls, ceiling and floor of the transformer room is analyzed, meaning – primary magnetic field with no shielding, similar to the primary magnetic field in the examined areas (step 3 above).
8. Setting up variety of magnetic shielding plates. This step determines shielding parameters as follows:
 - A. Amount and location of shielding plate installation, static and dynamic separately.
 - B. Plate size (surface area) for static and dynamic shielding separately.
 - C. Static shielding plate's material – magnetic permeability value; dynamic shielding plate's material – electric conductivity value.
 - D. Plate width for static and dynamic shielding separately.
9. Determination of weighted value. In this step we prepare the parameter matrix for static and dynamic shielding for the analysis following in step 10.
10. Analysis of the secondary magnetic field created by the shielding plates in the examined area. The analysis is carried out by a computer program based on a Numerical finite element method.

The starting data for analysis are the results of the primary magnetic field analysis described in step 7 above and the data of the shielding plates described in step 8.

At the beginning of the analysis the shielding plate areas are divided into elements in order to reach a state wherein in most separate elements there is a uniform magnetic field incident the single element. The data of the complex vector of the magnetic flux density, \vec{B} that permeates through the shielding area element, we receive from the primary magnetic field analysis (7).

The elements of the high magnetic permeability shielding material are forced to become magnetic moments under the effect of the primary magnetic field. The magnetic flux density B_{mag} in the area of these elements increases according to the formula:

$$B_{mag} = \mu_r \times B_0$$

Where:

B_0 – primary magnetic flux density
 μ_r – relative magnetic permeability through the static shielding material.

The main direction of the moment vectors from the static shielding plates is tangential to the plane of the plates. Magnetic moments of the static shielding material elements emanate a secondary magnetic field, and thus affect the overall magnetic flux density in the examined areas. Alternating magnetic flux creates eddy currents of elements in the dynamic shielding material with the high electric conductivity. These currents create a secondary magnetic field. The direction of the secondary magnetic field flux is opposed to the direction of the primary magnetic flux, known in physics as Lenz's law. Eddy currents in the dynamic shielding elements are considered to be magnetic moments. The main direction of the moment vectors from the dynamic shielding plates are normal to the plane of the plates. These moments emanate a secondary magnetic field. And thus affect overall magnetic flux density in the examined areas.

11. Analysis of overall magnetic field in the examined areas. The analysis is carried out using a computer program based on a complex vector superposition method.
12. The realization of the $SE_{clc} \approx SE_{rqr}$ (YES) condition ends the analysis, while (NO) causes the continuation of the analysis in a loop including stages 8 – 11. SE_{clc} – the analyzed value of the shielding effectiveness.

Back to the practical example – an analysis is performed based on this algorithm. The following results were obtained:

Primary flux density analysis (without the shielding plates):

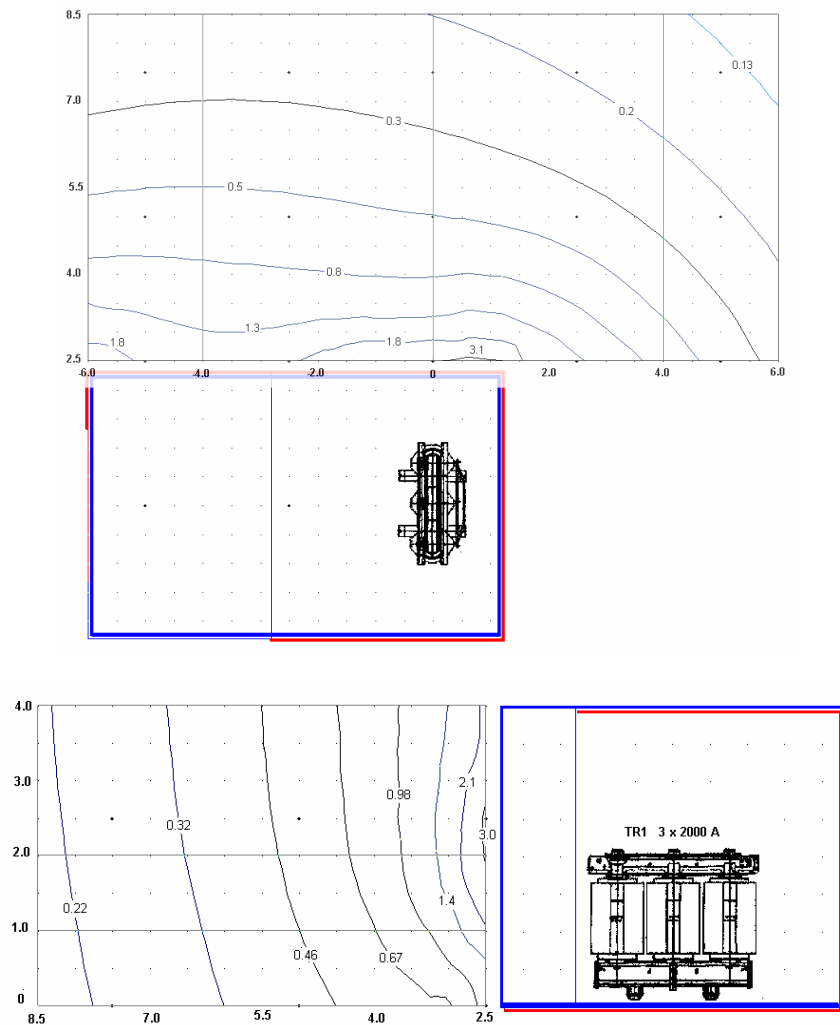

Based on the results it was decided to shield only the transformer adjacent to the residential area.

Analysis show that the field level decreased to the following levels:

Simulations of ELF Magnetic Shields

Conclusions

The question of potential adverse effects due to ELF magnetic fields exposure has been discussed and hypnotized in the past years. The potential magnetic field adverse effects on the human body are still under ongoing studies; nevertheless, the adoption of the precautionary principal by many countries and environmental conservation offices owes to minimize personnel exposure². Many countries have already established regulations and limitations for the maximal magnetic field allowed at the workplace and residential areas which is much lower than the WHO ICNIRP¹ guidelines. The best situation exists when a building design (both architecture and infrastructure) considers magnetic flux reduction design. In reality, this does not happen often. At best, magnetic field surveys and shielding design (if needed), is the very last stage before construction is completed. In many cases, construction is completed; inhabited and only thereafter magnetic flux reduction is taken care by the building management. This paper describes a multi-stage algorithm for efficient analysis of magnetic flux contours, for optimizing the design of structural magnetic shielding. The multi-stage algorithm enables albeit medium-power computer system to calculate the effect of shielding materials with a given geometry, in a reasonable timeframe without compromising precision. The outcome results are a large number of electrical utility models and the best cost-effective shielding materials and geometries for ELF magnetic flux reduction per Authority regulations and requirements.

Abstract

When large structures such as residential compounds or public buildings are under the influence of extremely low frequency (ELF) magnetic fields, such as the one generated by a system of railways fed by 16 ⅔ Hz, standard methods of designing shielding structures by numerical methods usually fail. The latter can be explained by the difficulty posed in the computing process by the large aspect ratios involved due to thin layers of metal (a few millimetres or centimetres) in contrast to the large dimensions of the affected structure (several tens of meters). In some cases one has to utilize special approximations such as surface conductivity, which are not easy to handle when the designed shielding structure is clearly 3-dimensional. Other alternatives such as experimentation *in-situ* are very costly. Here, a new technique is presented of mitigating the field by using 3-dimensional propagation of induced currents optimizing the field reduction factors and minimizing the cost of shielding material. The particular designing method is a hybrid of numerical simulations combined with lab experimentation using scaled models of the large structure. The method is rather cost-effective and flexible as various designs can be easily tested. Results are presented in the form of magnetic field values, at various locations in the buildings, *before* and *after* this mitigation technique is applied.

Introduction

There are two major sources of extremely low frequency magnetic fields (ELF/MF) which are able to affect large scale areas in their extended vicinity (i.e. tens or in some cases even hundreds of metres). One of them is overhead power lines and the other is AC powered railway systems. Mitigation techniques for the first source have been extensively studied for more than two decades and there are a manifold of references in the literature. On the other hand, although some studies related to magnetic fields originated in rail systems have been published [1-6], there is a lack of literature on mitigation techniques of magnetic fields originated from AC railway sources. In this investigation, the magnetic field produced by a system of trains operating at 16 ⅔ Hz (~16.67 Hz) is analyzed and mitigated using a combined technique, i.e. designing a structure able to redirect induced currents improving their effectiveness and performing cost-effective experimental settings at reduced scale. The present study was made before starting the construction of the

buildings. Fig. 1 shows the location of the railway system in the central area of the city of Stockholm. The configuration of the buildings is also shown, which is “L”-shaped formed by two type of buildings, namely: “A+B” and “C” or correspondingly *Frontal and Lateral* the first notation is from the architectural map while the second notation is related to the ways the trains pass with respect to the buildings. Two reasons motivated this study. Firstly, there is a growing concern on suspected harmful effects of ELF/MF on human health. Although several epidemiological studies suggest that long-term exposure to fields in excess of 0.2-1 μT (depending on the study) can explain some bias in the statistics of some deceases. The issue is still not resolved at the moment and there is no clear indication that there will be a conclusive answer in a near future. Some countries are adopting some policies upon limits in residential and public buildings, as low as 1 μT , while others subscribe to ICNIRP recommendations of 100 μT for 50 Hz, limit based on effects of induced currents in the human body [7], [8]. Secondly, this type of field is able to produce interference on electronic equipment driven by electron beams such as TV and computer screens, oscilloscopes and electron microscopes. This interference becomes evident at field values over 0.5-1 μT , depending on the device. For the present study, we have chosen to aim at averaged (per floor) after-mitigation field values not exceeding 0.5 μT while trying to keep peak values at the sub-microtesla level. The feasibility of achieving these values will be explained in the next sections.

Fig. 1 Location of the buildings in the central part of the city of Stockholm; the pictures are virtual as the study was performed before the buildings were constructed. The lower picture shows the way the trains would pass with respect to the buildings.

REDUCING ELF/MF EMISSIONS IN LARGE BUILDING STRUCTURES

The Sources of the Field

Power is supplied to the train system by the overhead wires of 15 kV carrying an average current of 200A (rms). The current's return path follows the rail track (Fig. 2). In fact, the amount of traction current depends on the power consumption of the engine needed to accelerate these trains; which reverts in a complex time-variability. The magnetic field rms values against time are shown in Fig. 3. The measurements shown were taken during 1-hour at a high traffic time. In spite of the short duration of the pulses, these are still rather long compared with the period corresponding to 16.67 Hz. Therefore, this study is concern only with the influence of the periodic signal. The number of trains considered is 10. Two of them, the closest to the lateral buildings, will stop before reaching the frontal buildings. The other eight trains will either not stop or stop for a few minutes and then continue to the next station crossing the frontal buildings.

Fig. 2 A simplified diagram of the source of magnetic field. The train is powered by an overhead wire carrying an average current of 200 A. The return path is by one of the rail tracks.

Fig.3 Time variability of the magnetic field. The values were taken at the nearest floor to the rails, near the intersection of the lateral buildings with the frontal buildings. Although the short duration of the pulses; these are still rather long compared with the period of the feeding current

The Shielding Challenges

The dimensions of the building are, for the lateral buildings: (20-30)m x 100m; and for the frontal buildings: 18mx65m. The height of both buildings is 34 m. Traditional methods of mitigating magnetic fields suggest placing a metallic plate (shield) between the source of magnetic fields and the affected area. The most commonly used materials for the shield are steel (ferromagnetic), or aluminium (pure conductive). Because of the large dimensions of the building, iron would be excessively heavy, thus aluminium seems to be the obvious choice. However, when an aluminium shield is applied to the **frontal buildings**, some issues arise. The nearest floor (5th floor) to the railway track has an average distance of 1 m to the upper cable of the feeding source; the extreme proximity of the cable poses a challenge to the shielding properties, for most of the eddy currents will be behaving as if they were induced by a homopolar (single cable) source. Fig. 4 shows the similarity of the eddy current pattern on a shield placed on the floor in close proximity to the upper cable of the railway dipole and a single cable in the same location. In the same figure one can also observe that eddy currents try to generate a cancellation field to the source that originated the effect (by Faraday and Lenz laws) with a concentration in the middle of the plate. At the same time they also go towards the edges as they try to reach for a return path. Thus, the result is that an aluminium plate *alone* would not be very effective shield when a train is passing through just under and in close proximity to the shield. The simulations were performed using 3d software Opera and its solver ELEKTRA [9].

Fig. 4 Comparison between a railway feeding-dipole and a homopolar source; both sources behave similarly in the proximity of an aluminium conducting plate.

A proposed solution to this issue is to redirect the induced currents in a spatial configuration such that the returning paths will become useful to mitigate the field inside the enclosed area. This can be achieved by conductive ribbons joining two plates. The upper plate is used as part of the currents' returning path, thus it can be thinner than the bottom plate (Fig. 5). In some designs the upper plate or even both plates can be replaced by a set of ribbons providing further cost reduction. Yet, as different shielding configurations will yield different results, balance between material cost and mitigation factors has to be considered.

REDUCING ELF/MF EMISSIONS IN LARGE BUILDING STRUCTURES

Fig. 5 extended shielding structure that redirects the induced currents creating effective current loops resulting in a minimization the field inside the enclosed region. In some designs, the upper conductive plate (or even both plates) can be replaced by ribbons resulting in further cost reduction.

Considering the **lateral buildings** we note that the sources pass alongside the buildings at different distances, some even under the building, such as the one shown in Fig.1. An aluminium shield alone, even if thick relatively to the skin depth (δ), will neither be optimal nor cost effective. The solution is a combination of optimally positioned system of loops and shields. Because the lateral region is 100m long with a cross-section area 20m(width)x34m(height), such a section can be modelled approximately assuming YZ symmetry (fields do not change in the X direction). Such a simplification can be considered accurate for the central part of the lateral buildings, but it does not model its ends, which are in fact interconnected. From the latter, is noticed that the total eddy current (at the cross section) must be zero. This condition comes from the fact that the eddy currents must find a return path when they meet the physical ends of the longitudinal extension. After performing numerical 2d simulations for the cross section (see Fig. 6), it was found that the results depend on the kind of boundary condition assumed (the total domain boundary is far from the region of interest).

Fig. 6 The lateral shielding structure is shown which can be modelled using YZ symmetry (the field does not depend on the x coordinate). The eddy currents (dotted arrows) on the shielding structure are shown as well as the source (continuous arrows). This simplification can be considered accurate for the central part of the lateral buildings, but it does not model the endings.

It is observed that the boundary condition: $A_x = 0$ at $\partial \Omega$ (A_x is the x- component of the magnetic vector potential and Ω is the problem domain) allows a net eddy current flowing at the shielding structure. If the total domain boundary $\partial \Omega$ is far from the region of interest, we can assume the magnetic field intensity $\mathbf{H} = \mathbf{0}$ at $\partial \Omega$ as the boundary condition. This boundary condition makes the net eddy current be zero because its circulation on $\partial \Omega$ is zero. Figure 7 shows 2d numerical results using both boundary conditions; the 2d simulations were performed using the code Femlab 3.1 [10]. A line L was added for comparison reference between the two conditions; this will be plotted later when contrasted with experimental validation.

Fig. 7 Numerical results are shown for the two boundary conditions discussed above. In (a) the boundary condition is assumed $A_x = 0$ at $\partial \Omega$, while in (b) it was assumed $\mathbf{H} = \mathbf{0}$ at $\partial \Omega$. The line L is added as comparison reference when contrasted with experimental validation.

Scaling rules

The computation of shielding factors for the frontal structure (which is evidently 3-dimensional) by numerical simulations, is rather complicated as a result of the large aspect ratios involved. Something similar can be said for a fully 3d numerical simulation of the lateral structure, since the 2d- simulations presented can only represent accurately the central region. Here an experimental technique, based on scaling rules, is combined with the suggested 3d structures which are the paths of the induced currents. This technique will make it possible to experiment in a lab with various shielding designs and to predict shielding factors of 3dimensional structures more accurately.

Let the scaling factor between two shielding systems M and M' be k then length, surface and volume scale as $L' = k L$; $A' = k^2 A$; $V' = k^3 V$ respectively. A current I is scaled assuming a homogeneous scale-invariant current density J. Then: $J' = J$, $I'/A' = I/A$, and $I'/(k^2 A) = I/A$, therefore: $I' = k^2 I$. Having units of length, the *skin depth* δ scales linearly: $\delta' = k \delta$. This expression allows the computation of the scaling rule for the frequency: $(2\mu\pi\sigma' f')^{-1/2} = k (2\sigma\mu\pi f)^{-1/2}$. Assuming scale-invariance and homogeneity of the materials ($\mu = \mu'$, $\sigma = \sigma'$), then the frequency scales as: $f' = (1/k)^2 f$. The application of Ampere law yields the scaling rule for the magnetic field: $B' = k B$, i.e. it is linear with respect to scaling. Finally the shielding factors (SF) which are relative comparisons between the magnetic field before and after mitigation become invariant with respect to scaling, i.e. $SF' = SF$. When applying this method [11], [12] to our study we will adopt a scaling factor $k = 1/10$. Therefore the frequency for the small system is 1667 Hz. These settings were implemented in a laboratory where the frontal and lateral structures were built and tested independently. Figures 8, 9 and 10 show details of this structure and Fig. 11 shows values obtained, before and after mitigation procedures were applied, for one of the floors (level two stories above the train tracks).

REDUCING ELF/MF EMISSIONS IN LARGE BUILDING STRUCTURES

Fig. 8 Scale model ten times reduced ($k = 1/10$) of the shielding structure for the frontal buildings. The model was built in an electronic laboratory and low power was used to feed the source, which represented the effect of the current loop and the corresponding magnetic field generated by it. Different location of the loop represented different trains.

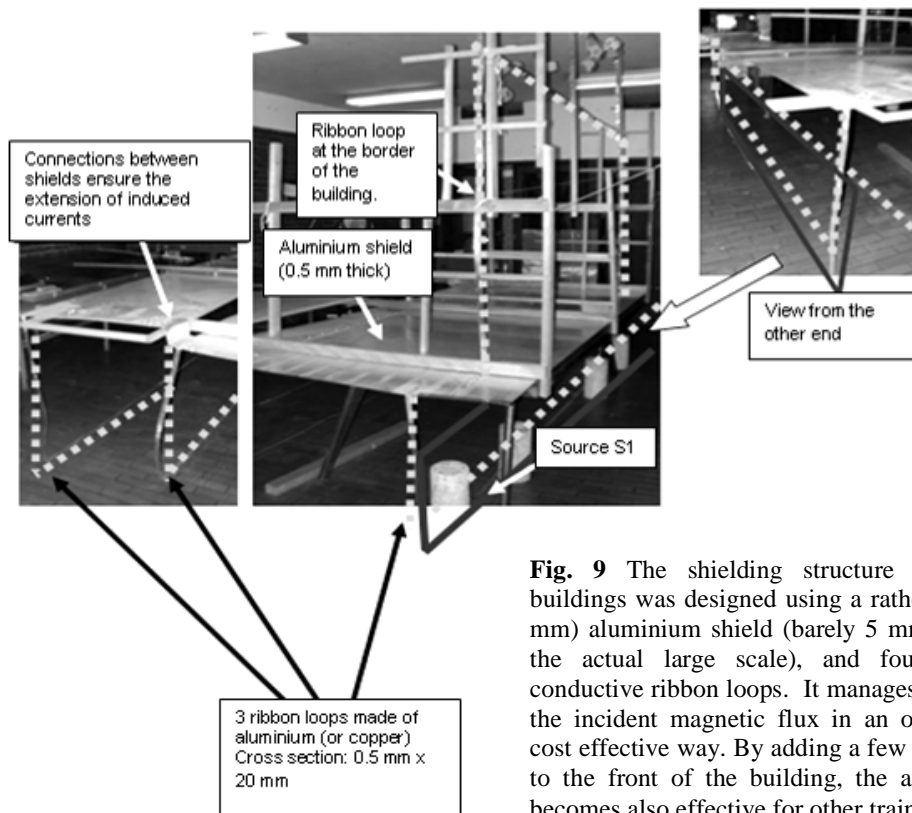

Fig. 9 The shielding structure for lateral buildings was designed using a rather thin (0.5 mm) aluminium shield (barely 5 mm thick for the actual large scale), and four attached conductive ribbon loops. It manages to restrain the incident magnetic flux in an optimal and cost effective way. By adding a few more loops to the front of the building, the arrangement becomes also effective for other trains.

Fig. 10 Cross section (left) and a 3D picture (right) are shown of the final shielding structure for the lateral buildings. The extra loops have been added to consider the influence of any of the 10 trains, namely, B1, B2, S1, S2...or S8.

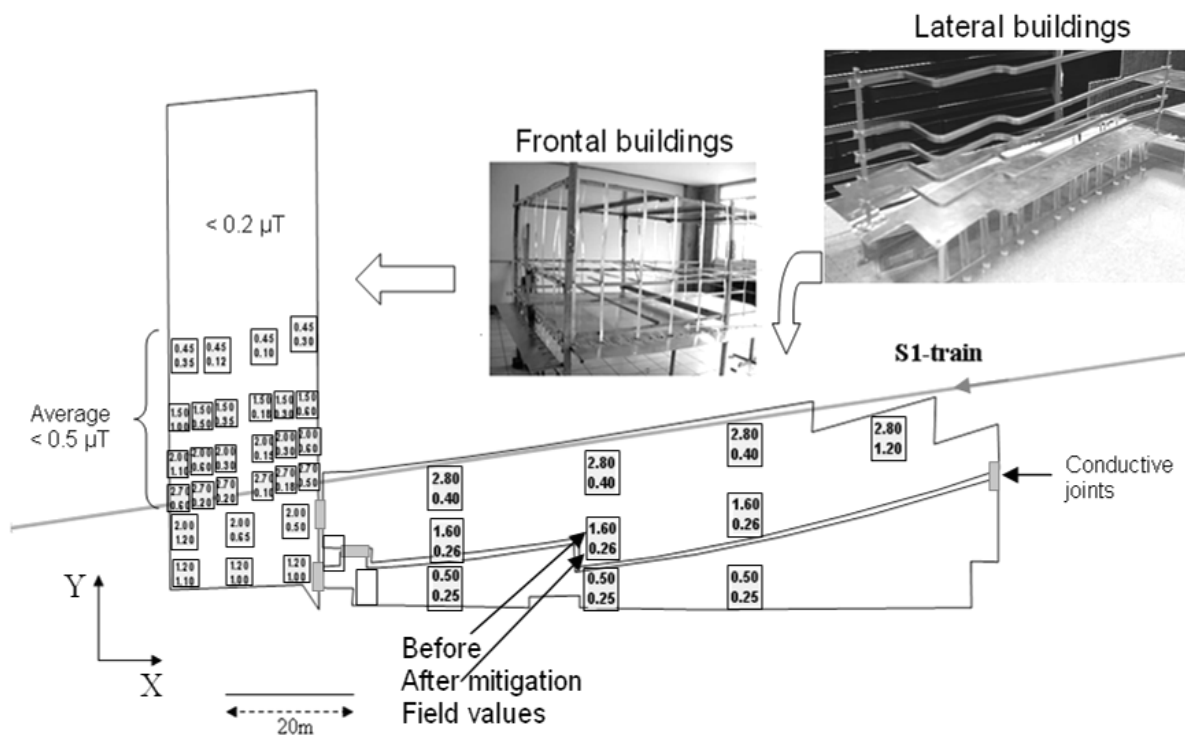

Fig. 11 Before and after mitigation field values are shown for the level located two floors above the train tracks. The resulting average magnetic field levels in each floor were kept below $0.5 \mu\text{T}$.

REDUCING ELF/MF EMISSIONS IN LARGE BUILDING STRUCTURES

Returning to the shielding issues and numerical modelling, a comparison was made (Fig. 12) between the experimental results and the two results applying two different boundary conditions mentioned in the two-dimensional modelling (see Fig. 7). The line L was taken at $z = 22.7$ m. The result is that the condition $H = 0$ fits the obtained data more accurately than $A_x = 0$. This boundary condition is also physically more realistic as it makes the net eddy current be zero; which is demanded in the experiments due to the connecting paths of the shielding loops.

Fig. 12 Comparison between numerical results and experimental data is shown. The values taken over the line L at $z = 22.7$ m (see Fig. 7). Notice that the boundary condition $H = 0$ agrees more with experimental data. The experimental data is obtained by using the scale model described in this article.

Conclusions

The problem of shielding extremely low frequency magnetic fields of 16.67 Hz that affect large buildings certainly poses several challenges to standard field mitigation schemes and to modern numerical modelling methods too. A new technique was used based on re-directing eddy currents towards ribbon paths that effectively contributed to reduce the magnetic field inside the buildings. Due to the 3-dimensional character of the proposed models the design was elaborated using scaling rules and performing tests in a low-power laboratory. The scaling factor for the experiment was 1/10 and the frequency 1.67 kHz. The division of lateral and frontal buildings proved to be useful in the design of shielding structures. Complex but cost-effective structures based on conductive material consisting on plates and ribbons were built. Good mitigation factors (up to $SF=10$) were achieved. After shielding averages field values were measured under 0.5 microtesla and peak values were kept (with a few localized exceptions) under 1 microtesla.

DAILY PULSED ELECTROMAGNETIC FIELD (PEMF) THERAPY INHIBITS TUMOR ANGIOGENESIS VIA THE HYPOXIA DRIVEN PATHWAY: THERAPEUTIC IMPLICATIONS

IVAN L. CAMERON, NICOLAS J. SHORT, MARKO S. MARKOV

**University of Texas Health Science Center at San Antonio, Department of Cellular
and Structural Biology, San Antonio, Texas 78229 [I.L.C., N.J.S.], Research
International, 135 Arielle Ct, Suite E, Williamsville NY, 14221 [M.M.]**

Abstract

Ten minute daily PEMF inhibits hypoxia driven angiogenesis and tumor growth (Williams *et al.* 2001, Cameron *et al.* 2005a) but does not inhibit angiogenesis that normally occurs during embryogenesis and tail fin regeneration in zebrafish (Short *et al.* 2006). As discussed, the reason for this difference may be due to the hypoxic state of the tissues. Daily pulsed electromagnetic field (PEMF) was found to retard angiogenesis and growth of a human breast cancer xenograft, causing the tumor to develop proportionately larger areas of necrosis and hypoxia and smaller areas of proliferatively active cancer cells. It was also demonstrated that the daily PEMF therapy continued to inhibit tumor angiogenesis and tumor regrowth for two weeks following a standard course of ionizing radiation (IR) therapy (Cameron *et al.* 2005a). However, this PEMF therapy renders large areas of the tumor hypoxic and therefore is expected to lessen susceptibility to oxidative damage caused by further IR treatments or by oxidative dependent chemotherapy. The need for a 2-4 day recovery from the anti-angiogenic effects of PEMF prior to the next round of oxidative IR therapy is discussed.

Introduction

There appears to be only two previously published original research reports on use of pulsating electromagnetic field (PEMF) to reduce tumor angiogenesis and tumor growth (Williams et al. 2001, Cameron et al. 2005a). These two previous reports both indicated that a 15 mT PEMF given for 10 minutes per day safely reduces tumor growth and tumor vascularization. In an accompanying report in these proceedings the effects of the exact same PEMF exposure condition on zebrafish development and tail fin regeneration was reported to be ineffective in retarding fish embryonic development or fin regeneration or to retard the vascularization accompanying these processes (Short et al. 2006). What factor or factors might be responsible for the difference in response to the same PEMF exposure conditions between the transplantable tumors in mice and the development and fin regeneration in the fish? Thus, an aim of the current report is to briefly reexamine the results of these two prior reports on growth of a transplantable tumor and on fish development and tail fin regeneration and to explore possible differences in responsiveness to the same PEMF exposure conditions.

It seems likely that clinical oncologists might not be inclined to use PEMF as the sole method of cancer therapy. Thus, it was decided to combine a commonly used form of cancer therapy, specifically a standard course of ionizing radiation (IR) with PEMF therapy in hopes of finding additive or synergistic benefits. The therapeutic implications of the results of the IR and PEMF study are presented and discussed.

Materials and Methods

EMF on Tumor Growth/Angiogenesis—Green fluorescent protein transfected with MDA-MB 231 breast cancer cells were injected into the mammary fat pad of young female athymic mice. Six weeks later, mice were randomly divided into four treatment groups: untreated controls; 10 minute daily PEMF; 200 cGy of IR every other day (total of 800 cGy); IR plus daily PEMF. Detail of the PEMF method and the IR method are given in Cameron et al. (2005a). Tumor size and body weight measurements were made

PEMF INHIBITS TUMOR ANGIOGENESIS

throughout the course of treatment. Some mice in each group were euthanized 24 hours after the end of the IR treatment. PEMF treatment continued for three additional weeks. Tumor sections were stained for: endothelial cells with CD31 and PAS or hypoxia inducible factor 1 α (HIF). Tumors were scored for angiogenesis, for metaphase index and for lung metastases.

EMF on Zebrafish Embryonic Development—Newly fertilized zebrafish embryos were given daily PEMF and developmental stages were scored versus untreated control embryos based on developmental designations made by Kimmel *et al.* (1995). Details of the methods are given in accompanying report in these proceedings (Short *et al.* 2006).

Results

Whole body IR and PEMF therapy suppressed tumor growth (Fig. 1), cell proliferation (Fig. 2), lung metastases (Fig. 3) and angiogenesis (Fig. 4).

Figure 1. Illustrates the effect on tumor growth of: the 8-day course of gamma irradiation therapy (IR), the daily exposure to the TEMF therapy (TEMF), a combination of gamma irradiation and TEMF therapy (TEMF/IR), and no treatment (Control). The tumors were all 35mm³ or less at the start of treatment.

Figure 2. Number of metaphase figures per midaxial histological section of tumor. Column height indicates mean \pm SEM. The columns that do not share a common letter are significantly different ($p < 0.01$). TEMF significantly suppresses metaphase index in the tumor. Data from the untreated mice (Control) and the TEMF treated mice were pooled from mice of the early and the late sacrifice because there were no significant time of sacrifice differences within these groups. Not shown are data on number of metaphase figures per midaxial histological section of duodenal crypts from mice sacrificed one day after last IR exposure. The data reveal significant decreases in IR treatment. Treatment with IR but not TEMF caused a significant decrease in metaphase index in the intestinal crypts.

Figure 3. Metastasis of GFP-expressing human breast MDA MB231 cells from the site of inoculation in the inguinal mammary fat pad to lodge in the lungs of mice in each of the four treatment groups. The lungs were removed and smashed between microscopic slides and microcolonies of GFP cells were observed by epilumination using blue light and detected by presence of green fluorescence microcolonies observed using both 3.5 \times and 10 \times objective lens. The untreated mice had a significantly higher number of GFP positive microcolonies than the groups of mice that received gamma irradiation therapy or those mice that received EMF therapy. There were no other significant differences between groups in either mean number of microcolonies per lung or in incidence. Horizontal lines indicate mean values for each treatment group.

PEMF INHIBITS TUMOR ANGIOGENESIS

Figure 4. Quantification of changes in tumor vascularization between treatment groups. The percent of area (volume density) of blood vessels was determined using an ocular grid intercept counting method. The mean \pm SEM of each treatment group is graphed. Columns that do not share a common letter within a graph are significantly different ($p < 0.01$). The data indicate that gamma irradiation and EMF alone or in combination decreased the total area of blood vessels and increased the total area of pseudopods compared to the control. Data from the untreated mice (Control) and the EMF treated mice (TEMF) were pooled from mice from the early and from the late sacrifice because there was no significant time of sacrifice difference within these groups.

Figure 5. Mean \pm SEM tumor growth rate data from day 7 to day 15 post IR therapy in each treatment group. ANOVA was used to determine any statistical differences in growth rates between treatment groups. Different letters demonstrate significant differences. Tumors in the untreated control group grew significantly faster than did tumors in the other three groups. Tumors in the IR/TEMF group had a growth rate significantly lower than that of the other three groups.

Continued daily PEMF therapy following IR treatment prevented angiogenesis and tumor regrowth (Fig. 4-5). PEMF therapy did not result in the body weight decreases nor the decreases in blood elements that IR did (not shown). Embryogenesis was not inhibited by daily PEMF therapy (Fig. 6).

Figure 6. Temperature and 10 minute daily exposure to PEMF on development. The time post-fertilization to reach each stage at 28.5°C (from Kimmel et al., 1995) is plotted on the left y-axis. Corresponding morphological stages are listed along the right y-axis. Stage abbreviations used are 8 somite (8s) and protruding mouth (pro-mouth). Times of PEMF exposures are labeled on the x-axis.

Discussion

Angiogenesis in the tumor was hypoxia driven. (see Fig. 7 that summarizes a model of human MDA MB231 breast cancer tumor). Continued daily PEMF therapy following IR treatment prevented tumor angiogenesis and regrowth. However, it did not suppress metaphase index in intestinal crypts. This suggests that PEMF works selectively on hypoxia driven angiogenesis such as that in growing tumors. Angiogenesis during embryogenesis in fish was not inhibited by daily PEMF treatment. Had hypoxia occurred in fish development then developmental retardation or arrest has been demonstrated to occur (Padilla and Roth 2001). Lack of effect of angiogenesis in the fish versus the tumor suggests the difference in response to PEMF is because PEMF interferes with hypoxia driven angiogenesis that occurs in tumors but not in normal fish embryogenesis.

PEMF INHIBITS TUMOR ANGIOGENESIS

PEMF is an effective adjunct therapy following IR therapy but the continued daily PEMF therapy should be stopped sometime (2-4 days) prior to a second round of IR therapy. The temporary cessation of PEMF prior to the second round of IR is necessary for resumption of angiogenesis, decrease of hypoxic areas and increase in proliferative activity in well oxygenated areas within the tumor, all of which are needed for an effective second round of IR treatment.

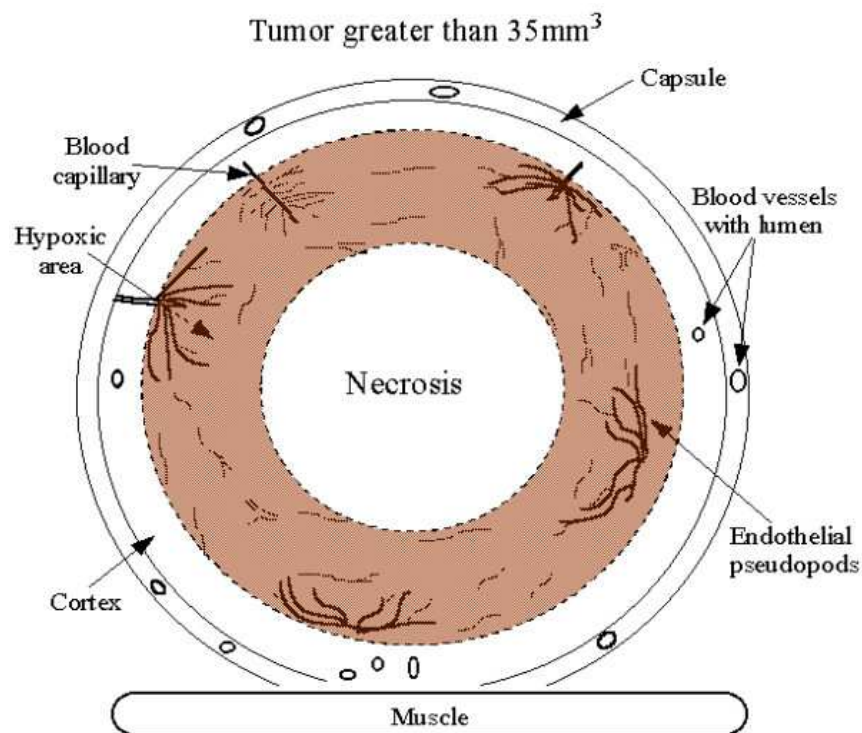

Figure 7. Model of vascularization as observed in the human MDA MB231 breast cancer cell tumor grown as a xenograph in a female nude mouse. The well vascularized tumor capsule overlies the tumor cortex. The cortex extends between 100 and 150 μm beneath the capsule. The HIF- α positive region is located in the subcortical region, at distances greater than 150 μm of the capsule. More endothelial pseudopods are located in this subcortical region than are located in the cortical region of the tumor. Even further away from the vascularized capsule is the region of tumor necrosis which contains no blood vessels or endothelial cell pseudopods. This model is consistent with the conclusion that the hypoxic regions of the tumor produce HIF leading to production of vascular endothelial growth factors and sprouting of endothelial cell pseudopods (Cameron *et al.* 2005b).

PEMF INHIBITS TUMOR ANGIOGENESIS

Abstract

A rectified semi-sinewave signal with an amplitude of 15mT and a frequency of 120 pulses per second (PEMF) given as a 10 minute daily session has proven to be a safe means for retarding tumor growth and angiogenesis in a transplantable tumor in mice. The experiments reported here were designed to test the same PEMF exposure on embryonic development and on caudal fin (tail) regeneration in zebrafish. The results of single and multiple exposures to PEMF at different times during embryonic development and tail fin regeneration demonstrated no significant delay in either embryo development or in tail fin regeneration. Possible difference between the inhibitory effect of PEMF on tumors compared to the lack of effect of the PEMF on embryo development and on tail fin regeneration is discussed.

Background

It has been reported that a 10 minutes per day exposure to a 15mT pulsed electromagnetic field (PEMF) given at 120 pulses per second reduced tumor growth and vascularization and resulted in increased survival time in mice with a breast cancer xenograft [Williams et al., 2001, Cameron et al., 2005]. The study reported here was designed to investigate the potential effects of the same PEMF on embryonic development and tail fin regeneration of zebrafish (*Danio rerio*).

In the present study it was decided to exactly repeat the PEMF exposure conditions used in the previous breast cancer xenograph experiments. No attempt was made to increase the dose of exposure (time or intensity). Thus, no claims are made to any possible effects outside the dosage range used in the present fish study.

Zebrafish are excellent organisms for the study of embryonic development. A single mating pair can provide 200 newly fertilized eggs that progress through development in synchrony. The zebrafish is a leading model for studies of vertebrate development because one can obtain a large number of transparent, externally and rapidly developing embryos [Kimmel *et al.*, 1995]. Thus, even modest experimental perturbations can influence the rate of sequential development in a subset of these fertilized embryos.

The caudal tail fin is an excellent model organ for studying regeneration. It has a comparatively simple architecture, consisting of several segmented, bony fin rays composed of concave hemirays, which are surrounded by connective tissue, nerves, and blood vessels [Ferretti and Géraudie, 1998]. Hundreds of amputations per hour may be performed. Regeneration is rapid and reliable, with most structures replaced within 1 to 3 weeks. Zebrafish survive their amputation wound, allowing for study of formation of new blood vessels and nerve regeneration [Johnson and Weston, 1995].

Because of the critical events associated with blood vessel formation and circularization between the 21 and 26 somite stages of embryogenesis [Stainier *et al.*, 1993] and the need for angiogenesis during tail regeneration as well as the past report that PEMF has anti-angiogenic action in rapidly growing mammalian tumors [Williams *et al.* 2001, Cameron *et al.* 2004], it was decided that exposure of fish embryos and regenerating fish fins to the PEMF at known times of angiogenesis might shed light on the mechanism of action the PEMF on suppression of tumor growth and angiogenesis.

Materials and Methods

A pulsed electromagnetic field (PEMF) system having a proprietary signal designed by EMF Therapeutics, Inc. (Chattanooga, TN, USA) was used (Figure 1). The system generates a pulsating half sinewave magnetic field with a frequency of 120 pulses per second. An ellipsoidal coil with 21" large diameter and 14" small diameter is used to deliver the signal to the target. In the experiment reported here, the magnetic flux density measured in the exposure chamber was 15 mT. This value of magnetic field flux density was chosen based upon our previous dose response experience and data (Williams and Markov 2001 and Williams *et al.* 2001). A thorough 3-D mapping of the magnetic field was performed for the entire space covered by the coil.

Pulsed (120 pps) rectified
semi-sine wave

Figure 1. Photograph of the EMF device and a separately suspended exposure table that was used to avoid vibration of the exposure chamber (left). An illustration of the fully rectified 60Hz signal transferred to 120 pulses per second pulsating magnetic field (right).

The flux density of the magnetic field in the exposure chamber (25 cm long, 10 cm wide and 13 cm high) was consistent within the entire volume of the chamber. The same type chamber was used on sham controls. The temperature inside the exposure chamber before and at the end of the PEMF treatment was the same. The exposure chamber is suspended separately from the EMF device and no vibrations were detected in the chamber during

EMF AND ZEBRA FISH DEVELOPMENT

operation of the EMF device. Zebrafish (4 months old) were purchased from Ekkwill Waterlife Resources (Gibsonton, FL). Zebrafish were cultured according to Westerfield [1989]. Developmental times were determined from the morphological features of the embryos under a dissecting microscope. All experiments were conducted at 21°C. A time point for a particular stage as judged by the morphological staging of each individual embryo in the cohort was assessed and the corresponding time value from Kimmel *et al.*, 1995 was then used for statistical analysis. Linear regression analyses of all data obtained revealed a significant linear fit between hours post-fertilization (hpf) from this study and hpf from Kimmel *et al.*, 1995 when plotted against one another at various morphological stages. This indicates that the method of scoring development in numerical hours, as done in this study, is justified.

In an attempt to determine an action of the PEMF on embryogenesis, fertilized zebrafish eggs were exposed to the PEMF at designated stages of development. A first group was exposed daily to the PEMF beginning at the 64 cell stage (2.5 hpf) for a total of 7 daily pulses. A second group of fertilized eggs was exposed at either the 8 cell stage (1.6 hpf) or at the 64 cell stage (2.5 hpf), both at times during synchronous cell divisions. The third group was exposed to the PEMF pulse at the sphere/blastula stage (7 hpf), shortly after the initiation of embryonic mRNA transcription [Zamir *et al.*, 1997]. The fourth group was divided into four subgroups: embryos not exposed to the PEMF (controls), embryos exposed to the PEMF at the 4 somite stage (27 hpf), embryos exposed to the PEMF at the 13 somite stage (31 hpf), and embryos exposed to the PEMF at the 25 somite stage (48 hpf). The timing of exposure to the PEMF pulses of these four subgroups was designed to coincide with the time of cardiovascular development in zebrafish (between the 21 and the 26 somite stages) [Stainier *et al.*, 1993].

For the caudal fin regeneration study, adult zebrafish were anesthetized in a 10µmol Tricaine solution and the distal one-half of each fish's caudal fin was amputated. Afterwards, the fish were returned to tanks of distilled water and fed brine shrimp every third day. To assess regeneration at 2 days, 7 days and 13 days post-amputation, the fish were anesthetized in 10µmol solution at these times and the amputated fin regeneration areas were determined by assessment of the ratio of the tail fin area regeneration to the tail fin area remaining after amputation. Tail regeneration was observed using images captured using a Nikon CoolPix 995 CCD camera mounted on a Nikon Optiphot microscope using a 4x objective.

To further assess tail fin regeneration, the number of new bone centers per fin ray of the middle five rays from each fish was scored. Finally, the number of fin rays with bifurcated bone segments at the distal end was scored.

Statistical analyses consisted of one- and two-way ANOVA followed by Student Newman Keuls multiple range test. Linear regression analyses were used to assess correlations.

Results

Figure 2 summarizes the results of daily exposure of zebrafish embryos to the 10 minute PEMF. Both the PEMF and the no PEMF controls each had at least 20 embryos. There were no significant differences at any of the times of scoring and the variance from the mean values was so small as not to be visible within the experimental points on the figure. No significant differences were found between the two groups at any time post-fertilization. Linear regression analysis gives a significant linear fit of data.

The slope of the mean rate of embryo development was 0.4983 ± 0.0142 for the control embryos and was 0.4985 ± 0.0147 for the embryos exposed to the daily PEMF. These slope values are not significantly different. The slopes of both the control and the daily PEMF groups, both at 21°C, differed significantly from the reference values at 28.5°C ($p < 0.001$).

When embryos were exposed to a single pulse of the PEMF at either the 8 cell stage (1.6 hpf), the 64 cell stage (2.5 hpf), or the sphere/blastula stage (7 hpf) and were followed to the 4 somite stage (26 hpf), no significant differences in development were detected compared to the untreated controls (data not shown).

Figure 2 Temperature and 10 minute daily exposure to PEMF on development. The time post-fertilization to reach each stage at 28.5°C (from Kimmel *et al.*, 1995) is plotted on the left y-axis. Corresponding morphological stages are listed along the right y-axis. Stage abbreviations used are 8 somite (8s) and protruding mouth (pro-mouth). Times of PEMF exposures are labeled on the x-axis.

In an attempt to bracket PEMF pulse exposure to the time of cardiovascular development in the fish embryo, a single pulse of PEMF was given to subgroups of embryos at: the 4 somite stage (27 hpf), the 13 somite stage (31 hpf), and the 25 somite stage (48 hpf). The results are illustrated in Fig. 3.

Figure 3 Effect of the PEMF exposure before (4 somite stage, 27 hpf) just prior to (13 somite stage, 31 hpf) and at the end of (25 somite stage, 48 hpf) development of a functional cardiovascular system in the zebrafish embryo (21 to 26 somite stage) [Stainier *et al.*, 1993] on rate of embryonic development. The time post-fertilization to reach each stage at 28.5°C (from Kimmel *et al.*, 1995) is plotted on the left y-axis. Corresponding morphological stages are listed along the right y-axis. Stage abbreviations used are 64 cell (64c), 4 somite (4s), 13 somite (13s) and 25 somite (25s). Linear regression analyses of the slopes of each of the four groups of embryos from the time of the first PEMF exposure (27 hpf) to the conclusion of the experiment (100 hpf) revealed no significant differences in the rate of development due to PEMF exposure compared to the untreated controls (see text for slope statistics).

EMF AND ZEBRA FISH DEVELOPMENT

There were no significant differences between the four groups at any time after treatment. Variance around the mean values was so small as not to be visible within the points in Fig. 3. Statistical analyses of mean rate of development slopes of each of the four embryo groups yielded the following linear regression slopes: 0.445 ± 0.0075 for the control embryos, 0.4441 ± 0.0073 for the embryos exposed to TEMF 27 hpf, 0.4443 ± 0.0070 for the embryos exposed to the PEMF 31 hpf, and 0.4449 ± 0.0072 for the embryos exposed to the PEMF 48 hpf. These mean slope values are not significantly different.

Table 1 summarizes the results of zebrafish caudal fin regeneration with and without a 10 minutes per day exposure to the PEMF. The ratio of the area regenerated to the area remaining after amputation is presented at 2, 7 and 13 days post-amputation. Statistical analysis reveals a significant increase with time post-amputation but no significant difference between the fish that were exposed to the PEMF and the fish that were not exposed to the PEMF. Likewise, the scoring of newly forming bone centers per fin ray reveals differences with time after amputation but no significant differences between fish with or without the daily PEMF. As fin rays increased in length, they were each observed to have a centrally located artery with veins on each side. Capillaries with circulating blood cells were observed between adjacent rays, indicating return of normal blood vessel morphology by 19 days post-amputation.

Table 1 Analysis of Zebrafish Caudal Fin Regeneration With and Without Daily PEMF Treatments Mean \pm SEM ($n=5$ fish per group)^a

Time after amputation in day	<u>Area regenerated</u> Area remaining after amputation	New bone centers/fin ray ^b
Day 2 - PEMF	$.042 \pm .008$	0
Day 2 + PEMF	$.045 \pm .010$	0
Day 7 - PEMF	$.739 \pm .140$	$.600 \pm .167$
Day 7 + PEMF	$.536 \pm .087$	$.320 \pm .136$
Day 13 - PEMF	$1.279 \pm .247$	$4.320 \pm .361$
Day 13 + PEMF	$1.258 \pm .168$	$4.320 \pm .382$

^a Results of two-way ANOVA: Significant increases with time ($p < 0.001$) but no significant differences between the group receiving daily PEMF exposure and the group not receiving daily PEMF exposure.

^b Five middle fin rays were scored in each fish.

Another measurable indicator of fin regeneration is bifurcation of fin rays. As time of regeneration increased, the number of fin rays demonstrating bifurcation increased. The mean percentage of fin rays demonstrating bifurcation did not differ significantly between the control and the PEMF treated experimental groups. For instance, at 13 days post-amputation the PEMF group had (21.0 ± 5.6) % of rays with bifurcation while the control group had (18.8 ± 7.3)% of rays with bifurcation. At 19 days post-amputation, the PEMF group had (70.2 ± 9.4) % of rays with bifurcation while the control group had (68.3 ± 19.0) of rays with bifurcation. Adults whose tails were not amputated and all of the fish in this study with tail amputation demonstrated 100% of the fin rays with bifurcation by 24 days post-amputation.

Discussion

It was shown that a single 10 minute exposure to the PEMF given at either the 8 cell stage (1.6 hpf) or at the 64 cell stage (2.5 hpf) did not delay development indicates that the PEMF is not acting to slow or to interfere with nuclear DNA synthesis, mitosis, or cytokinesis, all of which take place during these synchronous cell division stages. A single 10 minute exposure to the PEMF at the sphere/blastula stage (7 hpf) did not delay development indicates that the PEMF did not interfere with production of zygotic mRNA synthesis known to be needed for continued embryonic development at this stage of development [Zamir et al., 1997].

The timing of a pulse of the PEMF at the 4 somite (27 hpf), the 13 somite (31 hpf) or the 25 somite (48 hpf) stages (at times before, just prior to and just after initiation of heart tube formation, respectively)

suggests that the PEMF exposure at these stages of development did not delay normal cardiovascular development known to occur between the 21 and 26 somite stages [Stainier et al., 1993]. Clearly, use of the PEMF did not delay embryonic development using any of the experimental conditions tested.

Zebrafish continue to grow throughout life, and fin ray growth occurs by distal addition of bony segments [Iovine and Johnson, 2000]. The caudal fin is a usable model for studying genetics of regeneration [Poss et al., 2002, Akinemko et al., 1995] and also as a tool for evaluation of the effects of drugs and natural products [White et al., 1994, Santos-Ruiz et al., 2001, Zodrow and Tanguay, 2003]. The regeneration process involves: blastema formation, bone formation, nerve regeneration, and formation of new blood vessels (angiogenesis). Because of the usefulness of the regenerating tail fin model for the evaluation of the action of drugs and natural products, it was decided to evaluate the effects of a 10 minutes per day pulse of the PEMF on tail fin regeneration. The question was would a daily 10 minute pulse of PEMF treatment suppress regeneration of the caudal fin of adult zebrafish following partial amputation of the fin? Based on the experimental data in this report, the answer is no.

The failure of daily PEMF to delay development of fish embryogenesis and to delay fin regeneration indicates that daily exposure to the PEMF is without measurable effect. However, the same daily PEMF exposure was effective at slowing growth and angiogenesis of a rapidly growing transplantable tumor in mice [Williams et al., 2001, Cameron et al., 2005]. What might account for a lack of effect of PEMF on fish development and on wound repair as well as the report that the PEMF inhibits growth and angiogenesis of a transplantable breast cancer in nude mice. One possible explanation may be differences in angiogenesis in the different experimental systems. In the rapidly growing tumor, the cancer cells proliferate so rapidly that development of the needed vascular supply cannot keep pace, thus resulting in hypoxic regions within the tumor. The hypoxic cancer cells respond by production of hypoxia inducible factor, leading to release of vascular endothelial growth factor, which stimulates the subsequent sprouting of new endothelial cell pseudopods into the hypoxic areas of the tumor [Wachsberger et al., 2003, Cameron et al., 2005]. This eventually leads to formation of new capillaries and blood vessels. Clearly, the angiogenesis process in this tumor system is hypoxia driven. On the other hand, angiogenesis during normal fish development and tail fin regeneration appears not to be hypoxia driven, perhaps because diffusion of oxygen to the embryo and to the regenerating tail fin is adequate enough to avoid hypoxic conditions during normal embryonic development and tail fin regeneration. Thus, angiogenesis in the fish embryo and in fin regeneration may not be hypoxia driven whereas angiogenesis in the rapidly growing tumor is hypoxia driven. This difference between systems may account for the observed differences in response to PEMF. It seems unlikely that zebrafish embryos and adults experienced hypoxia under the experimental conditions based on the fact that induced oxygen deprivation does cause arrest of zebrafish development and heartbeat until returned to normoxia (Padilla and Roth, 2001). A testing of this hypothesis is planned by the authors.

EMF RISK FOR OPERATORS MOUNTING, ADJUSTING AND MAINTAINING BASE STATIONS

Ts. Shalamanova, I. Iliev, M. Ivanova, M. Israel

National Center of Public Health Protection, Sofia, Bulgaria

ABSTRACT

There are many publications in the last years about the risk of radiofrequency (RF) exposure to the general population from base stations for mobile communication. Unfortunately, very few of them concern the risk to the personnel mounting and maintaining these systems.

Here, we present a pilot study of the exposure to the personnel in selected objects with different types of antennae mounting.

The exposure assessment is made according to the typical work positions corresponding to the operations of the personnel. Calculations of the energetic load are made on the basis of the Bulgarian national legislation.

The data show that the maximal values of power density measured at distances up to 50 cm in front of the antennae reach to 2.5 mW/cm². In other locations of the worker: behind, aside and under the antenna, measured values are logically much lower, and corresponding to the exposure limits of ICNIRP Guidelines.

Basing on the results, we recommend future studies in this fields and a special attention to this personnel because of the possible risk of RF overexposure

We propose special protective measures for this particular work group.

INTRODUCTION

There are a lot of recent publications dealing with the emission of mobile communication antennae in settlements affecting the population health. Unfortunately, the results are contradictory and more evidences are needed for the possible effect of electromagnetic fields (EMF) at frequency 900 MHz and 1800 MHz which provokes diseases like cancer, cardiovascular disorders and other health consequences among the population.

Furthermore, little attention was paid to the risk of RF exposure on service staff of base stations and mobile communication antennae up to now. There is evidence that despite the special requirement of the manufacturers that service operations should be performed when antennae are switched off, the personnel frequently works when the antennae emit, i.e. without interrupting the emission, and very close to them. Mild (1) reports similar practice among the service staff of base stations and antennae in Sweden.

AIM AND SCOPE

This study is aimed at assessing the risk of the microwave EMF radiation for the service staff of base stations and mobile communication antennae.

For this purpose typical antennae systems were investigated on routine operations of the personnel which they perform close proximity and around antennae. EMF values were measured and exposure assessment is made for each particular operation. Energetic loading of the organism and whole body SAR were calculated as well. The scenario, technological operations and their average duration were presented by the mobile operator.

The object of investigation is personnel working on base stations antennae emitting EMF with frequencies about 900 MHz, and UMTS systems with 2100 MHz.

On pictures No. 1, 2 and 3 are presented various technological operations in the close proximity of a single antennae for which were made corresponding measurements and evaluations.

Operation between antennae

Pic. 5
*Operation close to lower edges of
antennae*

This study does not deal with the exposure close to antennae, mounted on telecommunication masts.

The study covers temporary workplaces for adjustment, maintenance and repair of antennae, mounted on base stations. The selected sites cover all possible working conditions, under which the respective service tasks are performed by the staff.

EXPOSURE ASSESSMENT

The evaluation of electromagnetic effects was performed at two stages:

1. Measurement of EMF for various procedures performed by the personnel and evaluation of the compliance with the respective exposure limits

Ts. Shalamanova, I. Iliev, M. Ivanova, M. Israel

2. Evaluation of the energetic loading (exposure assessment) for various processes, activities and shifts and its compliance with the respective limit values of Bulgarian and European standards.
3. Calculation of Specific Absorption Rate, SAR W/kg.

METHOD AND MATERIALS

Measurement equipment:

Power - meter 'NARDA', model EMR-21C of "NARDA Safety Test Solutions"

The evaluation was performed according to national [2,3], and international standards. [4,5]

Pic. 6
Measurement equipment

Table 1. shows the limit values according to the normative documents listed above.

Table 1

Standard	Power density $S, \mu\text{W}/\text{cm}^2$	Average time t, h	SAR W/kg	Energetic loading $W, \mu\text{W}\cdot\text{h}/\text{cm}^2$

MEASUREMENT METHOD

Measurements were made in wide frequency range by nonselective method.

All measurements were made in few selected typical sites. Measuring device was chosen with probe sensitive to electrical component of EMF.

To avoid human influence on the measurement process handle and optical cable connected to the device. Data were collected using Narda EMR-21C software, installed on laptop. In cases when the height of antenna mounting allows performing measurements from the rooftop level the equipment was mounted on tripod.

Data were collected considering the typical work positions of base station service workers. The average (averaged over 1.5 min) and maximum power densities were measured. The average values for 1.5 min were measured in order to assess the compliance with the international guidelines (ICNIRP), which require determining the (measured) 'reference' values for 6-minute period (0.1 h). This facilitates also the further determination of the energetic loading performed for 1 h. It was calculated with respect to the mean time for performing the above-mentioned work tasks.

EMF RISK FOR BASE STATION'S OPERATORS

In the far field zone, the values of SAR and energetic loading coincide for external exposure to radiation of a 'human equivalent antenna' (receiving antennae equipment corresponding to the resonance and subresonance absorption of incident energy by an average human body size).

Energetic loading of the organism was calculated considering average time duration for performing the described above operations.

On pictures No. 7 to 11 are shown spots where measurements were performed according to the technological operations of the personnel.

RESULTS OF MEASUREMENTS AND CALCULATIONS

The results of measurements are shown according to the tasks performed by the service staff of mobile communication antennae and base stations. The measurement points correspond to the location of the subjects at work with respect to the antennae.

In Table 2 are shown the measured values of power density, calculated values of energetic loading of the organism, permissible time duration and whole body SAR values as well.

ANALYSIS OF RESULTS AND CONCLUSIONS

The average and maximum power density S measured at the temporary workplaces for adjustment, maintenance and repair works exceed the limit values of both Bulgarian and European standards. The same is true for all works performed close to antennae at a distance up to 1 m during radiation. Even for short-duration tasks (for up to 2 h) the EMF values exceed the limits. When they are below them, the calculated energetic loading is above the limit.

The energetic loading is within the permissible limits only during works done behind the antennae or along the antenna-feeder lines.

Nevertheless high measured values of power density and calculated values of energetic loading of the organism calculated whole body SAR values correspond to the ICNIRP guidelines basic restriction for occupational exposure. Our legislation is stringent and in some operations forbids stay in such conditions. Although compliance of SAR values to the guidelines we consider that the personnel exposure especially on particular operations is significant. Therefore employers should take the following measures in order to protect the workers' health:

- technological operations in the close proximity of antennae should be performed after switching off emitters;
- use of personal protective equipment (clothes, glasses, etc.) when it is not possible to switch antennae off,
- when protective equipment is not used, combinations of technological operations should be made respecting the following limitation of the exposure:

$$\frac{\sum W_i}{W_{\text{lim}}} \leq 1,$$

where W_i is the total energetic loading of the organism resulting from the "i" - technological operation;
 W_{lim} is the maximum permissible energetic loading of the body according to the national standards.

Others not less important recommendations for the operators' safety work are the followings:

- permissible time duration specified in Bulgarian regulations should be kept;
- workers should use personal dosimeters, which provide data about the cumulated dose;
- periodical training of the staff about the risks of EMF and protection;

In conclusion, a high risk for EMF exposure is found for workers mounting and maintaining base stations for mobile communication. Hence, measures should be taken to improve the working conditions with respect to EMF by decreasing radiation, carrying administrative and organizational measures, ensuring continuous monitoring and personal protection. The energetic loading should be regularly assessed, while the field should be currently monitored by personal dosimeters. Periodical medical check-ups done by neurologist, cardiologist, therapist and ophthalmologist should be included into the prophylaxis program. Last but not least, the qualification of the staff in standards, biological effect, methods of measurement and protection against microwave fields should be currently maintained. Special attention should be paid to workers with active implants.

Abstract

In addition to bactericidal effect of “noise” electromagnetic irradiation (EMI) of extremely high frequencies [1-2], the coherent EMI of such frequency (the range of frequencies from 45 to 53 GHz) or millimeter waves (the wavelength of 5.6 to 6.7 mm), with low intensity (the flux capacity of 0.06 mW/sm²), upon direct irradiation (during 30 min or 1 h), affected *Escherichia coli* K12, wild-type, grown under anaerobic conditions with fermentation of sugar (glucose): it caused a decrease in bacterial growth rate, maximal inhibitory effect was achieved at the frequency of 51.8 or 53 GHz. This effect depended on medium pH, the maximal one was at pH 7.5. The noticeable changes in membrane proton conductance, membrane potential, proton fluxes through the membrane of whole cells and total and *N,N'*-dicyclohexylcarbodiimide (DCCD)-inhibited ATPase activity of membrane vesicles were determined. These membranous effects might be accounted in action of EMI. A decrease in sensitivity to reagents (DCCD) by cells was also determined. Moreover, EMI had mediated effects on bacteria. Separate irradiation (the frequency of 51.8 and 53 GHz) of doubly distilled water or some inorganic ions containing Tris-phosphate buffer (pH 7.5), into which grown cells were transferred, during 30 min or 1 h, had changed further growth of these bacteria in different, opposite directions; irradiation of water only caused inhibitory effect. These might point out a role of water in the effects of EMI of extremely high frequency on bacteria. A significant action disappeared upon repeated irradiation at the frequency of 51.8 and 53 GHz during 1 h and with interruption for 2 h. This result indicates some compensatory mechanisms within bacteria.

The *keywords*: coherent electromagnetic radiation of extremely high frequency, bacterial growth, membranous effects, resonant frequencies, water.

INTRODUCTION

The bacterial effects of the electromagnetic irradiation (EMI) of extremely high frequencies, or millimeter waves, with low (low-energetic) intensity and with non-thermal action, are of interest because of two reasons, at least. First of all, bacteria and other cells can interact with each other through EMI (for reviews, see [3-4]). It has been shown, for instance, that bacteria possess the ultrasonic radiation [5-7] or reemission of secondary photons in sub-millimeter frequency range [8]. However radiation of extremely high frequency is not clearly registered in spite of the fact that fine methods have been developed and enough sensitive instruments have been already constructed for last years [9-10]. Secondly, EMI of extremely high frequency is widely used in telecommunication technology and therapeutic practice [2, 11] although low-orbital systems of cosmic communication and different elements of mobile one, and in addition, low-energetic devices used in therapeutic practice radiate EMI of this frequency, small and very small doses of which (low flux capacity of 0.005 mW/sm²) might affect cells.

The coherent and so named “noise” (with broadband frequencies and accidentally changing phases) EMI of extremely high frequencies with low intensity have been shown to cause different, including bactericidal effects on *Escherichia coli* and the other bacteria [10-14]. Such effects depend on phase and anaerobic or aerobic conditions of

the bacterial growth, composition of growth media, genetic features and peculiarities of the metabolism in bacterial strains. Together with these, coherent and noise EMI of extremely high frequencies can render the different bacterial effects depending on frequency and intensity of EMI, duration of the irradiation and the other parameters [1-2]. Moreover, studies on repeated and mediated action of noise EMI on *E. coli* [2] have allowed expecting compensatory mechanisms and role of other factors.

Among cellular mechanisms of bacterial effects of EMI of extremely high frequencies, the membranous changes connected with surface characteristics of plasma membrane, ion and other substances transport across the membrane and energy-converting processes [1-2, 12-13] are of significance. Action of EMI of extremely high frequency is offered also on structure and properties of water [14-16] leading, for instance, to increase in chemical activity of water or hydration of proteins and other cellular structures. These could also relate to modifications of structure, properties and function of membrane, especially membrane proteins. On the other side, conformational changes in bacterial genome or DNA are also suggested [17]. Bactericidal effect might be determined by transition of bacterial pro-phages from lysogenic to lytic state [18-19].

Finally, effects of such EMI can be a result of the resonant interaction, when in case with *E. coli* it is shown that, regardless of intensities of EMI of extremely high frequency, resonance is at the frequencies of 41.5, 51.8 or 70.6 GHz [17-19]; other resonant frequencies are not ruled out. However, effects of EMI on these and other bacteria and cells in generally, especially primary cellular mechanisms of these effects, require the further study.

In the present report with fermenting *E. coli*, grown in anaerobic conditions, it is shown that maximal inhibitory effect of coherent EMI of extremely high frequency on bacterial growth rate was observed at the frequencies in 51.8 or 53 GHz. The changes in membrane properties and functions have been determined. The certain effects might be mediated by the other factors and changed by repeated irradiation.

MATERIALS AND METHODS

E. coli K12, wild type strain, was used in the study.

The methods for bacterial growth in peptone medium (0.2 % peptone, 0.5 % NaCl and 0.2 % K_2HPO_4) at slightly alkaline (pH 7.4) or the other (specified in text) pH in anaerobic conditions upon fermentation of sugar (glucose, 0.2 %) [1, 20] and determination of bacterial specific growth rate (μ) [1, 21] were described elsewhere. The methods for preparation of whole cells for assays and isolation of membrane vesicles [21-22], for determination of membrane proton conductance ($G_m^{H^+}$) [23], membrane potential ($\Delta\Psi$) [24] and energy-dependent proton efflux (J_H^+) [1, 23-24] from whole cells as well as of ATPase activity of membrane vesicles [21-22], and, in addition, for data processing [25] did not differ from widely described.

The pH of growth medium and assay solutions was measured by using a fine pH-potentiometer with selective (pH) electrode and adjusted by means of HCl and NaOH, although pH of doubly distilled water was 6.5 and did not changed when kept during 2 days at 4 °C in spite of its less-buffering capacity. The dry weight of bacteria and protein were determined by the method described by Trchounian and Vassilian [21] and Lowry et al. [26], correspondingly. Bacterial titer was calculated by counting colonies grown on solid media with glucose after plating of diluted bacterial suspension.

The irradiation of *E. coli*, water or the other solution was produced by means of generator G4-141 (radiating the coherent electromagnetic waves with frequency within the range of 45 to 53 GHz, wavelength of 5.6 to 6.7 mm, correspondingly; the flux capacity was of 0.6 mW/cm²). The generator was assembled in the Institute of Radiophysics and Electronics of the National Academy of Sciences of Armenia (Ashtarak City). For the others, the conditions of the irradiation of bacteria were similar to those described previously [1]. After direct irradiation of bacterial suspension (grown cells concentrated by centrifugation in water), cells were immediately transferred into the fresh growth (with glucose, 0.2 %) or assay medium.

At determination of the mediated influence of EMI of extremely high frequency on *E. coli*, grown cells were transferred into the distilled water or buffer (Tris-phosphate, pH 7.4) containing 0.4 mM $MgSO_4$, 1 mM KCl and 1 mM NaCl, and then, after incubation of 10 min, growth or other assays were carried out immediately. Water or buffer was irradiated during 30 min or 1 h as specified in text. The repeated influence of EMI of extremely high frequency was conducted with interruption of 2 h.

The data processed to be statistical with determination of the standard error and of the Student's validity criteria (p) [26].

RESULTS AND DISCUSSION

Inhibitory effect of coherent EMI of extremely high frequency on bacterial growth

BACTERIAL EFFECTS OF MILLIMETER WAVES

Bactericidal effect of “noise” EMI with frequencies of 53.5 to 68 GHz on *E coli* was installed earlier [1-2]. If such effect is conditioned resonant interaction of EMI of extremely high frequency with bacteria, the range of frequencies of “noise” EMI used does not include the resonant frequencies in 41.5, 51.8 or 70.6 GHz shown for *E coli* [17-19]; the other resonant frequencies may be allowed. Therefore a study of bacterial effects of the coherent EMI with resonance frequency in 51.8 GHz, which is radiated by the generator used (see Materials and methods) was done. Together with this, effects of EMI of extremely high frequency hang from conditions of the growing bacteria [1-2, 11-13] and they can differ in anaerobic conditions, favorable for the majority of pathogenic and conditionally pathogenic bacteria, therefore studies conducted with *E coli*, grown in anaerobic conditions under fermentation of sugar.

Irradiation of *E coli* K12 by coherent EMI with the coherent frequency of 45 to 53 GHz during 30 min (not shown) or 1 h (Fig. 1) brings a gradual decrease in the specific rate of bacterial growth for the frequency of 49 GHz, moreover maximal inhibitory effect was observed at the frequency of 51.8 or 53.0 GHz. Such result complies with those the frequency of 51.8 GHz is resonant for *E coli* [17-19] and, on the other side, the exposition of 1 h is effective to inhibit bacterial growth [11]. The resonances in which proteins and other macromolecules can be entered probably are the basis of membranous and the other mechanisms of the action on bacteria and define bactericidal effect of EMI of extremely high frequency.

Fig. 1. The changes in the growth rate of *E coli* K12 after direct irradiation with coherent EMI of extremely high frequency. The specific growth rate (μ) was defined as $0.693/\text{time}$ of the reduplication to absorbance (OD) in bacterial suspension (when logarithm of OD linearly increased at time) [10-11]; in checking control, bacteria without irradiation. For the others, see Materials and methods. The average values are from not less than three independent experiments with standard errors.

Note that the inhibitory effect of coherent EMI of extremely high frequency on bacterial growth depends on duration of the irradiation: increase in time of the direct irradiation from 30 min to 1 h at the frequency of 51.8 or 53.0 GHz brings about reinforcement of the effect in 2.2- or 1.6-fold, respectively.

A dependence of the action of EMI of extremely high frequency on *E coli* from pH is of interest: under pH 6.0 and 8.0 in contrast with pH 7.5, inhibitory effect noticeably decreased (Tabl. 1.). Since the specific growth rate practically does not depend on medium pH in noted range (not shown), the change in this rate after irradiation can be indicative of some process as in cells themselves, so and in water medium with determined reaction (pH), in which bacteria grow. Probably, a slightly alkaline medium (pH 7.3-7.5) is chosen not accidentally as the most optimal for growing *E coli* (neutrophilic bacteria) [27].

Table 1. The specific growth rate of *E. coli* K12 irradiated by EMI of extremely high frequency at different pH.

pH*	Growth rate (h ⁻¹)		
	Control	51.8 GHz	53.0 GHz
6.0	0.86 ± 0.05 (100 %)	0.63 ± 0.03 (73.3 %) (p<0.05)**	0.60 ± 0.03 (69.8 %) (p<0.05)
7.5	0.82 ± 0.03 (100 %)	0.52 ± 0.02 (34.7 %) (p<0.01)	0.34 ± 0.02 (26.7 %) (p<0.002)
8.0	0.77 ± 0.03 (100 %)	0.70 ± 0.05 (91.0 %) (p<0.05)	0.50 ± 0.02 (64.9 %) (p<0.05)

* irradiation time was 1 h, for the other conditions, see Materials and methods and the legends to Fig. 1.

** p is calculated for the difference between the values in checking control and obtained ones; percentage is determined in relation to checking control (100 %).

On mechanisms of bacterial effects of EMI

Determination of some properties and of activity of some key membrane-associated enzymes having a key role in ion and the other substances transport and energy conversion could be of much interest to reveal mechanisms of bacterial effects of EMI. The marked changes in $G_m^{H^+}$ (Fig. 2A), $\Delta\Psi$ (Fig. 3) and energy-dependent proton efflux (Fig. 2B) were shown followed irradiation of *E. coli* K12 by EMI with the resonant frequency of 51.8 [17-19] or 53 GHz. It is possible to suggest some relationship between these properties of the membrane since the changes in the values of $G_m^{H^+}$ and $\Delta\Psi$ were in opposite directions and moreover $J_H^{H^+}$ decreased upon irradiation. Such relationship between $G_m^{H^+}$ and $\Delta\Psi$ has been proposed by Akopyan et al. [23] requiring a further study. These changes in the properties of the bacterial membrane might be of significance and could be accounted for decrease in bacterial growth rate.

Fig. 2. Changes in membrane proton conductance ($G_m^{H^+}$, A) and energy-dependent proton fluxes ($J_H^{H^+}$, B) of *E. coli* K12 after direct irradiation with coherent EMI of extremely high frequency. The irradiation time was 1 h, the frequency was shown. $G_m^{H^+}$ was determined by an acid-pulse technique used before [23]. Energy-dependent ion fluxes were determined by using selective (pH) electrode upon glucose (22 mM) adding; the values represented are for bacterial count of 10^{12} cells [23-24]. For the others, see Materials and methods and the legends to Fig. 1.

Furthermore, total and DCCD-sensitive ATPase activity was inhibited significantly by irradiation with coherent EMI of the frequency of 51.8 or 53 GHz although ATPase activity in the presence of DCCD (0.1 mM) has no changes or, in opposite, is increased a little (Fig. 4). Taken into consideration the fact that DCCD is inhibiting the F_0F_1 -ATPase in *E. coli* under fermentation [28], the results obtained indicate that this ATPase may be a target for action of EMI of extremely high frequency.

Fig. 3. *E. coli* K12 membrane potential ($\Delta\Psi$) values after irradiation with coherent EMI of extremely high frequency. The irradiation time was 1 h. $\Delta\Psi$ was calculated from distribution of tetraphenylphosphonium cation (initial external concentration of 1 μM) between the cytoplasm and the external medium determined with appropriate selective electrode [24]. For the others, see the legends to Fig. 1.

BACTERIAL EFFECTS OF MILLIMETER WAVES

In addition, it should be noted that, in the K^+ -less assay medium (concomitant K^+ was of 0.02 mM [21]), total ATPase activity was of lower values close to those in the presence of DCCD (see Fig. 4) having no any marked changes by irradiation with the frequency used (not shown). This is of importance since K^+ -sensitive and DCCD-inhibited ATPase activity in *E. coli* has been shown clearly be the F_0F_1 -ATPase activity that is associated with K^+ uptake TrkA system [21, 29-30]. Therefore, EMI of extremely high frequency affected K^+ -sensitive and DCCD-inhibited ATPase activity suggesting that the F_0F_1 -ATPase could be a target for EMI.

Moreover, inhibitory effect of DCCD (in different concentrations of 0.1 to 1 mM) on J_H^+ markedly decreased after irradiation with EMI at the frequency of 51.8 or 53 GHz (Fig. 5) in spite of different proton fluxes (comp. with Fig. 2B) suggesting that sensitivity of bacteria to inhibitors (DCCD) may be also affected by irradiation with coherent EMI of extremely high frequency. Such an effect was determined with "noise" EMI before [1]. A less sensitivity to DCCD could result from conformational changes in subunits of the F_0F_1 -ATPase [31] having a key role in effects of EMI on bacteria. This seems to be in accordance with results reported by Bulgakova et al. [13] that EMI of extremely high frequency with non-thermal intensity could change the sensitivity of *Staphylococcus* to various antibiotics having membranotropic properties. The irradiation (during up to 1 h) is of importance can result in opposite changes inhibiting and stimulating bacterial growth [13]. In all cases, these results might be extrapolated to different reagents and drugs and should be accounted in therapeutic practice. Moreover, this would lead to further study to reveal primary cellular mechanisms for bacterial effects of EMI of extremely high frequency.

Fig. 4. The ATPase activity of membrane vesicles isolated from *E. coli* K12 after irradiation with coherent EMI of extremely high frequency. The irradiation time was 1 h. ATPase activity was calculated by colorimetric determination of liberation of inorganic phosphate (P_i) per time and protein [21-22] upon ATP (3 mM) adding. DCCD was added in final concentration of 0.05 mM in parallel assays. For the others, see Materials and methods and the legends to Fig. 1.

Fig. 5. The changes in inhibitory effect of DCCD on J_H^+ from *E. coli* K12 after direct irradiation with coherent EMI of extremely high frequency. The irradiation time was 1 h, for the others see Materials and methods and the legends to Fig. 1.

Mediated action of EMI on bacteria

The action of EMI of extremely high frequency on bacteria studied under separate irradiation of water or buffers containing different ions (see Materials and methods), in which bacteria are kept under assays [2, 12].

Table 2. Mediated action of EMI of extremely high frequency on the following growth rate of *E. coli* K12.

Conditions*	Growth rate (h^{-1})		
	Control	51.8 GHz	53.0 GHz
Doubly distilled water	0.82 ± 0.03 (100 %)	0.52 ± 0.02 (63.4 %) ($p < 0.01$)**	0.34 ± 0.02 (41.5 %) ($p < 0.002$)
Assay medium	0.78 ± 0.03 (100 %)	1.22 ± 0.05 (156.4 %) ($p < 0.01$)	1.41 ± 0.08 (180.8 %) ($p < 0.01$)

* irradiation time was 1 h, for the other conditions, see Materials and methods and the legends to Fig. 1.

** see the legends to Table 1.

When irradiation by the duration of 30 min (not shown) or 1 h (Table 1) and with the frequency of 51.8 or 53.0 GHz was subjected to water, the specific growth rate for *E. coli* K12 (after premises in such water during 10 min and then their moving into growth medium with glucose, see Materials and methods) decreased on more than 35 % in comparison with control (Tabl. 2.). But this mediated action was with less effects than direct irradiation of bacteria in the water (comp. with Fig. 1 and Tabl. 1). When irradiation was subjected to the buffer, the growth rate, on the contrary, increased on more than 56 % (Tabl. 2). Evidently, cells may be affected by Tris (hydroxymethylaminomethane) or the other buffer components, but data are very poor [2, 32].

Note that water has acidic reaction and transferring cells from slightly acidic medium or slightly alkaline medium could affect growing bacteria. In addition, osmotic shock should be also taken into consideration, since cells are transferring into the medium with greater osmolarity. However, such procedures were shown before do not affect growing *E. coli* [33].

Thereby, mediated action of coherent EMI of extremely high frequency on *E. coli* might be of different nature. This was observed earlier with “noise” EMI depending on bacterial growth phases and other factors [2]. The results point out a role of water and medium composition in effects of EMI of extremely high frequency on bacteria.

Repeated action of EMI on bacteria

If bacteria have any compensatory mechanisms [2], then these mechanisms possibly become to be important under the repeated irradiation with coherent or “noise” EMI of extremely high frequency. Indeed, the repeated action of coherent EMI with the frequencies in 51.8 or 53.0 GHz on *E. coli* K12 (irradiation during 1 h with interruption of 2 h, in checking control repeated irradiation was absent but bacteria were kept with the same time) reduced considerably an inhibitory effect (in 1.7- or 1.9-fold for the frequency of 51.8 or 53.0 GHz, correspondingly; $p < 0.01$).

Certainly, compensatory mechanisms in bacteria have not studied, although miscellaneous defensive proteins like those discovered in animal cells [34] might play a role.

Thereby, the results obtained are indicative of negative action of coherent EMI of extremely high frequency on bacteria, when maximal effect is observed at the frequency in 51.8 and 53.0 GHz. The frequency of 51.8 GHz in studied range of EMI (see Materials and methods) is probably a resonant frequency causing maximal effect.

Concluding remarks

The study done defines the bacterial effects of coherent EMI of extremely high frequency with low intensity causing changes in *E. coli* growth and points out some membranous aspects of the mechanisms of such an action. The effects of coherent EMI of the frequency of 51.8 or 53.0 GHz on bacterial growth rate and some properties of the bacterial membrane (see Results and discussion) should be noted to be much stronger than appropriate effects of “noise” EMI of extremely high frequency reported [1-2].

Bacterial effects of “noise” and coherent EMI of extremely high frequency with low intensity shown in the present paper and by different groups [1-6, 10-13, 17-19] are of significance to understand distinguishing role of bacteria in biosphere nowadays leading to changed metabolic pathways and, for instance, to antibiotics resistance (for review, see [35]).

The present results are principal to the further study of mechanisms of biological effects of EMI, on the one hand, and in the same time, for determination of the allowed doses of the long irradiation of the persons and the

BACTERIAL EFFECTS OF MILLIMETER WAVES

other organisms by means of EMI of extremely high frequency to manage appropriate preventive ways. Moreover, it should be necessary to improve using EMI of extremely high frequency in therapeutic purpose, when repeated action can turn out to be inefficient. It is also possible to use EMI for product protection from bacteria. In addition, the results are important for construction of new generators of EMI of extremely high frequency and facilities for telecommunications.

The authors thank L. Arutyunyan and K. Akopyan for help in undertaking some experiments. This study was done within the framework supported by Ministry of Education and Science of the Republic Armenia (Grant # 54).

MICROWAVE IONOSPHERIC EMISSION AS A NEW FACTOR OF SOLAR-BIOSPHERE RELATIONS

SERGEI V. AVAKYAN

S.I. VAVILOV STATE OPTICAL INSTITUTE, Tuchkov lane 1, 199034, St. Petersburg, Russia, avak2@mail.ru

Abstract

This paper proposes and provides substantiation for a hypothesis concerning the mechanism by which solar and geomagnetic activity (mainly of solar flares and magnetic storms) affects the biosphere, including man. The hypothesis, including a physical mechanism introduced by the author and new for aeronomy, is that high-lying (Rydberg) states of all gases of the earth's upper atmosphere are excited by ionospheric electrons. Rydberg atoms, molecules and ions of all atmospheric gases emit characteristic radio emission in the spectral range from decimeters to millimeters. This radiation can easily penetrate to low atmosphere and biosphere carrying complete information about power and duration of solar flare and geomagnetic storms to biosphere. The microwave radioemission have the resonances at the spectral range $10^9 \div 10^{12}$ Hz at the biological cells and membranes, DNA and RNA, molecules of hemoglobin, human erythrocytes, and this fact can explain the extremely small threshold for influence of ionospheric radioemission at the monochromatic (characteristic) Rydberg transitions on biological objects, including the viscosity of blood.

The energy estimates of the flux intensity of microwave radiation of the ionosphere from Rydberg states are used to prove for the first time that the values of this flux agree with the experimental data. A method is proposed for distinguishing the contributions of microwave radiation and magnetic perturbation in the geobiocorrelations, taking into account the effect that the magnetic-field variations are not in phase with the flux of corpuscles from the radiation belts in the ionosphere during the period of a geomagnetic storm.

There are several problems in ionospheric and atmospheric physics, biophysics and medicine concerning the investigations of Rydberg excitation role:

- determination of the real spectral distributions for Rydberg ionospheric emission at all transparency windows;
- determination of the perception threshold for the characteristic sharp-resonance microwave Rydberg emission for healthy and sick persons;
- modelling investigations of negative influence of cell telephone. The sporadic increase for the microwave ionospheric Rydberg radioemissions during power solar flares and principal magnetic storms will be taken into account for consideration of the stochastic resonance.

Introduction

One of the fundamental problems of modern natural science is the search for biophysical mechanisms by which solar and geomagnetic activity, and especially solar flares and magnetic storms, affect people and the biosphere as a whole. The accumulated experimental material is mainly evidence, at least in indirect form, of the presence of heliogeobiocorrelations. It is obvious that such correlations are very complex because of their multifactorial nature. At the same time, they indicate that there is some physical mechanism responsible for the transport of the energy given off into the thickness of the lower atmosphere and biosphere when the solar and geomagnetic activity increases. In fact, the main energy flows that vary when there are variations of the solar and geomagnetic activity do not reach the lower atmosphere but are completely absorbed in the earth's upper and middle atmosphere (above 20 km). The chief variations in the electromagnetic radiation flux from the sun actually occur in the region of far- and extreme-UV radiation and soft x rays, which is completely absorbed in the upper atmosphere. It is well known that the radiation flux which ionizes the earth's upper atmosphere in the range from soft x rays to the vacuum UV (with wavelengths from 0.1 to 134 nm) increases most strongly (by a factor of several thousand and sometimes by tens of thousands) in the periods of solar flares. The energy of this flux is 6–7 orders of magnitude higher than that of solar rf radiation in the periods of strong flares.

Corpuscular solar radiation (the solar wind, energetic solar protons and electrons) also do not penetrate into the lower atmosphere. When the geomagnetic activity increases—magnetic storms and substorms, there is a sporadic precipitation of electrons and protons from the earth's radiation belts into the ionosphere, but these flows also completely dissipate at higher altitudes (above 40 km).

The fluxes of charged particles, mainly electrons, as well as protons, that precipitate into the earth's upper atmosphere from the overlying radiation belts also increase by several orders of magnitude during strong

magnetic storms. In periods of solar flares and during magnetic storms, the very first process of complete dissipation of the energy of particle fluxes intruding into the earth's upper atmosphere is the ionization of all the atmospheric gases with the formation of photoelectrons, secondary electrons, and Auger electrons.

The energetics of the variations during the period of geomagnetic perturbations of the geomagnetic field itself with respect to the mean value and even more in absolute magnitudes are insignificant. Therefore, the “ kT problem” in magnetobiological effects¹ is continually being discussed in the literature [1].

In this connection, there is interest in discussing the arguments in favor of the hypothesis of [2, 3] on the importance in heliogeobiospheric correlations of the contribution of the microwave radiation of the earth's ionosphere, detected as sporadic rf radiation when the solar and geomagnetic activity increases [4-6].

Microwave Rydberg radiation of the ionosphere as a factor of the action of solar and geomagnetic perturbations on the biosphere

In 1994, we were the first to propose [7] that the fact that the plasma of the earth's upper atmosphere (and of other planetary atmospheres) unconditionally contains highly excited Rydberg states of atoms, molecules, and their ions should be taken into account in aeronomy and ionospheric physics. Rydberg states correspond to strong excitation of a valence electron that had been in orbit with high principal quantum number $n > 10$. In practice, this is a state of an atomic-molecular particle of any gas of the upper atmosphere close to its ionization potential. The corresponding atomic spectra were experimentally studied for the first time by the Swedish physicist Johannes Robert Rydberg (1854–1919). These Rydberg states are metastable (long-lived), since most radiative quantum transitions from them have low probability. Transitions from the Rydberg states fill virtually the entire region of the electromagnetic spectrum of the upper atmospheric emissions, beginning from the extreme UV radiation. According to the selection rules for electric dipole transitions, the allowed transitions will be those for which the orbital-momentum quantum number change by an amount $l = \pm 1$. Therefore, because of the high values of n and hence of l ($l = n - 1$ and below), transitions from high l can occur only between adjacent Rydberg states and consequently lie in the rf region [8].

It should be emphasized that there has been no monitoring of the variations of the absolute magnitude of the fluxes of solar ionizing (soft x rays and EUV) radiation and their spectral composition. There are no experimental data on the spectra or increments of the fluxes in the periods of flares on the sun of various levels and classes. And the only experiment that carries out the tasks involving the total monitoring of solar shortwavelength activity is the Permanent Space Solar Patrol that we proposed. This experiment includes measurements in the entire spectral interval with the spectral resolution needed for solar-terrestrial physics of about 1 nm in the constant regime with continuous scanning of the spectrum every 72 sec, which is close to the duration of subflares and to the pulse phase of powerful flares [9, 10].

In [2, 3, 7, 8] for the physical mechanism of the generation of microwave radiation of the ionosphere, using the process of excitation by electron impact (by ionospheric photoelectrons, auroral and secondary electrons, and also Auger electrons) of the Rydberg states of the components of the upper atmosphere and ionosphere. Specific emissions from Rydberg levels are constantly recorded when the optical radiation of the upper atmosphere is observed [11] as well as in active experiments [12]. These experiments consisted of heating the ionosphere with powerful pulses of radio waves at frequencies of 4.7–6.8 MHz. In response, the ionosphere generated microwave decimeter radiation from the altitude interval from 185 to 240 km, as well as additional emission of the red lines of the oxygen atom. The analysis given in [12] of various ways to generate the detected microwave radiation includes the following: scattering of the earth's thermal radiation at artificial inhomogeneities of the electron concentration, bremsstrahlung of electrons accelerated by high-frequency plasma turbulence to energies of the order of 10–15 eV, and transitions of the electrons between high Rydberg levels of the molecules of the neutral components of the ionospheric plasma excited when they collide with accelerated electrons, showed that the last of the three enumerated mechanisms is the most probable. It was also emphasized in [12] that the region of artificial generation of microwave radiation coincides in altitude (about 200 km) with the position of the maxima of the altitude profiles of the excitation rates of the Rydberg states, calculated in [8] for the ionosphere under natural conditions. Thus, [12] is the first experimental proof of the excitation mechanism of Rydberg levels by energetic ionospheric electrons proposed in [8].

In this investigation the results of calibration for excitation rates of Rydberg states at the altitudes of 95 to 360 km are presented. The main process of this excitation at ionosphere is electron impact, by photoelectrons at the low and middle latitudes and by precipitating from magnetosphere electron at auroral zones. In the upper atmosphere and ionosphere there are three types of electrons with energies up to several tens and hundreds of electronvolts for which the Rydberg excitation cross sections are maximal:

- photoelectrons, which arise when gases are ionized by the sun's x radiation and extreme UV radiation;
- secondary electrons, formed during ionization by corpuscles (electrons and protons from the radiation belts) precipitated into the upper atmosphere during geomagnetic storms and substorms;
- Auger electrons, formed both during photoionization and during corpuscular ionization.

The Auger effect in all its manifestations in the ionospheres of the planets also was considered for the first time in our papers [13]. All these ionization electrons in their flux intensity directly track any variations of the solar and geomagnetic activity – from quiet periods to the strongest solar flares and geomagnetic storms and substorms. The Rydberg rf radiation of the ionosphere excited by these electrons accordingly carries full spatiotemporal information concerning all the variations of the ionizing fluxes; i.e., it scans all forms of heliogeophysical activity.

The excitation rate increases with the growth of geomagnetic and solar activities in particular during the solar flares (up to 10 times and more) and during the principal magnetic storms (up to 100 times and more). Unlike the auroral zone, where the excitation rate as a rule shows only one main maximum at the altitude about 100 km, during the solar flare there are usually two maxima. The first maximum, connected with EUV solar radiation, occurs at the altitude near 200 km and its value increases during a flare by several tens per cents. The second maximum at the altitude above 100 km becomes the main one the large flare. Its increase comes up to ten times and resulted from the X-ray solar radiation. During the quiet Sun the excitation rate of sum of the Rydberg states exceeds the value $10 \text{ cm}^{-3}\text{s}^{-1}$ for atoms and molecules of oxygen and $100 \text{ cm}^{-3}\text{s}^{-1}$ for molecules of nitrogen. During solar flare 2B the integral intensity in vertical column is $10^9 \text{ photons cm}^{-2} \text{ s}^{-1}$. It is important that the increase of excitation rates of the non-Rydberg states in the visual and UV spectral range (for example the LBH system of bands of nitrogen) at the same flare is smaller by factor of three. The centimeter radioemission results from transition with changing the orbital quantum number on 1, for example in atomic oxygen at $n = 10 - 20$, and the decimeter radioemission occurs at $n = 20 - 40$, if n is constant. If $\Delta n > 1$ and $n > 10$, there are the millimeter emissions of ionosphere. In the experiments, which registered sporadic ionospheric radioemission in the range from 3 cm to 2 m with intensity increase of several times during solar flares, particularly when there were sudden ionospheric disturbances (SID), associated with X-ray flux of solar flare [5, 6, 14-17].

It should thus be assumed that a direct information channel from the lowest layers of the atmosphere and the biosphere itself concerning variations of the solar and geomagnetic activity has been determined [2, 3, 8]. For the biosphere and in particular for the human organism, this information, in the form of flux variations of the microwave radiation, can be just the Agent X that was postulated by A.L. Tchijevsky. It should be emphasized that the sun itself emits in the rf region, but this radiation does not directly correlate with the main flare flux—the flux of geoeffective short-wavelength (extreme UV and x-ray) radiation, whose energy is seven orders of magnitude greater than the solar rf flux. The main thing, however, is that the rf radiation of the sun is not monochromatic and consists not of separate lines and bands but has a continuous spectrum.

The latter circumstance can be decisive in demonstrating that the microwave radiation of the ionosphere is biologically effective. In fact, numerous experimental and theoretical papers on studies of the mechanisms by which millimeter and centimeter radiation acts on a living organism emphasize the resonance character of the response of biological cells and erythrocytes to such irradiation. So, there are several works about the theoretical and experimental resonance of living systems: biological cell at the $f = 41.782 \cdot 10^9 \text{ Hz}$ ($\lambda = 7.2 \text{ mm}$) and $f = 83.564 \cdot 10^9 \text{ Hz}$ ($\lambda = 3.6 \text{ mm}$) [20]; DNA-spirale at the $f = 4 \cdot 10^{10} \text{ Hz}$ ($\lambda = 7.5 \text{ mm}$) [21]; molecule DNA at the $f = 10^9 \text{ Hz}$ ($\lambda = 3 \text{ dm}$) [22], molecule RNA at the $f = 10^9 \text{ Hz}$ ($\lambda = 3 \text{ dm}$) [22], cellular membrane at the $f = 10^{10} - 10^{11} \text{ Hz}$ ($\lambda = 3 \text{ cm} - 3 \text{ mm}$) [22], human erythrocytes at the $f = 10^{10} \text{ Hz}$ ($\lambda = 3 \text{ cm}$) [23]. It is very important that experimental Δf less than $10^{-3} \div 10^{-4} f$ [21]. Consequently, not only cells of the human organism, but also the blood, have resonance microwave frequencies at which the Rydberg ionosphere excited by flares and magnetic storms radiates. The explanation of how flares and storms act on cardiovascular patients follows from this. Thus, the influence of geomagnetic perturbations on the capillary circulation in patients of ischemic disease of the heart [24] on the day of a magnetic storm and the influence of solar flares and magnetic storms on patients with vascular pathology of the heart and brain [25]. are directly explained by the action of Rydberg rf radiations on the blood, including an increase of the viscosity and deformability of the erythrocytes.

The influence on the blood of a hypothetical signal associated with solar activity and manifested in the period of a flare on the sun and during the subsequent geomagnetic storm (in terms of the statistics of cardiovascular diseases) was discussed in [26]. Of course, these questions were discussed earlier by A. L. Tchijevsky. He proposed in this case that Agent X is (among other things) “electric vibrations of a definite frequency” [27]. and later that the agent of the action of solar activity “is in particular millimeter radiation” [28]. Recently Russian scientists [25] have discovered that the reason that flares on the Sun and following geomagnetic storms have influence the cardiovascular system lies in the change to the physical attributes of the blood. During solar flares changes are experienced in human blood viscosity, red corpuscle proportion in the blood, in the concentration of fibrinogen and the aggregation of blood corpuscles and platelets. These processes take place differently in healthy and meteo-dependent people with cardiovascular problems. In the latter, the blood thickens when magnetic disturbance on the Sun reach the Earth. In the case of healthy people, the organism prepares for the event two days before its advent, immediately after a solar flare. The microwave radioemission have the resonances at the spectral range $10^9 - 10^{12} \text{ Hz}$ at the biological cells and membranes, DNA and RNA, human erythrocytes, and this fact can explain the extremely small threshold for influence of

ionospheric radioemission at the monochromatic (characteristic) Rydberg transitions on biological objects. We propose the next scheme of the heliogeobiocorrelations: see Fig. During of high solar activity specially flares at the Sun and also large geomagnetic activity (magnetic storms) there are increased fluxes of EUV and X-rays and precipitating particles from geomagnetosphere, during magnetic storms, which generate the additional ionization of terrestrial ionosphere. This ionization results in production of photoelectrons and secondary electrons and especially Auger electrons. Rydberg excitation of atoms and molecules by these electrons generate microwave monochromatic radiation: (mm, cm, dm), which can produce the resonance reaction of living systems [20-23] during “unfavorable days” for sick people. It is important that microwave radiation in the system that we proposed is capable of acting as the carrier frequency, with modulation by infrasound and internal acoustic-gravity waves of the upper atmosphere, as well as by vibrations of the background electromagnetic field (Alfven and Schuman resonances at the terrestrial ionosphere), including in the region of biorhythms. This amplifies the influence of low-frequency vibrations of the background electromagnetic field, with its high biological efficiency but low energetics of its action [29]. especially because of the surprisingly strong action on biological objects from the side of microwave radiation [1].

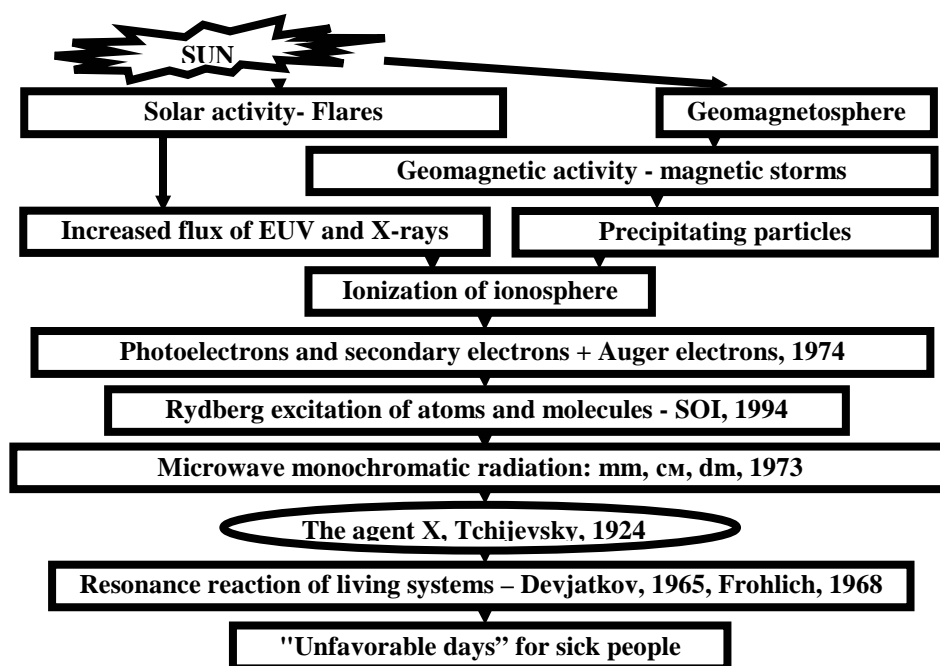

Fig. Biological effects of solar activity and Rydberg states.

There are numerous experimental confirmations that microwave radiation has a biological effect. From the aggregate of such studies, it is possible to expect uniquely low levels of threshold action, all the way to 10^{-15} W/cm², which is close to the thresholds of perception of vision and hearing [1]. There are a number of considerations in favor of the reliability of such anomalously low threshold levels:

- Fixed action through acupuncture points makes it possible to speak of the possibility of reducing the threshold in actual laboratory experiments.
- Low-frequency modulation of microwave radiation (including in the range of biorhythms) can reduce the action threshold of this radiation.
- When determining spectral resonances, a contribution of the inaccuracy of the resonance is possible when laboratory sources of microwaves are used.
- The contribution of a synergetic effect when several factors are combined (for example, in the period of a geomagnetic storm, microwave radiation of the ionosphere and storm-induced variations of the geomagnetic field become active).
- The appearance of a synergetic effect from the reaction to an external stimulus (for example, a solar flare or magnetic storm) simultaneously of several individuals associating with each other in this case and influencing each other (including via biomagnetism [30]) under the action (in the case under discussion) of sporadic microwave radiation of the ionosphere.

There is an extremely nontrivial effect for the case of a geomagnetic storm, and taking this into account can fundamentally alter the technique and treatment of numerous experiments on magnetobiology. Actually, unlike the standard understanding of the changes of the geomagnetic field during a storm (with a maximum at

the center of the main phase), the precipitation of particles from the radiation belts that accompany these changes experience sharp attenuations (to the recording threshold in the course of 1.5–3 h) at the beginning and end of the main phase. Only at the center of the main phase at middle latitudes in 2–4 h do they actually reach the maximum values – to the level of auroral precipitations [31, 32].

Thus, the mapping of a biophysical experiment on magnetobiology to the values of the generally used indices of geomagnetic activity that semi-quantitatively describe the variation of the earth's magnetic field (Kp , Ap , or Dst), as it is usually done, does not perfectly reflect the intensity of the corpuscular precipitation into the ionosphere in the period of a magnetic storm and hence does not correspond to the intensity level of sporadic microwave radiation of the ionosphere. This may be associated with the appearance of null results when modelling the conditions of a magnetic storm in laboratory experiments on biological objects. The papers [2, 3], showed that it is the microwave radiation of the ionosphere that must play the main role in the biospheric effect of a magnetic storm. This is confirmed by the increase of the probability of phenomena detected in various statistical studies of the effects of a magnetic storm in medical indices among people [33–35] concurrent with the period of the storm and also for 24–48 h after the storm, when variations in the geomagnetic field no longer exist. At the same time, the experimental fact is well established that the fluxes of corpuscles that pour out in just this time period increase after a storm ([32], p. 290). Incidentally, it is noteworthy in a number of such papers on the statistics of medical cases that the maximum of the effect occurs two days before the storm. [33, 35]. A flare occurs on the sun at just this time [2, 3, 32], and sporadic microwave radiation of the ionosphere also is observed [4–6, 14–17]. A direct correlation has been recorded [36] with solar x-ray flares in the statistics of medical events.

We will discuss more closely at the energy aspect of the problem of how the sporadic microwave (Rydberg) radiation of the ionosphere affects the biosphere and the lower atmosphere. Radiant energy from the sun with a flux density of 1367 W/m^2 reaches the earth's surface, and about 10^{-2} W/m^2 (all of the solar flux of soft x rays and UV radiation with a wavelength of $\lambda < 134 \text{ nm}$, including the L_α line of the hydrogen atom) is absorbed in the ionosphere under quiet heliogeophysical conditions. However, the ratio of the value of absorbed energy per unit mass of atmospheric gas is substantially different: 10^{-3} W/g in the ionosphere, and $7 \cdot 10^{-5} \text{ W/g}$ at the bottom of the troposphere. Thus, per unit mass of atmospheric gas or per one atomic-molecular particle of this gas, an order of magnitude more electromagnetic energy reaches the ionosphere from the sun than reaches the lower layers of the atmosphere. This ratio is still greater in periods of solar flares and geomagnetic storms. The greater part of the energy of the solar EUV radiation and soft x rays with wavelength $\lambda < 50 \text{ nm}$ (capable of producing energetic photoelectrons) generates microwave radiation of the ionosphere from the Rydberg levels of all the atmospheric gases, including the minor components. This generation is supplemented by the action of fluxes of charged particles in the auroral zone under virtually any conditions of heliogeophysical activity. The fluxes of short-wavelength solar radiation double (in the spectral region $\lambda < 120 \text{ nm}$) during periods of flares on the sun, and the fluxes of precipitated electrons increase by a factor of 100 or more during geomagnetic storms, not only at high but at middle latitudes. The energy of the electron fluxes precipitated into the upper atmosphere in this case is about a factor of 50 greater than the energy of the ionizing radiation of the quiet sun. It is important that the energy flux of the microwave radiation of the ionosphere completely reaches the earth's surface. We can estimate the energy flux of the sporadic microwave radiation of the ionosphere recorded in [5]. It is important that the radiation signal of the ionosphere exceeded the intensity of the rf flux from the quiet sun by a factor of 2–40 (at a wavelength of $\lambda = 50 \text{ cm}$), where the latter equals $(4\text{--}6) \cdot 10^{-21} \text{ W cm}^{-2} \text{ m}^{-1}$ ([32], p. 13). The width of the surge reached 1 GHz. The flux of ionospheric microwave radiation of the ionosphere at $\lambda = 50 \text{ cm}$ in the period of a solar flare is then (according to the data of the measurements of [5]) $(3\text{--}70) \cdot 10^{-16} \text{ W cm}^{-2}$.

This is orders of magnitude greater than the sensitivity threshold of biological objects to microwaves [1] Thus the "Porog" generator [37] for medical purposes, which works efficiently in a wide range of microwaves from superhigh to extremely high frequencies, provides a spectral power density level of $10^{-16} - 10^{-18} \text{ W cm}^{-2} \text{ Hz}^{-1}$, i.e., an even smaller value. At the same time, a further decrease of the output power of devices with a monochromatic signal (we recall that, according to [2, 3], the microwave radiation of the ionosphere in Rydberg transitions has indeed a monochromatic character) all the way to $10^{-10} - 10^{-12} \text{ W}$, and noise to $10^{-18} - 10^{-20} \text{ W cm}^{-2} \text{ Hz}^{-1}$ [1], does not reduce the efficiency of the treatment. Moreover, such radical reductions of the output power to the level of counted quanta even increase this efficiency. In [37] pointed out that an explanation of this effect can be found by using a quantum-mechanical approach. When the energy of the entire spectrum of sporadic rf radiation of the ionosphere is taken into account, the threshold value for biological objects ($10^{-16} - 10^{-17} \text{ W cm}^{-2}$ [1]) can be exceeded even by a factor of 10–100. The ratio of the energies dissipated in the ionosphere when there is a medium solar flare and during a geomagnetic storm shows that the flux of microwave radiation can be factor of 10–100 greater in intensity in the period of a magnetic storm. In this case, the radiation in the centimeter and decimeter ranges can now exceed $10^{-11} - 10^{-12} \text{ W cm}^{-2}$. On the other hand, a calculation of the excitation rates of the Rydberg states of the oxygen atom [8] gave a value of about $10^9 \text{ particles cm}^{-2} \text{ sec}^{-1}$ in a column of the ionosphere during the period of a medium class-2B solar flare. Then, for values of the quantum energy in the centimeter range of $2 \cdot 10^{-23}$ (for $\lambda = 1 \text{ cm}$) – $2 \cdot 10^{-24} \text{ J}$ (for $\lambda = 10 \text{ cm}$) in this

column in ten allowed transitions, we have a flux density of microwave radiation of $2 \cdot 10^{-13} - 2 \cdot 10^{-14} \text{ W cm}^{-2}$. This flux density is the lower limit for transitions with $\Delta n=1$ (only for $\Delta l=1$), i.e., those of the type $n', l'=n'-1 \rightarrow n'-1, l'=n'-2$, where $n'=11-20$ for an oxygen atom. This value increases to $10^{-11} - 10^{-12} \text{ W cm}^{-2}$ during a magnetic storm. Because the densities of oxygen atoms and nitrogen molecules are about equal at an altitude of about 200 km, where, according to [8], there is a maximum of the altitude profiles of the Rydberg excitation rates, and recalling the identical character of the allowed radiative transitions in highly excited (hydrogen-like) atoms and diatomic molecules, it should be expected that the total flux of sporadic rf radiation, taking into account the nitrogen molecules, is approximately doubled [38].

Our energy estimates, without claiming to be complete, show that the experimentally observed sporadic rf radiation of the ionosphere in the period of solar flares and geomagnetic storms is well explained by the energetics of the allowed microwave transitions from the Rydberg excited states of the main gases of the upper atmosphere at altitudes of about 200 km – the oxygen atom and the nitrogen molecule. Thus, the resulting energies of the microwave radiation flux of the ionosphere make it possible to regard this radiation as the main agent in heliogeobiocorrelation effects. According to [2, 39], the microwave radiation itself mainly provides the energy component of the effect, and its modulation by low-frequency oscillations of the electromagnetic and infrasound geomagnetic fields provides the information component. Laboratory experiments in which modulated microwave radiation acts on biological objects show that it is substantially stronger than microwaves with constant intensity. The effect of modulation is most pronounced at lower intensity levels of the microwave flux and also depends on the initial state of the biological system.

Conclusion

Ways of experimentally checking the possible role of the microwave radiation of the earth's ionosphere in heliogeobiocorrelations have been considered, taking into account the variability of its intensity at the different phases of a geomagnetic storm. Energy estimates are presented for the density of such a flux during periods of a moderate solar flare and a magnetic storm, reaching values of $10^{-11} \text{ W cm}^{-2}$. It follows from what has been said that it is necessary to provide constant monitoring of the intensity and spectrum of the microwave radiation of the earth's ionosphere, not only in terms of a methodological improvement of biophysical experiments under conditions of elevated solar and especially geomagnetic activity but also possibly for recording the level of "unfavorability" of the heliogeophysical situation. The medical and biological mechanisms of this problem should be considered, taking into account the phenomenon of stochastic resonance [1], where the background microwave radiation of the ionosphere (before a storm and a flare) plays the role of the noise component. The same phenomenon can be significant in studies of the influence of the microwave frequencies of cellular telephones [38]. Here the role of the noise signal, which sharply increases in the period of solar flares and magnetic storms, will be played by the ionospheric microwave radiation. Since it is very variable, the possible resulting medical effect from cellular telephones and ionospheric sporadic radiations significantly varies in magnitude, and this creates indeterminacy when it is studied. The phenomenon of dissipative resonance can also be relevant to the study of these problems.

There are also other problems in ionospheric and atmospheric physics, biophysics and medicine concerning the investigations of the ionospheric Rydberg excitation role:

- determination of the real spectral distributions for Rydberg ionospheric emission at all transparency windows;
- determination of the perception threshold for the characteristic sharp-resonance microwave Rydberg emission for healthy and sick persons.

These problems can be solved at several Russian institutes by support of the International Science and Technology Center [9, 10, 39].

Abstract

Previous our works have shown that magnetized physiological solution (MPS) has dual effect on heart muscle contractility: from one hand it leads to muscle relaxation, from the other hand- it stimulates the frequency of heart contractility. If the first effect is explained by the activation of $\text{Na}^+/\text{Ca}^{2+}$ exchanger, then the mechanism of the second effect is still unclear. It is known that the magnetization of aqua solutions leads to the elevation of the concentration of hydrogen peroxide (H_2O_2) and the later is suggested as one of the possible candidates through which the biological effect of MPS is realized. The purpose of our work was to check this hypothesis for which the comparative study of the effects of MPS and H_2O_2 on isolated and intra-cordially perfused snail heart muscle contractility and intracellular messenger contents were performed.

It was shown that MPS and H_2O_2 have the following synergic effects: it depresses the Na^+/K^+ pump-induced relaxation, intracellular cAMP/cGMP contents and ^{45}Ca -uptake and leads to cell dehydration. It is suggested that the H_2O_2 -induced activation of cyclic nucleotide-dependent $\text{Na}^+/\text{Ca}^{2+}$ exchanger has pivotal role in MPS-induced stimulation of heart contractility; however, the nature of this mechanism could be the subject for future investigations.

Introduction

At present the biological effect of magnetized physiological solution (MPS) on different cells and organisms can be considered as proven fact (Klassen 1982; Ayrapetyan 2006). But the nature of the messenger transferring the signal of EMF-induced water structural changes to the metabolic cascade is not clear yet. By previous our works have shown that MPS has dual effect on heart muscle contractility: from one hand it leads to muscle relaxation, from the other hand- it stimulates the frequency of heart contractility. If the relaxing effect of MPS on heart muscle could be explained by the activation of cGMP-dependant Ca efflux bringing to the deflection of intracellular Ca ions and reactivation of Na^+/K^+ pump (Ayrapetyan et al., 2005), the stimulatory mechanism of the MPS on heart beating is still unclear. As the water molecule dissociation is the most variable water property, it is suggested that the magnetization of water could change the quantity and quality of its dissociation products which are potential messengers through which the biological effect of SMF and EMF on cells could be realized (Ayrapetyan et al. 1994). By previous our study was shown that SMF and ELF EMF has depressing effect on specific electrical conductivity (SEC), It was also shown that the depressing effect of LF EMF on water SEC as well as its biological effects on various cells are most pronounced at frequency of 4 Hz (Stepanian et al. 1999; Ayrapetyan 2006).

Therefore, it is suggesting that the H_2O_2 could serve as one of the most reliable candidate for the messenger transferring EMF-induced water structure changes to cell metabolic cascades (Klassen 1982; Bistolfi 1991). For testing this hypothesis the comparative study of the effects of magnetized and H_2O_2 containing physiological solution (PS) on heart muscle contractility and ^{45}Ca uptake by muscle was performed.

The isolated and intra cordially perfused snail heart muscles, which is able to contract *in vitro* state for more than 24 hours (Azatian et al., 1998), was chosen as an experimental model for the present study.

Methods

Removed snail (*Helix pomatia*) hearts were cannulated and suspended in bath with physiological solution (PS) for snails that contains (in mM): NaCl (80), KCl (4), CaCl₂ (7), Tris-HCl (5), pH 7.5. Continuously intra- and extra-heart perfusion with PS was applied. The intra cordial pressure was controlled by keeping the perfusion solution in reservoirs vessel at a constant level.

The transducer was fixed to the bottom of the heart by a silk suture. To monitor the heart contraction with the electrical signals for subsequent recording with a computer a special setup was constructed, which is schematically presented in Figure 1.

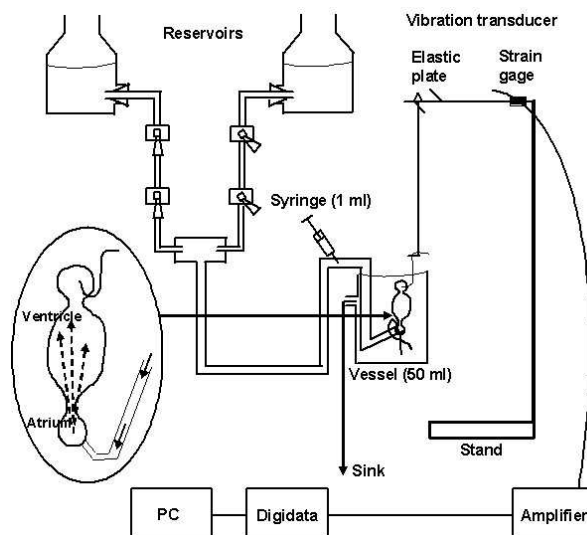

Figure 1. The setup for the registration of heart muscle contractility. Heart contractions were recorded isotonicly and displayed on PC through Digidata 1322A.

The up and down movements of the baseline of records showed the heart contraction and relaxation, correspondingly. Usually, after heart isolation from the snail, its cannulation and suspension in bath with normal PS, its contraction stops in systole phase (which can be detected visually) or has irregular bursting with short amplitudes of contractions which sometimes could continue 1-2 hours, and then it is gradually relaxed and starts its regular contractions.

The PS treatment by Static Magnetic Field (SMF) was performed by the method described earlier (Ayrapetyan et al. 1994a). PS in a 20 ml glass chamber (50x30x15 mm) was exposed to SMF at intensities of 27 mT generated by a strong magnet for 60 minutes. The magnetic field was homogeneous within the gap in the centre of the magnet (the size of the gap varied from 0 to 15 cm, and at 50 mT the field varied by no more than 5% within a sphere with a diameter of 6 cm. Thus, the size of the vessel was small relative to the size of the homogeneous region). The background of magnetic field in the area of experimental setup in the laboratory, due to the 60 Hz electricity system, was less than 0.001 mT.

The magnetic field intensity was measured with a Teslometer W1-8 (Armenian Radiophysical Institute). This instrument measured magnetic fields in the range 10^{-3} to 1.6 T ($\pm 5\%$). This magnetic induction converter was a crystal type X511-1, $1.5 \times 0.2 \text{ mm}^2$ and was fixed on nonmagnetized material (PX13-1).

The sham treatment of PS was performed on the same table and in a same 20 ml glass chamber located at same geometric place, i.e. the sham exposed PS was in the same environmental medium excluding SMF (the static magnet was moved away from the exposure table for ~10m). The both sham and SMF exposed solutions were taken from the same container of stock solution, which was preliminary kept in water bath with stable temperature ($21 \pm 0.5^\circ \text{C}$) during no less than one hour. The temperature of the heart incubated in the chamber was continuously recorded by needle-type thermometer having sensitivity of $\pm 0.1^\circ \text{C}$. The room temperature was 22°C .

In physiological experiments only the reversible effect of MPS-induced changes of heart contractility (frequency, amplitudes and basic line) were considered as a reliable, i.e. when after replacing the MPS by sham exposed solutions, the initial activity of the heart muscle was restored. For each individual heart muscle the number of repetitions of such protocol was varied from 1 to 10 depending on the duration of stable heart muscle contractility *in vitro*, which for some preparations could prolong until ~24 hours.

The stock solution (10^{-2} M) of H_2O_2 was prepared each day by diluting 3% H_2O_2 by physiological solution and protected it from light to minimize its photo-degradation. H_2O_2 was added to the intra-cordially perfused solution to a final concentration from 10^{-4} to 10^{-12} M . All the experiments were carried out at $18 \pm 0.5^\circ \text{C}$.

⁴⁵Ca uptake by muscles incubated in normal and magnetized PS was measured by ⁴⁵Ca isotope having specific activity: 0.185-1.85GBq/mg Ca, 5-50mCi/mg Ca (Amersham Life Science production). Control and experimental groups contained per 10 hearts each(total n=40) Isolated hearts were incubated in four plastic tubes with control and magnetized normal or K-free solutions containing ⁴⁵Ca isotopes (0,45 mCi/ml). Then hearts were washed three times per 5min with cold normal or K-free PS (where 4mM KCl was replaced by 4mM NaCl) to remove isotope from the extra cellular spaces. Radioactivity was measured using a liquid scintillation spectrometer (production of Packard TRI-CARB Canberra Cambridge Company) and calculated as pM/mg of wet weight.

The mean value, standard deviations, and the statistical probability, determined by Student Test were calculated with the help of computer program Sigma Plot (Version 8.02A).

Results

For estimating the role of H₂O₂ in realization of biological effect of MPS on heart contractility the dose-dependent effect of H₂O₂ on heart contractility was studied in normal and K⁺-free solution. As seen in Figure 2A the low concentrations (10⁻¹²- 10⁻¹⁰ M) of H₂O₂ had elevation effect on amplitude of heart contractility, while at higher concentrations (>10⁻⁷ M) this amplitude was depressed.

In order to estimate the role of electrogenic Na⁺-K⁺ pump in H₂O₂-induced effect on heart contractility, similar experiments were repeated in K-free solutions, when Na⁺-K⁺ pump is in inactive state (Figure 2B). It was known that K ions removal from extra cellular medium led to the inactivation of Na⁺-K⁺ pump, and the restoration of K ions in the medium caused the reactivation of the pump leading to hyper polarization of the cell membrane (Thomas, 1972).

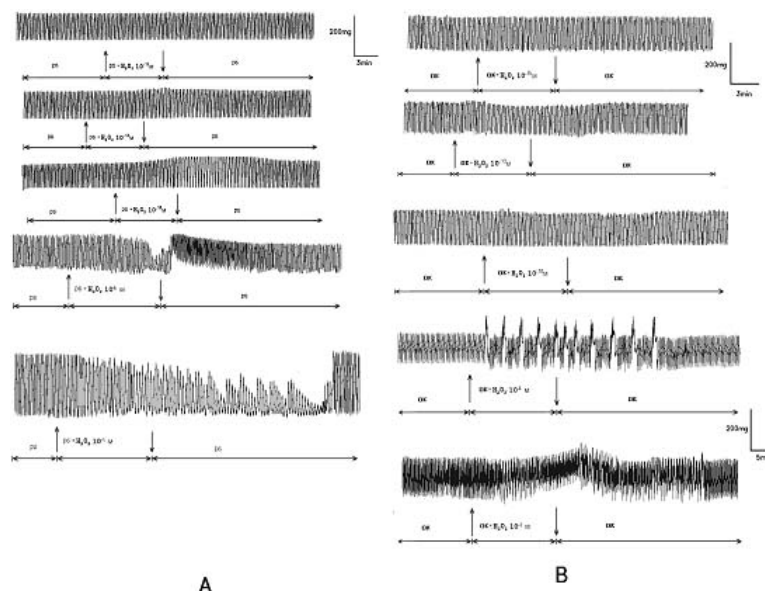

Figure 2. The dose-dependent effect of H₂O₂ on heart muscle contractility in normal (A) and K-free (B) PS.

In K-free medium the sensitivity of heart contractions to H₂O₂ was increased compared to those in normal PS (Figure 2A). If the minimal concentration of H₂O₂ in normal PS able to modulate the heart contractility is 10⁻¹² M, in K-free solution it was 10⁻¹³ M. Previously it was shown that Na⁺-K⁺ pump activation leads to the inhibition of heart beating (Azatyan et al., 1998). At the same time it was shown that this effect disappeared after perfusion of heart muscle by MPS (Ayrapetyan et al., 2005). In order to find out whether this effect is due to the H₂O₂ formation in MPS, the dose-dependent effect of H₂O₂-containing K-free PS on Na⁺-K⁺ pump-induced transit inhibition of heart beating was studied (Figure 3A).

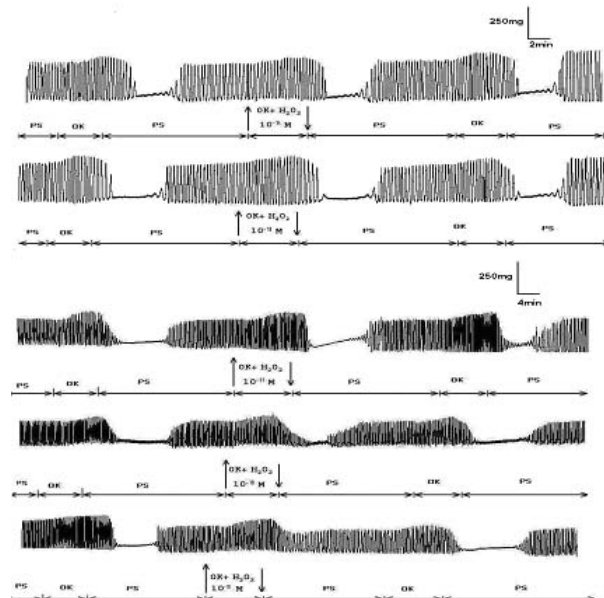

Figure 3. The dose-dependent effect of hydrogen peroxide in K-free solution on Na-K pump-induced transient inhibition of heart muscle beating.

It is known that the muscle incubation in K-free solution leads to the increase of intracellular Na ion concentration because of inactivation of $\text{Na}^+\text{-K}^+$ pump and its re-incubation in normal K-containing medium, the pump activation was accompanied by depression of heart contractility (Azatyan et al., 1998). As can be seen in Figure 3 the muscle incubation in 10^{-10} M H_2O_2 containing K-free medium in period of pump-induced inhibition of heart beating, the small amplitude of vibration of heart muscle appeared, while in case of 10^{-9} M H_2O_2 this pump-induced transit inhibition of heart beating fully disappeared. Similar effect was obtained when the Na enrichment of muscle was performed in normal K-free and then was re-incubated in H_2O_2 -containing normal PS (Figure 4).

Figure 4. The dose-dependent effect of hydrogen peroxide in normal PS on Na-K pump-induced transient inhibition of heart muscle beating.

H₂O₂ EFFECT ON SNAIL HEART MUSCLE CONTRACTILITY

Thus, the H₂O₂-induced stimulation of heart muscle contractility in period of pump-induced transit inhibition of heart beating is very similar to the effect of MPS (Figure 5).

Figure 5. The effects of magnetized PS (upper) and 10^{-8} M hydrogen peroxide (lower) on Na-K pump-induced transient inhibition of heart muscle beating.

As intracellular Ca ions concentration has pivotal role in muscle contractility in the next series experiments the comparative study EMF –treated PS and H₂O₂ on ⁴⁵Ca uptake by muscle was study in Na⁺-K⁺ pump active (in normal PS) and inactive state (in K-free medium).

Figure 6. The effect of MV- and EMF-treated PS (A) and K-free PS (B) in ⁴⁵Ca uptake by heart muscles (expressed in %, compared to their control value).

As can be seen in Figure 6 the both EMF-treated and H₂O₂- containing solutions have activation effect on Ca uptake in normal PS, while in K-free solution this effect was reversed, i.d. the both factors have inhibitory effect on ⁴⁵Ca uptake.

Summary

Previously it was shown that MPS had dual effect on heart muscle contractility: relaxation and stimulation of pacemaker activity (Ayrapetyan et al., 2005). If the relaxation effect of MPS on heart muscle was explained by Ca-deflection of muscle in result of activation of cGMP-dependent Na⁺/Ca²⁺ exchanger, the mechanism of MPS-induced stimulation of heart contractility in period of pump-induced inhibition of heart beating still remains unclear. At the same time in literature the experimental data showing the H₂O₂ generation in water medium upon the effect of magnetic fields are available (Klassen 1982). The obtained data on the synergic effects of H₂O₂ and MPS on Na⁺-K⁺ pump-induced muscle relaxation following the pre-incubation of the heart in K-free medium allow us to conclude that MPS-induced stimulation of heart contractility is due to the H₂O₂ formation in MPS. The data that the activation effects of H₂O₂ and MPS on Na⁺-K⁺ pump-induced muscle relaxation following the pre-incubation of the heart are present in both cases: in K-free medium or in case of heart re-incubation in K-containing solutions treated by EMF or containing H₂O₂, i.e. when the pump was in active and inactive states, correspondingly, could serve as an evidence on the pump-independent stimulation effects of MPS and H₂O₂ on heart. It is strange that this effect does not depend on Ca metabolisms: in spite that the MPS and H₂O₂ in normal PS have activation and in K-free solution- inactivation effects on Ca uptake, in

both cases MPS and H_2O_2 have stimulation effects on heart muscle contractility.

Thus, the main conclusion from the presented data is that H_2O_2 is one of important messenger through which the biological effect of ELF EMF on heart muscle contractility is realized.

EFFECTS OF SURFACE CHARGE AND DC EF FIELDS ON CELLS

RICHARD H.W. FUNK THOMAS K. MONSEES

**DEPARTMENT OF ANATOMY, UNIVERSITY OF TECHNOLOGY,
DRESDEN, GERMANY**

Abstract

In this paper we will concentrate on the effects of surface charge patterns of surfaces which are the substrate for cell adhesion and migration as well as on the effects of static direct current electric (dc EF) fields. Findings in the literature and own results will be discussed.

Results and Discussion

In vitro, the application of static dc EF of physiological power causes directed movement and guiding of bone cells and various other cell types. This phenomenon is called electrotaxis (or galvanotaxis) [Zhao et al., 2002]. In vitro, at field strengths of 0.1–10 V/cm, cells often migrate to the cathode (neural crest cells, fibroblasts, keratinocytes, chondrocytes, rat prostate cancer cells and many epithelial cell types). Only few cell types move to the anode (corneal endothelial cells, bovine lens epithelium, human granulocytes and human vascular endothelial cells). Speed and direction of the movement are voltage dependent: human vascular endothelial cells migrate towards the anode, whereas bovine aortic endothelial cells move to the cathode. During movement, ruffled membranes, lamellipodia and filopodia are formed preferentially in the direction of the anticipated electrotaxis migration [Sulik et al., 1992; Zhao et al., 2002]. Several cell types changed their initial direction of movement by 180° when the current polarity was reversed [Soong et al., 1990; Brown and Loew, 1994; Chao et al., 2000; Wang et al., 2000b]. EF-induced cell migration can be modified by proteins of the ECM. For example, highest cathodal migration was noticed with keratinocytes plated on collagen and plastic, whereas lowest locomotion occurred on laminin. Cell response on fibronectin was in between the two. Similar results were observed for epithelial cell electrotaxis on laminin or fibronectin coatings. Sun et al. [2004] noticed directed movement of fibroblast migration at a field strength as low as 0.1 V/cm in 3-dimensional collagen gels, but not in conventional 2-dimensional cultures. Thus, 3-dimensional conditions seem to reflect the in vivo situation, where dc EF of 0.1 – 0.2 V/cm occur that are important for embryonic development [Nuccitelli, 2003]. Several steps are involved in cell migration: (1) due to their connection to several adaptor proteins, the growing of actin filaments will push the cell membrane in the direction of movement; (2) formation of focal contacts at the leading edge, i.e. specific bindings via membrane bound integrin receptors and ECM proteins, which will also influence several signaling pathways and structural elements of adhesion; (3) focalized proteolysis by recruitment of surface proteases to ECM contacts; (4) cell contraction driven by myosin II binding to actin filaments, and (5) disassembly of focal contacts and detachment of the trailing edge. Many of these events have also been observed in EF-induced cell movement.

If one looks at the level of a single cell in an EF, then elongation of the cell body and alignment of its long axis perpendicular to the field lines are striking phenomena. This behavior was first described for *Xenopus* myoblasts and thereafter observed in many other cell types including fibroblasts, osteoblasts, chondrocytes, keratinocytes, endothelial and epithelial cells. As dc EF trigger migration and orientation, cells must orchestrate cytoskeletal elements and shape in response to this trigger.

An accumulation of actin stress fibers was observed on the cathodal (leading) edge of several cell types [Sulik et al., 1992; Zhao et al., 2002]. Often, the total amount of filamentous actin transiently increased and became

selectively enriched in the leading lamellipodia. Here, focal contacts were also accumulated. Recent experiments showed that EF-mediated motility in fibroblasts can be halted by inhibition of microfilament dynamics, whereas inhibition of microtubules only reduced migration speed [Finkelstein et al., 2004]. Membrane extensions from the trailing edge of chondrocytes were concomitantly retracted [Chao et al., 2000]. Also osteoblasts and osteoblast-like cells undergo processes of retraction and elongation ultimately resulting in the realignment of the long cellular axis perpendicular to the EF [Curtze et al., 2004]. These authors presented a theory to explain the EF-induced perpendicular orientation of cells: cell attachment is made by the adhesive interaction of ECM proteins with a group of transmembrane adhesion receptors, the integrins. After binding to their specific ligands, integrins cluster within the membrane and recruit several adaptor and signaling proteins to form focal contacts (also called focal adhesions) that anchor the ends of intracellular actin filaments (stress fibers). Vinculin is one of these adaptor proteins and is frequently used as a marker for integrin-based focal contacts. As stated here and elsewhere [Jaffe, 1977; Poo, 1981], dc EF trigger the separation of charged membrane components. In order to achieve perpendicular elongation, a certain self-induced cytoskeletal tension is required along the axis. Assuming that all free integrin receptors drift towards an electrode and accumulate there, the cell is only able to connect to two focal adhesions and increase tension between them if they are on an axis perpendicular to the drift. Cell adhesion is a dynamic process, thus after some time, disassembly of focal contacts on the opposite side of the drift destination leads to another drift. Consequently, the cell is no longer able to maintain protrusions with the same orientation as the EF [Curtze et al., 2004].

Our experiments using corneal endothelial cells support this hypothesis: vinculin proteins, used as a marker for integrin receptors, are normally randomly distributed within the cell with a preference for the cell border. However, after dc EF application, they concentrate on two major spots of focal contacts oriented perpendicular to the EF vector. Mechanical load is also discussed as a possible transducer of EF. EF-induced effects such as dynamic changes in intracellular calcium concentration, cell traction and orientation are similar to the cellular response after mechanical stimulation [Curtze et al., 2004]. Converse flexoelectricity may thereby be a way for cells to sense small dc EF. Charged proteins in the lipid bilayer of the cell membrane repel each other, influencing membrane tension. If the charge on one side of the membrane is changed by dc EF, the membrane tension also changes, resulting in a modified curvature of the membrane. Such flexoelectric effects have already been demonstrated on voltage-clamped cells. Using traction force microscopy, Curtze et al. [2004] noticed a 5–30% increase in average traction force magnitude 10–30 s after dc EF exposure as the first detectable reaction of osteoblasts. The visible retraction phase started after 5–10 min, and then, cells subsequently elongated and oriented perpendicular to the EF lines. Traction forces at the margins tangential to the EF decreased 2–15 min after the start of EF exposure below their initial values. A mean delay of 85 s between EF application and first observable changes in Ca²⁺ levels occurred, suggesting that stretch-activated Ca²⁺ channels may be responsible for the Ca²⁺ influx. Static MF (10 T) also oriented glioblastoma cells in the presence of collagen fibers possibly due to the rearrangement of microtubules [Hirose et al., 2003].

Studies of Erskine and McCaig [1997] and Ohgaki et al. [2001] as well as our own results showed that negatively charged surfaces are a sometimes better interface for cell adhesion and further cell function than positively charged ones. Using controlled surface charge induction on implants, it was shown that the above mentioned charge densities are sufficient to alter cell growth, adhesion and phenotypic. Moreover, specific effects can be observed when cells are plated onto substrates which have been exposed to ELF EMF before plating [McLeod and Rubin, 1994]. Together, these results strongly suggest that the observed effects are associated with an alteration in absorption of charged proteins, and change in the cellular response results from the altered ‘charge environment’.

Seen ‘with the eyes of a cell’, the surface of an implant is covered with water and ions (in vivo serum, in vitro cell culture medium). Then, amino acids and proteins (especially albumin, fibronectin and vitronectin) are absorbed to the surface due to unspecific charge interactions [Vroman, 1988]. At negatively polarized (e.g., glass) and negatively charged surfaces, inorganic cations like calcium and cationic amino acids and proteins may bind to the surface, making it a suitable interface for the negatively charged surface of the cell [Ohgaki et al., 2001]. Additionally, Ca²⁺ ions are required for the formation of focal adhesions. Thus, a higher local concentration of Ca²⁺ will accelerate specific integrin receptor-mediated binding. In the next step of the attachment sequence, the cell recognizes RGD motifs (a sequence of amino acids which is important for binding processes) of surface-bound proteins, and finally, specific binding occurs at focal adhesions via integrin receptors (early and late). As the ‘missing link’ between the patterns of surface charges and special adhesion proteins described above, Botti et al. [1998] described a class of adhesion proteins that, because of their common electrostatic and structural motif,

EFFECTS OF SURFACE CHARGE AND DC EF FIELDS ON CELLS

were called 'electrotactins'. These proteins had a functional region common to cholinesterases and exhibited a special pattern of electrostatic surface potentials.

Responding to extracellular cues like EMF involves a cascade of events, transducing signals from the cell surface to the cytoskeleton. Due to the high dielectric property of the lipid bilayer membrane, externally applied dc EF will be considerably attenuated. For example, a dc EF of 5 V/cm will produce an intracellular field of only 0.5 mV/cm, which is unlikely to produce significant effects [Poo, 1981].

What is the sensor for EF gradients? A suggested mechanism is the electrophoretic mobility of charged molecules in the cell membrane in a dc EF [Jaffe, 1977; Poo, 1981]. In this respect, electroosmosis (see also above) plays a role: the imposition of a dc EF on the negatively charged cell membrane produces a flow of positive counter ions, which will result in a flow of fluid towards the cathodal site of the membrane. By this flow, a negatively charged receptor will be swept to the cathodal side of the membrane if its ζ potential is less negative than the potential of the cell surface; otherwise it will accumulate on the anodal site [Poo, 1981; McCaig et al., 2005]. The potential is the electric potential at the interface between a solid surface or membrane and a liquid. Such lateral movements and enrichments of membrane components towards the cathode have been observed in several cell types. Examples are concanavalin A and acetylcholine receptors or positively charged membrane lipids in *Xenopus* myotomal membrane [Poo, 1981], fibronectin receptor in fibroblasts [Brown and Loew, 1994], lipids and epidermal growth factor (EGF) receptor in keratinocytes [Song et al., 2002], membrane lipids or EGF and hepatocyte growth factor receptors in corneal epithelial cells [Zhao et al., 2002; McBain et al., 2003]. Thus, one can imagine that redistributed membrane molecules can be sensed inside the cell by components of the cytoskeleton and be used as an orientation cue. Some of these mechanisms have been explored in more detail. Finkelstein et al. [2004] recently demonstrated that microtubules are involved in EF-induced cell migration. Signaling molecules such as Rho GTPases and protein kinases interact with microtubules and can effectively hitchhike microtubule-based transport. In this way, they pass signals from the leading edge of the cell via the nucleus to the trailing edge. An EF induces redistribution of hepatocyte growth factor receptors and triggers the mitogen-activated protein kinase pathway downstream that is involved in epithelial cell migration [McBain et al., 2003]. Similarly, EGF receptor kinase activity and redistribution in the cell membrane are necessary for electrotaxis in keratinocytes. In chondrocytes, antagonists of the inositol phospholipid pathway were able to inhibit cathodal migration [Chao et al., 2000]. In contrast to the arising weak internal field, the externally applied dc EF can induce substantial alterations of the membrane potential. The resting potential of a nonexcitable cell is approximately -45 to -75 mV. A usual dc EF of 1–10 V/cm applied to a cell of 10 μ m in radius will hyperpolarize the membrane facing the anode by 1.5–15 mV and depolarize the cathodal site by the same amount. This is sufficient to induce several physiological effects such as changes in the levels of calcium ions [Poo, 1981; Mycielska and Djamgoz, 2004; Robinson, 1985]. In many cells, dc EF-induced migration depends on changes in intracellular Ca^{2+} concentration. Since the cytoplasm on the anode-facing site became more negative, the inward driving force of Ca^{2+} was increased at the anode, whereas that on the cathodal site decreased (passive influx). Increasing $[\text{Ca}^{2+}]$ often activates myosin light chain kinase that phosphorylates the regulatory light chain of myosin II. This in turn triggers the actin-activated myosin ATPase, a major regulator in cell contraction. In consequence, the anodal site contracts and the cell will be propelled towards the cathode. If voltage-gated Ca^{2+} channels are present, a cathode-faced membrane depolarization should open them, and the Ca^{2+} influx following this opening will cause cell migration towards the anode. The calcium waves measured were fast (22.5–50 μ m/s, i.e. faster than electroosmosis) which could possibly explain the very fast cell reactions reported in other EMF studies. However, the net movement (and direction of cell migration) depends on the balance of passive influx and voltage-gated influx of Ca^{2+} . Calcium ions are also essential for the coupling of other forms of EMF to a biological system.

In conclusion, the cell-guiding effects of static EF have a good explanation with the observations of the electrophoretic mobility of charged cell membrane molecules. However, a cascade of events must be initiated for this effect to be linked to classical biochemical pathways.

RETINAL SCANNING OF CRITICAL FUSION FREQUENCY (CFF) OF THE HUMAN EYE

MAGDY S. IBRAHIM

*DEPARTMENT OF ENGINEERING MATHEMATICS AND PHYSICS
FACULTY OF ENGINEERING, CAIRO UNIVERSITY, 12211
GIZA, EGYPT*

Abstract:

The aim of the present study is to introduce an electronic experimental setting for measuring of critical time (CT) and corresponding critical fusion frequency (CFF) for healthy subjects at different wavelengths and different acuities. The work introduces a simple measuring setting that utilizes an electronic device capable of controlling the frequency of illuminated monochromatic light source.

The investigation considered the size of the stimulus, its luminance, the distance from the eye to the fixed and movable light sources. Particular interest was given to scanning the retina for various CFF responses. The results show that, CFF has a maximum value at fovea and this value decreases nonlinearly as we move to the periphery, explanation of this results is introduced and related to cone and rod distribution at different retinal visual angle as well as the different response of cones to color.

Introduction:

Critical flicker frequency (CFF) is the transition point of an intermittent light source where the flickering light ceases and appears as a continuous light. Accordingly, it is the minimum frequency of a pulsating light source at which the light appears to be fused into continuous, rather than flickering, stimulus. There are a multitude of factors that determine our perception of flicker such as the intensity and size of the test stimulus¹.

Researches in this field are important in diagnosing by the measurements of fusion of the human eye. Braunstein² was one of the first to investigate CFF in cases of optic atrophy, optic neuritis and glaucoma. Since then measurements have shown to be sensitive to the presence of retinal or optic nerve diseases when other clinical tests remain unaffected^{3,4}.

Several factors such as the light intensity, the target size, and the luminance contrast⁵ are affecting on the CFF. Keesey⁶, illustrated that the visual target size affects flicker perception at frequencies higher than 20 Hz, CFF is known to increase with increasing target stimulus size; under 20 Hz, the sensitivity decrease with increasing target size. Delange⁷ demonstrated that for visual stimulus with a fixed temporal frequency; sensitivity to flicker increases as the amplitude of the luminance is increased.

At high frequencies, flicker sensitivity curves for different size of visual stimuli have similar shapes, Kelly⁸. This indicates the visual system responds the temporal characteristics of stimuli in a consistent fashion. At frequency higher than 20 Hz CFF thresholds decreased as target size increases. The age plays an important role, Kim⁹, showed that young people in general have higher CFF than older ones. In addition, women enjoy higher CFF than men¹⁰.

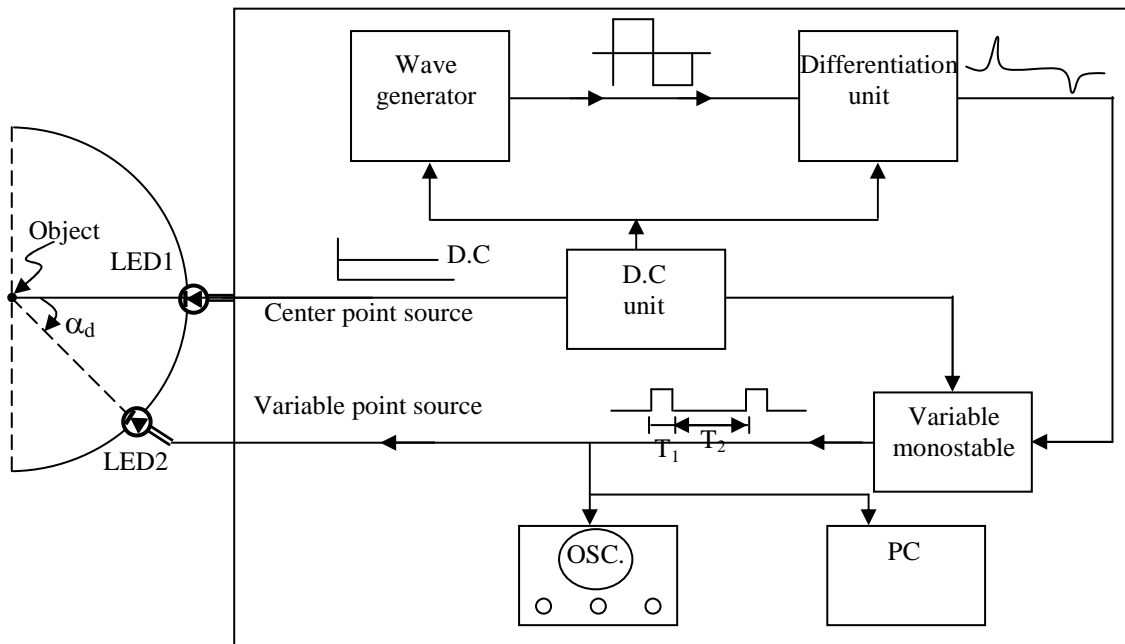

CFF is significantly higher than at the fovea when the image is projected at the fovea, also the flicker depends of the background illumination, for dark background, the CFF is lower than that for background at 50 lux¹¹. Wolfgang¹², studies the effects of the CFF at the accommodation, convergence and pupil diameter of the human eye. Toshiyuki¹³, studied the effects of illumination, distance between the eye and the light source and age on the CFF.

However, very little attention is given to the study of flickering at different point on the retina. Most of the reported literature is concerned with CFF when the image is received at the fovea. In the present work, the CFF at different locations in the visual field for different wavelengths is examined. It employs a device, which enable the researchers to obtain accurate data concerning the effect of the both locations and wavelengths on the CFF value.

Apparatus used:

An electronic device was designed so that light of several wavelengths can produced and jittered from different LEDs. The light pulses are supplied from a square wave function generator. The wave generator produces square pulse, which is differentiated electronically, and then the edge of the pulse was used to initial a rectangular wave using a monostable oscillator. This stage is necessary to control both the pulse duration (T_1) and the time interval between the successive pulses (T_2). At the end, the output of the monostable vibrator is sent to a movable LED 2 light source. The light is filtered so that only the concerned wavelengths are obtained purely.

The pulse is observed using an oscilloscope and fed to PC to record the results. The pulse duration was kept constant while the time interval between pulses varied electronically. The block diagram of electronic circuit can be shown in Figure 1.

**Figure 1**

The mechanical device consists of two stand and semi-circular arc of radius 49 cm , the length of the arc is calibrated such that the distance from the center of fixation point to any point on the arc (d) corresponds to an angle α_d which is called retinal visual angle at the center of the arc as shown in Figures 2 (a , b) .

Experimental setting for measurement of critical time
Figure 2-a Nasal and Temporal Vision of R.E

CFF OF THE HUMAN EYE

Figure 2-b Nasal and Temporal Vision of L.E

Procedure:

Ten subjects (mean age 30 ± 5 years) were examined for CFF, the visual acuity, sex, weight, occupation and the state of the health are recorded. The experimental setting is kept under dark conditions. Measurements were taken for each eye separately for each subject. The subject was asked to keep focusing on the center of the arc where a fixed light source LED 1 at the fixed wavelength is located. As the subject is focusing on this source, another source LED 2 of the same wavelength was made to slide slowly on the arc at different positions.

For each position, the light controlled from the second source is made to fluctuate electronically at different frequency, the subject was asked to tell when he sees the light continuously. At that time, the frequency of the light was determined using an oscilloscope. The value of the CFF is obtained an average value for more than six repetitions of the CFF thresholds were obtained.

The procedure was repeated for different wavelengths of $\lambda_1 = 540 \text{ nm}$, $\lambda_2 = 580 \text{ nm}$ and $\lambda_3 = 660 \text{ nm}$ at different locations on the retinal visual field for each subject. In addition, the effect of the visual acuity was investigated on the CFF thresholds.

Results:

The effects of the different wavelengths on the Critical Time (CT) are measured as shown in Figures 3 and 4. CT has a minimum value at the fovea for all wavelengths; this is because the fovea is the most region of the retina, which contains the maximum concentration of the receptors of, cons (337×10^3 cones). At the temporal side of the eye, CT increases due to the decreasing of the concentration of the cons. CT is higher throughout the periphery than the fovea CT for $\lambda_1 = 540 \text{ nm}$ is less than CT for $\lambda_2 = 580 \text{ nm}$ and for less than $\lambda_3 = 660 \text{ nm}$.

Fig . 3 - a Critical Time for R.E (Temporal)

CFF has a maximum value at fovea ($\pm 2.5^\circ$ from the visual axis) and this value decreases in the periphery, the reason of this return to the existing of different pathways long (SC) & short (LGN) CFF has a maximum value than in periphery. Also, the different rates, low (blue cone) & high (red and green cones) of neural signal causes that the CFF has a different value at different retinal visual angle, and at different wavelengths of light sources, the values of CFF at different locations of the retina for different wavelengths for right and left eyes respectively are shown in Tables 1,2.

Figure 5 shows the variation of the Critical Time (CT) with the different visual acuities at different locations of the retina. Critical Time has a minimum value at the fovea and this value is increasing at outside of the fovea. For good visual acuity (20/20), CT is minimum (CFF is maximum) than for low visual acuity (20/120). The values of CFF at different locations of visual angle for different visual acuities are shown in Table 3. In periphery, CFF values did not change almostly for different acuities.

CFF OF THE HUMAN EYE

Figure (6 - a) Visual field of R.E

Figure (6 - b) Visual field of L.E

The critical flicker frequency is often used as a measure of the current state of the optical nervous system. As such, it may be affected by several factors; internal as well as external. Internal factors concerned with the subject characteristics, such as stimulus, modulation, luminance (Intensity and area), and wavelength. There are two possible routes for the neural signal from the receptors across the optic nerve to the brain, via the lateral geniculate nuclei (LGN) or via the superior colliculus (SC) as shown in Figure 7. The presence of different pathways {long (SC) & short (LGN)} and different rates {low (Blue cone) & high (Red and Green cones)} of neural signal causes that the CFF has a different value at different retinal visual angle, and its maximum value at fovea.

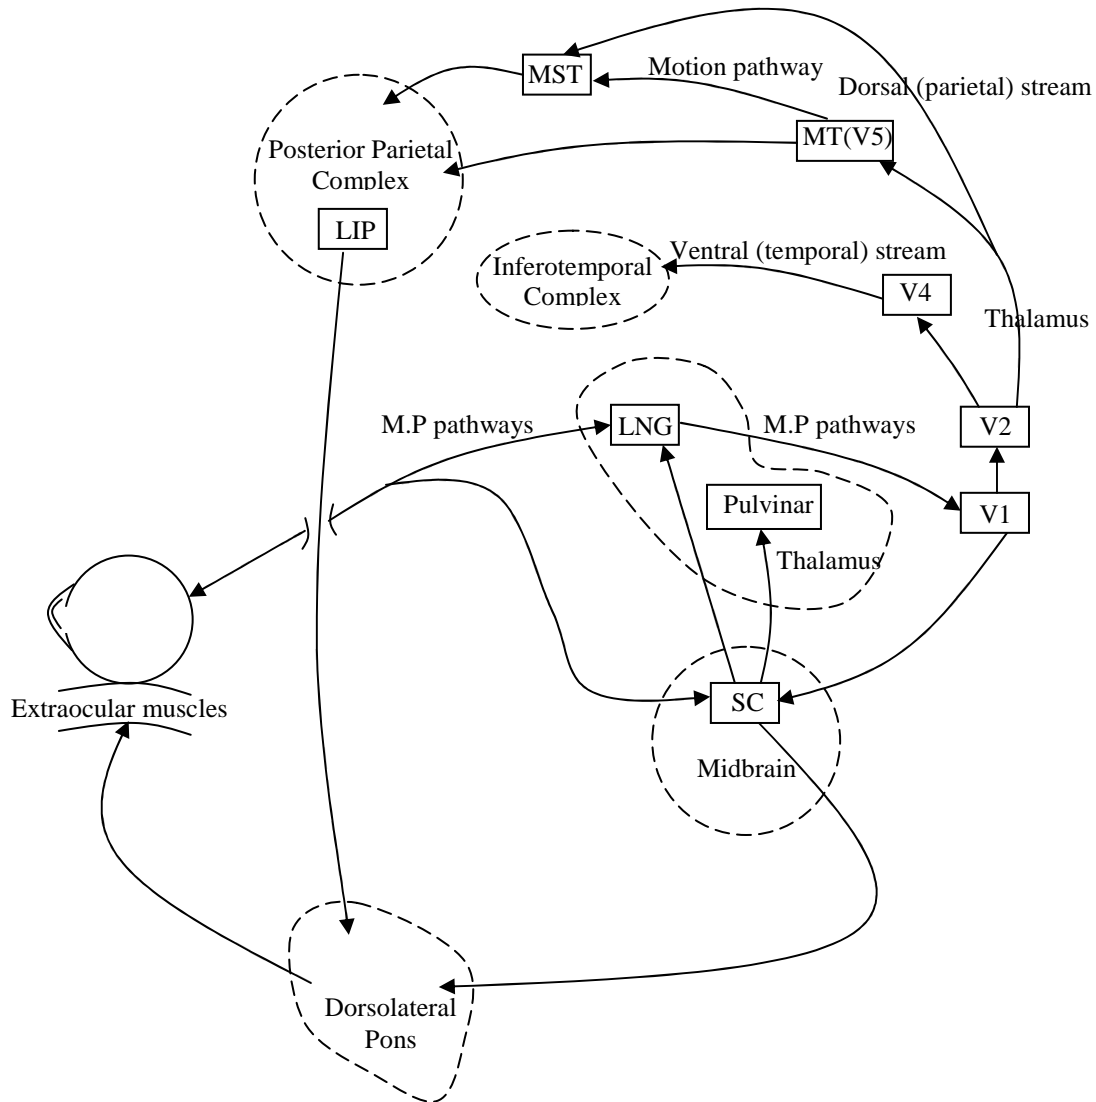

Fig. 7: The brain and the visual pathways

From the pervious results, it is clear that the retina and the occipital cortex synchronize with the flicker, and then CFF is regarded as a function of activity of both the eye and the cerebral cortex. The highest degree of cortical response that is registered when a subject is exposed to flicker is found in the occipital lobe.

Conclusion:

The precedence enables as to examine the variation of CFF with location on the retina as whole. The spatial approach overcomes the pervious literature, which concentrate on the measurement of CFF on the fovea itself. The work also examines the effect of light wavelength on the CFF at different spatial location on the retina and shows that for away from the fovea the CFF decreases.

Also the proposed electronic and mechanical setting have the advantage of simplicity and accuracy for the future work, varying wavelength may be examined and related to know diseases.

PLANAR ELLIPTICAL RING BANDPASS FILTER WITH CONTROLLED BANDWIDTH AND OPTIMAL SIZE

MAGDY. S. IBRAHIM

*DEPARTMENT OF ENGINEERING MATHEMATICS AND PHYSICS
FACULTY OF ENGINEERING , CAIRO UNIVERSITY, 12211
GIZA, EGYPT*

Abstract:

A design of a bandpass filter is presented in this paper and tuned at 2.4 GHz. The resonating element in this design is an elliptical ring with a specific width. The microstrip line is directly connected to the ring. Both the ring and the microstrip line are placed on one side of a dielectric substrate. The slotline is connected to the substrate below the ring. The slotline is electromagnetically coupled to the ring resonator.

A detailed parameter study has been performed for the proposed filter. The results show that both the bandwidth and the surface area of the filter can be controlled via controlling the width and the aspect ratio of the ring.

Introduction:

Bandpass filters play an important role in radio front-end systems. For example a bandpass filter is put immediately after the receiving antenna to reduce the susceptibility of the receiver to unwanted frequencies. Superheterodyne receivers make use of one or more intermediate frequencies with image reject bandpass filters on every intermediate frequency. A passive bandpass filter can be constructed by combining a number of elements¹. These elements can be either lumped components (such as inductors, capacitors, resistors) or distributed transmission lines². For the bandpass filter based on distributed transmission lines, any type of lines can be used (such as microstrips, coplanar waveguides, slotlines ...). Different topologies can be used to achieve the required frequency selection function of the bandpass filter. For example, parallel coupled lines³ and hairpin resonator^{4,5}.

In this paper, a new design of a bandpass filter is presented. The design is based on distributed transmission lines of the microstrip type. The resonator used takes the shape of an elliptical ring of a specific width. Two lines are coupled to this ring. The first line is of microstrip type and directly connected to the ring. The second one is of slot type and coupled electromagnetically, through the substrate, to the ring. Hence, the proposed design is perfectly planar and consists of two metal layers and one dielectric layer.

Section 2 introduces the proposed geometry of the filter. The method used for analysis is mentioned in Section 3. The steps to be followed in order to tune the proposed filter are given in Section 4. A detailed parameter study is performed in Section 5. The important conclusions are stated in Section 6.

Filter Configuration:

Figure 1 shows the proposed design for the bandpass filter. It consists of two planar metallic layers placed on both sides of a dielectric substrate. Without loss of generality, a glass substrate with dielectric constant of 6.2 and thickness of 0.7 mm is selected. This substrate is identical to that used in the multichip module with deposited thin films, MCM-D, technology⁶. The first metal layer is placed on top of the substrate. It includes a microstrip line connected to an elliptical ring resonator. Port 1 is assigned to the microstrip line. The second metal layer is placed on the other side of the substrate. Within this layer, a slotline is etched and connected to port 2. Both metal layers are assumed made up of copper with conductivity of 58×10^6 1/ Ω m and thickness of 5 μ m.

Figure 1 Geometry of the elliptical ring resonator bandpass filter

PLANAR ELLIPTICAL RING BANDPASS FILTER WITH MICROSTRIP LINE AND OPTIMAL SIZE

The proposed filter design has the advantage of allowing the antenna to be of microstrip type, and the rest of the transceiver circuit to be of slot type. This combination is attractive for many practical situations. Being of microstrip type, the integrated antenna, which will be connected to port 1, provides radiation from one side only of the substrate. This feature is desired in several wireless systems. On the other hand, the preferable technology for the rest of the system is either the slotline or the coplanar waveguide (CPW). This is due to the fact that in these technologies both the signal and the ground terminal(s) are brought in the same plane.

This simplifies the integration of shunt lumped elements and active devices and avoids the necessity of drilling via holes through the substrate. It is clear from Fig. 1 that the proposed filter design has 6 feature dimensions. These dimensions are: the minor and major radii of the elliptical ring resonator (a and b , respectively), the width of the ring t , the distance between the edge of the slotline and the center of the ring d , the width of the microstrip line W_m , and the width of the slotline W_s . Practically, the last two dimensions are adjusted to achieve specific values for the characteristic impedances of the feeding lines. Knowing the substrate properties and the resonance frequency, 2.4 GHz, the widths which correspond to 100 Ω for both lines are: $W_m = 0.21$ mm and $W_s = 0.8$ mm.

The theory of operation of the proposed bandpass filter is that at resonance, the electrical circumference of the elliptical ring equals one guided wavelength λ_g . The width of the microstrip line forming the ring, t , defines the corresponding value of the guided wavelength. The satisfaction of this condition, forces the two signal components excited from one port to travel distances of $\lambda_g/4$ and $3\lambda_g/4$ in the two branches of the ring to reach the other port. The resulting 180° phase shift is compensated by the 180° spatial opposition of the two arms at the other port, which results in an in-phase addition.

Method of Analysis:

The analysis of the proposed bandpass filter is carried out using Agilent-Momentum⁷. Momentum is a 2.5D full-wave solver based on the integral equation formulation solved using the Method of Moments. Since it is a well-known full-wave simulator validated many times in literature, it is possible to rely on its simulation results. For meshing the filter under development, mixed rectangular and triangular segments are used. Twenty five cells per wavelength combined with a narrow edge mesh are adopted.

Filter Design:

As stated in Section 2, the remaining 4 dimensions of the filter to be determined are: a , b , t , and d . The first two dimensions can be combined into one parameter called the aspect ratio of the elliptical ring resonator. This new parameter is defined as the ratio between b and a , i.e. (b/a). Knowing b/a and t , the last dimension d is determined via optimization such that the best impedance matching with the slotline is obtained. This leaves only two independent design parameters, namely b/a and t . Consequently, the design space is a 2D space. The selected range for b/a starts from 1 up to 5, while the selected range for t starts from 0.25 mm up to 0.75 mm. Outside these ranges it has been observed that the response of the filter is unsatisfactory.

The frequency response of the filter at the central point of the design space, $b/a = 3$ and $t = 0.5$ mm, is shown in Figure 2. As desired, the resonance frequency of the filter is 2.4 GHz. There are several criteria for defining the percentage bandwidth of a bandpass filter. The selected definition in this paper is $\Delta f / f_0$, where f_0 is the resonance frequency and Δf is the common frequency band which satisfies the following conditions: $|S_{11}| < -10$ dB, $|S_{21}| > -1$ dB, and $|S_{22}| < -10$ dB.

As mentioned in Section 2, once the width of the ring is defined, its circumference become available and equals to the guided wavelength of the microstrip line forming it. However, experimental iterations have shown that the ring circumference is slightly smaller than the corresponding theoretical value. This deviation is mainly due to the excitation of higher order modes around the feeding lines. For the selected width of the ring $t = 0.5$ mm and at $f = 2.4$ GHz, the guided wavelength is 60.62 mm, while the circumference of the ring is found to be 55.83 mm. Since the circumference of the elliptical ring equals $\pi(a + b)$, the specification of the aspect ratio b/a , results in determining the corresponding values for the minor and major radii, a and b , respectively.

Figure 2 S-parameters versus frequency of the proposed bandpass filter.

Parameter Study:

In this section the effect of varying the independent design parameters on the filter's geometry and response is studied. As mentioned in the previous section, the proposed filter has two independent design parameters, namely the aspect ratio b/a and the width of the elliptical ring resonator t . Of particular interest to many modern wireless systems, is the surface area occupied by the filter. There is a definite trend toward specifying severe restriction on the surface area. For our proposed design the surface area occupied by the filter can be defined as the area of the rectangular which entirely contains the ring. Referring to Figure 1, the surface area equals $(2a + t)(2b + t)$. The response of the filter is characterized by its percentage bandwidth, which is defined in Section 4.

Variation of b/a :

In this subsection the aspect ratio of the elliptical ring is continuously varied from 1 to 5. The other independent parameter t , takes three discrete values: 0.25 mm, 0.5 mm, and 0.75 mm. Figure 3 shows both the minor radius a , and the major radius b , versus the aspect ratio. It is clear from the figure that a decreases as b/a increases, while b increases. This behavior allows a and b to provide the required aspect ratio, while keeping their summation approximately constant. The approximately constant summation results in an approximately constant circumference for the ring at the corresponding value of its width. Both a and b decrease as t increases. The reason for that is the guided wavelength, and also the circumference, decreases as t increases.

Figure 3 Minor and major radii of the ring versus its aspect ratio

PLANAR ELLIPTICAL RING BANDPASS FILTER WITH MICROSTRIP LINE AND OPTIMAL SIZE

The surface area occupied by the filter is plotted in Figure 4 versus b/a at three different values of t . The figure shows that increasing the aspect ratio b/a , results in decreasing the surface area. The decrease in the surface area with the increase of the width t is expected, because of the decrease of the guided wavelength. Figure 5 shows the optimized values of d versus b/a at the selected values of t . The optimization is based on obtaining the best possible match with the slotline of port 2. It is clear from Figure 5 that as b/a increases the edge of the slotline moves continuously downward. The percentage bandwidth of the filter is plotted versus b/a , at different values of t , in Figure 6. The figure shows that the percentage bandwidth decreases as either b/a or t increases. However, the effect of varying t is more pronounced. Based on the surface area and bandwidth specifications, the designer can use Figures 3, 4, 5, and 6 to specify the corresponding values of a , b , t , and d .

Figure 4 Surface area occupied by filter versus the aspect ratio of its ring

Figure 5 Distance between the edge of the slotline and the center of the ring versus its aspect ratio

Figure 6 Percentage bandwidth of the proposed filter versus the aspect ratio of its ring

Variation of t

In order to examine the design space in the orthogonal direction, the width t of the ring is going to be varied continuously, from 0.25 mm to 0.75 mm, in this subsection. The aspect ratio b/a will be fixed at three discrete values: 1, 3, and 5. Figure 7 shows both the minor radius a and the major radius b versus t . As t increases, both a and b decreases. This is a result of the reduction of the guided wavelength as well as the circumference of the ring as t increases. It is also clear that as b/a increases a decreases, while b increases. This behavior allow a and b to preserve the required aspect ratio while keeping their summation approximately constant at a specific value of t .

Figure 7 Minor and major radii of the ring versus its width

PLANAR ELLIPTICAL RING BANDPASS FILTER WITH MICROSTRIP LINE AND OPTIMAL SIZE

Knowing a and b , the surface area occupied by the filter can be calculated. In Figure 8, the surface area is plotted versus t at three different values of b/a . The surface area decreases as either t or b/a increases. The parameter b/a has more impact on the surface area than that of t . After obtaining the radii of the ring, the value of d should be optimized in order to achieve the best matching between the slotline and the elliptical ring resonator. The optimum value for d is plotted in Figure 9. It is clear from this figure that the distance between the edge of the slot line and the center of the ring decreases as either t or b/a increases.

Figure 8 Surface area occupied by the filter versus the width of its ring

Figure 9 Distance between the edge of the slotline and the center of the ring versus its width

MAGDY. S. IBRAHIM

Finally, the percentage bandwidth is presented in Figure 10 versus t at the same three values of b/a . The figure shows that the percentage bandwidth decreases as either t or b/a increases. In consistence with Figure 6, the variation of t has stronger effect on the percentage bandwidth than that of b/a . It is clear from both Figures 6 and 10 that the proposed bandpass filter offers a wide range of bandwidth variation. For the selected ranges of b/a and t , the percentage bandwidth varies from 10% up to 35%.

Figure 10 Percentage bandwidth of the proposed filter versus the width of its ring

Conclusion :

This paper presents a new bandpass filter design. The proposed filter is of planar nature which makes it consistent with the modern microwave systems. A rigorous parameter study for the proposed design has been performed via a reliable full-wave commercial software. It has been found that two independent parameters are affecting the performance of the filter. Varying these parameters, it has been demonstrated that the percentage bandwidth of the filter can be controlled within the range from 10% up to 35%. This makes the proposed filter suitable for a wide range of microwave applications. At the selected resonance frequency of 2.4 GHz, it has been also found that changing the independent parameters of the filter results in controlling the surface area of the filter from 373mm² down to 182mm². This feature indicates that the proposed design is able to satisfy the size reduction requirement of some wireless applications.

Abstract

A model formed by chiral bioplasma with a set of macromolecules of DNA, which represents the human head inner structure, makes possible to analyze its behavior, when it is radiated by a microwave electromagnetic field WLAN's. The finite difference time domain, FDTD is used under multiphoton regime deduced from Maxwell equations. The numerical results of the Specific Absorption Rate, SAR, show the SAR behavior in function of the chirality factor. The main conclusions of our work is that the microwave absorption from WLAN's systems is enhanced, compared with classical models, when values of the normalized chiral factor are of order of one. This absorption appears under multiphoton regime in the brain region. To illustrate this effect in our simulations we considerer electromagnetic waves at frequencies of 5.2 and 5.8 GHz.

1. Introduction

Even though a lot of work has been done there is still no complete assessed knowledge about the interaction between electromagnetic fields and biological systems. However, there is a general agreement about the relevance of the correct evaluation of the real mechanism. It seems clear that RF fields can have some effects on tissue and it still remains to be determined whether these effects are functionally and pathologically significant.

Different models of human head range from simple models, such as homogeneous sphere to heterogeneous anatomically correct models based on magnetic resonance (MR) imaging. In this paper a FDTD method to determine the absorption of RF waves emitted by WLAN's is presented. We use a simple model, which takes into account the main interaction between the bioplasma of the brain neurons and the microwave radiation of WLAN's systems. To address the problem and on the basis of our previous approach [1-2], our method have three main steps: 1) modelling of human head through MRI, 2) evaluation of the electromagnetic fields distribution inside the biological target, considering the brain tissue as chiral bioplasmatric media, and 3) SAR simulation for to evaluate both the thermal effect and resonant absorption under multiphoton regime. A explanation of the theoretical base of the technique used and description of the models are given in section 2. Results comparing the computed SAR values in the different models are shown and discussed in the section 3. Finally, conclusions are presented.

2. Fundamentals and models

By looking a special natural chiroplasma like a citoplasma in the human brain the multiphoton mechanism can provide a new approach of the problem of absorption in the human brain. Here the eigenfrequency of collective twist excitation in proteins, DNA and other biological chain molecules can be in the gigahertz range [3-5].

Here, we assume that the electrons within chiral molecules oscillate along a helix and from the averaged electric current [1] we can find the polarization (P) and the magnetization (M) which in a helical geometry may be proportional to $\nabla \times E$ ($\nabla \times H$) respectively. For typical double helices, giving the moment of inertia per unit length, the

Multiphoton absorption in chiral brain under microwave radiation from WLAN's systems

torsional factor and the length of a typical chain (I, tor, L), and following [3], For double stranded DNA we estimate $I = 300 \text{ auA}^\circ$, torsion constant of 0.8 ev/A° , and L between 200 A° and 2000 A° the frequency falls in the interval between 1 GHz and 10 GHz [4]-[5]. Similar results we can obtain using the Ford's model [7].

In this work we propose that when the multiphoton effect is considered, this microscopic problem is reflected at macroscopic level as thermal absorption combined with resonant absorption. Here, besides the tissue conductivity and dielectric permittivity we consider the chiral effect caused by the interaction of microwaves and biomolecules of DNA. The chiral wave propagation in bounded helical structures may support mode excitation, mode interactions, mode conversion and amplification of molecular chirality by eigenwaves in a bioplasma [6]

This chiral effect in the brain is considered in this work as a macroscopic mechanism where the typical cell membrane of brain is a fluid bilipid layer with a lot big chiral protein molecules embedded in it. Every protein molecule is polar and will tend to align itself with an electric field and often helical rotate in its socket, so any volume of brain tissue must have a lot of cells bearing protein molecules that happen to resonate at its eigenfrequency which can be similar to the microwave frequency f or when there are n - multiphoton interaction the eigenfrequency can resonate with nf . By contrast with ionizing radiation which damage to genetic structures of cells, microwave may span thousands of cells with a single wavelength. Microwaves set up current in tissue, and any noticeable effect of such current would involve many, many of the relatively weak microwave photons, damage, if any, would be all over the path of the current and would be numerous cells in extend, so damage to general cytoplasm, mitochondria, and so forth would seem likely to be more salient than damage to genetic structure. Accordingly with the above discussion, we apply the Maxwell's equations to sets of microtubules and helical molecules embedded in a substrate, characterized by a global chirality factor, T , (equation 1). Chiral media can be characterized by a generalized set of constitutive relations in which the electric and magnetic fields are coupled. In this paper, we consider the Born-Fedorov approach

$$D_{x,y,z} = \epsilon_0 \epsilon_r E_{x,y,z} + \epsilon_0 \epsilon_r T \left[\frac{\partial E_{z,x,y}}{\partial y, z, x} - \frac{\partial E_{y,z,x}}{\partial z, x, y} \right]; B_{x,y,z} = \mu_0 H_{x,y,z} + \mu_0 T \left[\frac{\partial H_{z,x,y}}{\partial y, z, x} - \frac{\partial H_{y,z,x}}{\partial z, x, y} \right] \quad (1)$$

where ϵ , μ and T (meter) are the permittivity, permeability and the chiral scalar respectively. Solving Maxwell's equations for a plane electromagnetic wave of frequency ω ($\omega = k_t v = 2\pi f$, k_t is the tissue wavenumber and v is the phase velocity) propagating in a chiral medium, it can be shown that the left- and right hand circularly polarized waves have different wavenumbers, $k = k_t / (1 + k_t T)$, $k = k_t / (1 - k_t T)$ respectively [2]. The chiral parameter T has the dimension of a length, which in an exactly solvable two helical model for a set of oriented handed molecules, is proportional to $\beta N h^2 a \rho$. Here, β is some coefficient determined by the internal elasticity of a molecule, N is the number density of molecules of radius and a pitch h with the charge ρ per unit length of each [1].

Using the MKS system of units, the following system of scalar equations is the set of Maxwell's equations in the rectangular coordinate system (x, y, z):

$$\frac{\partial H_{x,y}}{\partial t} = \mp \frac{1}{\mu} \frac{\partial E_z}{\partial y, x} \pm T \frac{\partial^2 H_z}{\partial y, x \partial t}; \frac{\partial H_z}{\partial t} = \frac{1}{\mu} \left(\frac{\partial E_x}{\partial y} - \frac{\partial E_y}{\partial x} \right) + T \left(\frac{\partial^2 H_y}{\partial x \partial t} - \frac{\partial^2 H_x}{\partial y \partial t} \right) \quad (2)$$

$$\frac{\partial E_{x,y}}{\partial t} = \pm \frac{1}{\epsilon} \frac{\partial H_z}{\partial y, x} \pm T \frac{\partial^2 E_z}{\partial y, x \partial t} - \sigma E_{x,y}; \frac{\partial E_z}{\partial t} = \frac{1}{\epsilon} \left(\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} \right) + T \left(\frac{\partial^2 E_y}{\partial x \partial t} - \frac{\partial^2 E_x}{\partial y \partial t} \right) - \sigma E_z \quad (3)$$

where σ (mho/m) is the tissue electrical conductivity. The main difficulty for an analytic treatment of this system is in the partial derivatives of space and time in which the chiral parameter T is present. For this reason, equations (2)-(3) can't be reduced to a typical differential equation with known solution. In our formulation, the second order approximation of Mur is used for the near-field irradiation problems in an achiral-chiral interface case. After calculation of the induced chiral electric field by the FDTD method, the local specific absorption rate SAR, is

calculated as

$$SAR_{i,j}(T) = \frac{\sigma_{i,j} E_T^2|_{i,j}}{2\rho_{i,j}}; \text{with } E_T|_{i,j}(T) = \sqrt{\frac{1}{n} \sum_1^n \left(E_y^2|_{i,j} + E_x^2|_{i,j} + E_z^2|_{i,j} \right)} \quad (4)$$

3. SAR simulation and analysis of results

For the numerical calculation we normalize the chiral factor as kT where k is the wave number in the tissue layer, in some case it may be $k_t = nk_0$, ($k_0 = \omega/c$ is the vacuum wave number), with $n = 1, 2, 3 \dots n$. It is necessary to take into account the multiphoton absorption when the resonance absorption at macromolecular level become important. For the brain we considerer $k = k_b/(1 - k_b T)$ because, the clusters of DNA molecules have eigenwaves like right hand circularly polarized waves and for the rest of tissues we considerer $kT = k_t T = 0$. The values for kT are choose by considering $T \approx \beta N h^2 a \rho \approx 1 - 10 \mu m$, $k = k_b/(1 - k_b T) \gg k_b \approx k_0 \sqrt{\epsilon_b}$, $k_0 T$ is of the order of $10^{-4} - 10^{-3}$ so when the multiphoton effect appears, $k_b T \approx nk_0 T$, $1 - nk_0 T \leq 1$ and then kT is of order of one and this effect increases when kT increases Here we suppose that the macromolecules vibrations of the helical structures inside typical brain cells are likely to lead to reasonably absorption enhanced by the proteinic water in which these molecules are immersed (induced chirality).

Stages of the bioplasmatic model for SAR determination are shown in reference [1]. Using the linear FDTD algorithm with chirality, obtained from equations (4) simulations for the mobile phones microwave spectrum are made. The model of human head was constructed with 540,000 cubic cells of 2.5 mm side each. The total number of layers, counted from the bottom of head, used in this model was 54. Here we choose the layers 34, 35 and 36, because there are great concentrations of brain tissue. The figure 1 shows these layers in digitalized version (matrix of 100x100), likewise is exhibited the antenna position. Both, the dielectric constant and the conductivity of the brain were obtained from literature [9-10]. In order to study and isolate the chiral effect, calculations are made for plane wave assumption, powers of 0.1 W were used, at frequencies of 5.2 and 5.8 GHz respectively. Four types of tissues (skin, bone, blood and brain) are considered. Simulations were made in a systematic way, in order to determine the effect that the variation of the chiral coefficient have over the absorption of coefficient SAR and results, for layer 35th, are shown in figures 2-3. Owing to the different electromagnetic properties of the tissues the power absorption is not a monotonically decreasing function of depth. For $kT = 0$, absorption is highest in the skin, low in the skull, but higher again in the brain. These curves were obtained performing similar simulations and then obtaining a statistical average of the SAR. As the wave penetrates the head, it traverses the different parts of which the head model is made and the value of the SAR is attenuated quickly due to the change in medium and the increase of the distance from the emitting source (antenna). SAR maximum (hot point) is in outer part (skin). After passing through the bone level, the SAR is much attenuated (between cells 5 and 10) and around cell 10, the SAR increases at brain level. Here, starting on cell 10 approximately is important to analyze the performance of our bioplasmatic model.

The profile of the SAR for 35th layer, at 5.2 GHz, as function of distance for different values of chiral factor kT , is showed in figure 2, where the variation is observed for $0 < kT \leq 3.0$ values of chiral factor. A SAR of 0,48 W/kg, is observed in the brain region, for a null chiral factor ($kT = 0$). For $kT = 1$ the SAR found was 0,65 W/kg, an increase of 35% with respect to the achiral case ($kT = 0$) and a SAR of 0.75 W/kg was found for $kT = 3.0$, with an increase 56%. This increase corresponds to the power absorbed by the brain region.

Figures 3 shows the distribution of the SAR for 35th layer, as function of distance, for different values of the chiral factor when the work frequency is 5.8 GHz. The maximum SAR found, in the blood-brain region, was 0.6 W/kg for to $kT = 0$ and 0.8 W/kg for $kT = 1$, i.e. an increase of 33% with respect to the achiral case. For a high value of chiral factor, $kT = 3.0$, the maximum SAR found was 0.93 W/kg with an increase of 55%. Also, this increase corresponds to the power absorbed by the brain region. Following the same procedure, similar results for the layers 34 and 36 are obtained. Here with $kT=3$ we have an enhanced multiphoton effect which is reflected in strong absorption, SAR=0.93 (5.8GHz).

Apparently the SAR appears to increase as the square root of the power, because in the numerical calculation as initial condition we start with an initial varying electric field $E_i = (V / \Delta) \sin \omega t$ where the voltage is proportional to the square root of the power with constant impedance [5]. Important results are the values of SAR obtained for 5.2 and 5.8 GHz, where a remarkable characteristic is found: at higher frequency the absorption is bigger in the brain

Multiphoton absorption in chiral brain under microwave radiation from WLAN's systems

tissue where a lower absorption by skin effect was expected.

The classical skin effect does not occur in our simulation, because the effective induced current penetrate inside the head where the multiphoton resonance is active.

This "inverse skin effect" phenomenon is verified in the brain layers, as shown in figures 2 and 3, where it is possible to observe that in all cases, for any chiral factor and input power values, the maximum SAR at 5.8 GHz is larger than at 5.2 GHz.

4. Conclusions

A bioplasmonic chiral model of the human head has been presented that allows determination and evaluation of the absorption induced by the radiation of cellular phone. After having obtained the digitalized layers of correspondent MR images, the electromagnetic fields radiated were determined firstly by means of the FDTD technique and then the specific absorption coefficient (SAR). It is shown that the use of a more realistic model of the human head, derived from the magnetic resonance of images allows for improved determination of the chiral near fields induced in the head.

Using the proposed bioplasmonic chiral model, the simulation of SAR distribution in layers with high quantity of brain tissue (layers 34, 35 and 36) was made. These results shows that the power absorbed by the head increases with the chiral factor. Other important result found is that the absorption at 5.8 GHz, in the brain tissue, is larger than at 5.2 GHz, therefore there is an effect like an "inverse skin effect" phenomenon. In this calculation it is not possible that chain molecule can alter their conformation and a breaking of the chain can result having in mind the restricting forces which are higher than the EM forces.

Here we are studied a more elaborated model of the head (with chiral effect), but with a simple model for the antenna. For real antennas the proximity of tissue clearly alter the radiation pattern, the antenna gain and the input impedance a more general numerical simulation techniques and an accurate model have to be developed. However for left-hand circular, right-hand circular and helical antennas, now available for isotropic and omni-directional radiation, our analysis on SAR have correct conclusions regarding the chiral effect. Certainly for systems to greater frequencies (wireless LANs) the chiral effect will be more pronounced. This makes it worth to check the first results by means of still more advanced models.

INCREASE OF CELL DEATH IN SUSPENSION-CULTURED TOBACCO CELLS FOLLOWING EXPOSURE TO STATIC MAGNETIC FIELD

PARVIZ ABDOLMALEKI, FAEZEH GHANATI

**FACULTY OF SCIENCE, TARBIAT MODARES UNIVERSITY, P.O. BOX
14115/175, TEHRAN, IRAN.**

Despite to studies demonstrating the effect of static magnetic field (SMS) on animal and/or human cell death fewer studies have been conducted on plant cells. In the present study suspension cultures of tobacco cell in the exponential phase of the growth were exposed continuously for 5 days each 5 hours to SMF of 10 and 30 mT. The viability, lipid proxidation as well as morphological features of the cells were then studied and compared to those of the control cells. The level of peroxidation of membrane lipids in the treated cells was significantly increased compared to those of non-exposed (control) cells while the viability of the treated cells was decreased. In addition, certain characteristics of programmed cell death (PCD) or necrosis e.g., vacuolization and fragmentation of nucleus were remarkably visible in the treated cells, compared to the control cells which had intact nuclei with clear nucleoli. The control cells also excluded ethidium bromide from their walls, whereas most of the treated cells allowed ethidium bromide to penetrate into the cells, emphasizing induction of cell death by magnetic field. Our result suggests that SMF can increase the rate of death in tobacco cells.

Introduction

Electromagnetic fields (EMF) are widely distributed in the environment and their effects are increasing with the burgeoning development of electrical machines [1, 2]. This make the concern about the possible risk of functional disorders in biological systems being growing. Results of the numerous experimental, epidemiological and theoretical studies are rather controversial, and in all areas so far, no unanimous conclusions have been reached [1-3]. Several studies on bacterial and animal cells have shown that EMF exert influence on a large variety of cellular functions, nevertheless the exact mechanism of the interaction with living cells are still unclear [4, 5].

Considering the cell as an electrical system provide a framework to investigate the exact mechanisms of the effect of the electric, magnetic and electromagnetic fields in the physiological behavior of the cell. Taking into consideration the previous reports on the presence of window effect this question raised whether or not a cell absorbed the energy in EMF like a receiver which work in a special band of frequency. If it is positive these fields can therefore act like primary messengers such as hormones. Then it is justified to say that the cells respond to physical stimulus (like EMF) in the same way that they respond to the hormones. Also, it would be helpful to understand whether the exposure of cells to the magnetic fields has any effect on the apoptosis. In the other words the magnetic field works as pro-apoptosis factor or as anti-apoptosis factor. If the MF had a pro-apoptosis role it will be useful in cancer treatment because one possible mechanism through which cells are prompted to develop cancer is the disruption of the equilibrium between the processes of proliferation and apoptosis [6,7]. However, apoptosis is a part of normal cell physiology which includes both proliferation and differentiation. It is a major component of both normal cell development and disease. The morphological demonstration of apoptosis is characterized by rapid condensation of the cytoplasm and nuclear chromatin, resulting in DNA fragmentation and membrane blebbing followed by fragmentation of the cells into apoptotic bodies, made up of condensed cytoplasm, nuclear material and/or whole organelles surrounded by intact plasma membranes. [7-9].

There are reports about the short-term EMF exposure that elicited an immune response [10]. A potential link between EMF and its effects on living organisms is the fact that EMF causes an oxidative stress i.e., increase in the activity, concentration, and life time of free radicals [11-13]. Oxidative stress is a function of oxidative metabolites, free radicals and reactive oxygen species (ROS) which are highly reactive by-products of normal metabolism and immune defense [11-13]. It brings changes in enzyme activity, gene expression, and release of

calcium from intracellular storage sites. Oxidative stress also affects membrane structure, cell growth, and cell death, thereby contribute to cancers and leukemia [11-14].

Less studies of this kind have been conducted on plant cells and few available literatures, have particularly directed their attention to the effects of magnetic fields on the germination of seeds, pollen germination and plant growth and development [15, 16].

The goal of the present study was to determine a potential relationship between viability, lipid peroxidation as well as morphological features of the suspension-cultured tobacco cells which exposed to static magnetic fields. It may help us to improve the general knowledge about mechanism(s) of the responses of the living systems to EMF.

Suspension cultures established from calli of tobacco cells (*Nicotiana tabacum* L. cv. Burley 21) that had been maintained in our laboratory for 52 subcultures. Both calli and subsequent suspensions were grown in a modified Murashige and Skoog medium without glycine and containing 3% sucrose. The medium was containing: (NH₄)NO₃ 20.61 mM; KH₂PO₄, 1.25 mM; CaCl₂, 2.99 mM; MgSO₄, 1.50 mM; MnSO₄, 0.1 mM; Fe-EDTA, 0.1 mM; H₃BO₃, 0.1 mM; CoCl₂, 0.11 μ M; CuSO₄, 0.1 μ M;; Na₂MoO₄ μ M, 1.03; ZnSO₄, 29.91 μ M, KI, 5 μ M. pH was adjusted to 5.8. All chemicals were purchased from Sigma, Japan. Suspension-cultured cells were grown at 25 °C in darkness on an orbital shaker at 120 rpm and were sub-cultured every 7 day, when they were still in their logarithmic growth phase [17]. Frequent subcultures provided us homogenous and undifferentiated batches of tobacco cells that no longer have kept their original properties and their physiological response to EMF could resemble physiological response of plant cells regardless of their species. Exposure to EMF was performed by a locally designed EMF generator. The electrical power was provided using a 220 V AC power supply equipped with variable transformer as well as a single-phase full-wave rectifier. The maximum power and passing current were 1 KW and 50 A DC, respectively. This system was designed to generate EMF in range of 0.5 μ T – 30 mT with stable conditions. It consisted of two coils (each 3000 turns of 3 mm copper wire) equipped with a U-shaped laminated iron core (to prevent eddy current losses). Using two vertical connectors, the arms of the U-shaped iron core were terminated to four circular iron plates covered with thin layer of Nickel (each 23 mm thickness, 260 cm in diameter). A water circulation system around the coils was employed to avoid the increase of the temperature. The temperature between the circular iron plates (exposure sites of samples), measured by a thermometer, was almost the same as other parts of the room (e.g., the site of the control cells) \pm 1°C. Nevertheless, the control cells were kept far enough from the apparatus, to avoid any potential exposure to the magnetic field from aforesaid generator. Since no other appliance was working, the control samples were only exposed to the extremely low MF of the earth, as the treatment group was too.

An electronic board was used to stabilize the system so that we always got a uniform MF. Calibration of the system as well as tests for the accuracy and uniformity of the magnetic fields were performed by a teslameter (PHYWE, Germany) with a probe type of Hall Sound. The accuracy of the system was \pm 0.1% for static field and the range of measurements was 3 μ T – 30 mT.

It is generally accepted that household and office levels of magnetic fields vary between 0.01 to 0.1 mT and levels near a power transmission line are between 10-30mT and much higher levels are expected in occupational exposures [18]. A magnetic field of 30mT is also a limit requiring controlled access - being a level at which magnetic materials may move under the influence of a field. Therefore, the present study was undertaken to test the effects of 10 and 30 mT on plant cells. The cells in their exponential growth phase were continuously exposed to EMF by magnitudes of 10 or 30mT, for 5 days (from day 3 to 7). After the period of treatment the cells were harvested and frozen in liquid N₂ and kept at – 80 °C until used for biochemical analysis.

Viability of both treated and control samples of the suspension-cultured tobacco cells was obtained by staining the cells with 0.1% aqueous solution of Evans Blue for 3 min and washed with deionized water. Then it was observed using a light microscope (Olympus, BH2, Japan) with different magnifications. The cells with complete blue color was considered dead and the ones in which the membrane inhibited insertion of the blue dye was considered live. Consequently by counting the live and dead cells the viability of both treated as well as the control cells was obtained.

Level of damage of membranes was determined by measuring malonyldehydro (MDA) as the end product of peroxidation of membrane lipids [19]. In brief, samples were homogenized in an aqueous solution of trichloroacetic acid (TCA) (10% w/v) and aliquots of the filtrates were heated in 0.25% thiobarbituric acid (TBA). The amount of MDA was determined from the absorbance at 532 nm followed by correction for the nonspecific absorbance at 600 nm. The amount of MDA-TBA complex was calculated from the extinction coefficient 155mM⁻¹cm⁻¹ and expressed against mg of protein.

Cell wall preparations were obtained by homogenization of frozen samples in water with a mortar and pestle followed by centrifugation at 1000g and sequential washing of the pellet with EtOH, CHCl₃-MeOH (2: 1) and acetone and then drying in air. Lignin content of wall preparations was measured via a modified acetyl bromide

procedure. The lignin content was determined by measuring of absorbance at 280 nm using specific absorption coefficient value 20.0 g⁻¹ liter cm⁻¹.

Cells were stained with acridine orange (10µg/mL distilled water) or ethidium bromide (10µg/mL distilled water) to extract the morphological features of both treated and control cells. Observations were made with an Olympus BH2 fluorescence microscope equipped with filter combinations WU (330-385-nm excitation and 420-nm barrier filters) and WBV (400- to 440-nm excitation and 475-nm barrier filters).

All of the experiments were carried out with at least three independent repetitions, each three samples, and all data were expressed as the mean values \pm standard deviation (SD). Statistical analysis was performed using Student's t- Test and the differences between treatments were expressed as significant at level of $P < 0.05$.

The tobacco cells in suspension culture were seen in different shapes such as round, cylindrical as well as ellipse (Figure 1). As mentioned in material and method we exposed the prepared cells in exponential phase which started from day 3 - 8 (Figure 2). The dimension of these cells is presented in table 1. Our results showed that the average size of the treated cells with both 10 and 30 mT SMF was significantly decreased compared to the control cells. Although, the growth rate of the treated cells decreased compared to the control cells by measuring the weight of cells, but it was not significant (Table 1). Exposure to SMF significantly increased the level of the peroxidation of membrane lipids of suspension-cultured tobacco cells, compared to those of non-exposed (control) cells. The MDA level did not show a noticeable difference in both 10 and 30 mT.

Figure 3 shows the MDA level in treated cells compared with the control cells. The obtained average for MDA level on treatment group (10 mT) was 1.16 ± 0.03 (MDA/g Fw) while the obtained average for MDA level on control group was 0.89 ± 0.02 (MDA/g Fw). Similarly, the obtained average for MDA level on treatment group (30 mT) was 1.13 ± 0.04 (MDA/g Fw) while the obtained average for MDA level on control group was 0.84 ± 0.12 (MDA/g Fw). However, there was not significant difference between the levels of lipid peroxidation of 10 and 30 mT of SMF-exposed cells.

Figure 4 shows the lignin content of wall in treated cells compared with the control cells. The results showed that the exposure of the magnetic field caused a significant increase in the lignin content of wall in treated cells ($n=24$) compared with the controls ($n=24$). However the lignin content did not show a noticeable difference in both 10 and 30 mT. The obtained average for lignin content on treated groups (10 and 30 mT) were 7.09 ± 0.45 and 6.96 ± 0.08 , respectively. While the obtained average for lignin content on control groups were 6.17 ± 0.26 and 5.7 ± 0.06 , respectively.

The viability of the treated cells as well as control cells using Evans Blue and ethidium bromide were presented in figure 5 and 6. These results showed that the viability of the treated cell (30 mT) was approximately 68% while the viability of treated cells (10 mT) was 72%. The viability of the control cells was 84%.

Certain characteristics of programmed cell death (PCD) or necrosis e.g., nuclear vacuolization and fragmentation were observed in tobacco cells exposed to the static magnetic fields (Figure 7A, Figure 7B), compared to the control cells who had intact nuclei with clearly visible nucleoli (Fig.7D). The latter also excluded ethidium bromide in their walls (Figure 6), whereas most of the magnetic field-exposed cells allowed ethidium bromide to penetrate into the cells, emphasizing induction of cell death by magnetic field (Figure 7)

Table 1: demonstrating the obtained average diementions and weight of treated cells compared with control cells.

SMF(mT)	Diameter(μ_m)		Weight(g/flask)
	Width	Length	
0	48.2 ± 13^a	40.5 ± 12.5^a	$13.3 \pm .22^a$
10	37.8 ± 10.8^b	33.6 ± 8.3^b	12.1 ± 1.01^a
0	41.8 ± 17.9^a	49.2 ± 10.8^a	11.6 ± 1.07^a
30	29.3 ± 5.9^b	37.2 ± 10.2^b	10.9 ± 1.06^a

Cells were stained with acridine orange and observed under epifluorescence microscope. Magnifications of A, X1320 and of B, C, and D, X660.

Summary

Electromagnetic fields for many years were considered as an absolutely neutral form of radiation, but epidemiological data and results of experimental *in vivo* studies have attracted more attention to the biological effects of EMF. Primary action of SMF in biological systems is the induction of electrical charges and currents [18]. One of the major molecular effects of magnetic fields is their influence on nuclear spins of paramagnetic molecules. This mechanism plays an important role when in the course of a chemical reaction the chemical bond is disrupted and two molecules with unpaired electrons are formed (a pair of radicals). Depending on their spin orientations, radical recombination or diffusion and formation of free radicals (e.g., Oxygen radicals) may take place [20]. The radical pairs may be affected for a long and continuous time interval by the static magnetic field [21]. This may extend the life time of the free radical and its potential damage could be exaggerated. Although formed in normal cell metabolism, free radicals are potentially damaging and can initiate chain reactions to form new free radicals. A main protective role against free radicals is attributed to SOD in catalyzing and dismutation of superoxide anions to O_2 and H_2O_2 [22]. We showed somewhere else that the exposure to SMF increased the activity of SOD in tobacco cells compared to those corresponding control groups. It implies the first step of the increased production of free radicals by SMF in tobacco cells. An increase in SOD activity might enhance cytotoxicity by active oxygen species likely owing to the accelerated H_2O_2 generation and subsequent OH^\bullet overproduction by the metal catalyzed Haber-Weiss reaction [23]. Scavenging and detoxification of H_2O_2 that is produced by SOD, can be achieved by either non-enzymatic antioxidants or scavenging enzymes, e.g., CAT. Likewise, the activity of CAT was also reduced by SMF.

Accumulation of H_2O_2 and other reactive species of oxygen in SMF-exposed tobacco cells may subsequently result in peroxidation of membrane lipids as well as damage of DNA [24]. Ishisaka and his colleagues (2000) showed H_2O_2 -induced rapid fragmentation of DNA and a slow decrease in the viability of human cancer cell line HL-60 [25]. In the same cell line, Robison and his colleagues presented data demonstrating that a decrease in the DNA repair may occur following oxidative burst induced by EMF [26]. Although morphological features of programmed cell death and necrosis of plant cells, to some extent, differ from those in animal cells, however some of these features, e.g., cleavage of DNA to internucleosomal fragments and increase of lipid peroxidation (membrane lysis) were observed more in SMF-exposed cells, compared to the control cells.

MDA measurement also indicates that 10, 30mT SMF exposure induces lipid peroxidative stress. This implies that SMF is somehow involved with free radical reaction in tobacco cells. It means that increase in lipid peroxidation can be another proof for the accumulation of H_2O_2 in treated tobacco cells compared to the controls. These results indicate that exposing to the SMF can induce oxidative stress due to activity of the free radicals and it will therefore cause more lipid peroxidation. Increase in the lipid peroxidation of the membrane in both 10 and 30 mT SMF also showed that the failure of the antioxidant defence system of treated cells against the free radicals. The results presented in table 1 indicated that the treated cells become smaller in size and less proliferative compared to the control cells. This could be explained by this suggestion that the SMF shortened the cell cycle and it also inhibited the extension of the cell membrane. Exposing to the SMF was the main reason for increase in SOD activity may represent a compensatory reaction against oxidative stress. Increase in lignin content of treated cells (7.09 ± 0.45 and 6.96 ± 0.08 for 10 and 30mT) compared to the control (6.17 ± 0.26 and 5.7 ± 0.06) demonstrating the wall loosening through increasing the wall stiffening. This can possibly decrease the cellular growth.

Taken all together, the results presented here reveal that SMF can cause an inconsistency in the function of antioxidant enzymes in suspension-cultured tobacco cells thereby, lead to oxidative burst and cell death.

IMPLICIT FDTD METHODS AND THE SAMPLING THEOREM

LUBOMÍR ŠUMICHRASŤ

INSTITUTE OF ELECTROMAGNETIC THEORY, SLOVAK UNIVERSITY OF TECHNOLOGY, ILKOVIČOVA 3, SK-81219 BRATISLAVA, SLOVAKIA

Abstract

The numerical properties of two factorized implicit formulations of the method of Finite-Differences-in-Time-Domain (FDTD) for the simulation of electromagnetic wave propagation are investigated and compared with explicit Yee-FDTD and full Crank-Nicolson FDTD formulation. It is shown that the ADI-FDTD factorization approaches asymptotically the Nyquist limit and can be used with arbitrarily large time steps. Also from the point of view of numerical dispersion gives acceptably small deviations from the full Crank-Nicolson FDTD formulation. On the other hand the CNSS-FDTD factorization does not fulfill Nyquist limit for arbitrarily large time steps.

Introduction

Numerical simulations are routinely used for modeling electromagnetic wave propagation problems in the area of high frequency electromagnetics and photonics. The finite-difference time-domain (FDTD) method of explicit type designed by Yee [1] was for long years the preferred numerical technique for such simulations due to its flexibility, since it allows the inclusion of arbitrarily heterogeneous objects in the region to be simulated. In the course of numerical computations artificial artifacts are introduced, such as numerical amplification of the wave power-flow-density (stability issues) as well as the numerical dispersion. For the explicit-type methods the well-known Courant-Friedrichs-Levy (CFL) condition concerning the stability of the calculations must be met, limiting thus the step-length of the in-time-forward-marching algorithm. The extent of literature in this area is huge, including several book publications, e.g. [2].

Recently the implicit types of FDTD methods has been constructed - the "Alternating Directions Implicit" (ADI) FDTD method [3], [4] and the "Crank-Nicholson Split-Step" (CNSS) FDTD method [5], [6]. Both are implicit procedures requiring inversion of tridiagonal matrices in two half steps. Both are theoretically unconditionally stable, i.e. they enable one to avoid the severe CFL condition and use the unlimited length of the time step in the course of calculation. However, another kind of bounds on the length of the time step, due to aliasing effects with growing time step, is imposed on both these methods.

Explicit and implicit FDTD formulations

The Maxwell equations

$$\text{curl } \mathbf{H} = \varepsilon \frac{\partial \mathbf{E}}{\partial t}, \quad \text{curl } \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} \quad (1)$$

are for the simplicity taken in the simple form for lossless isotropic homogeneous linear medium without external sources, i.e. the permeability μ and the permittivity ε are constants. Here $\mathbf{E}(\mathbf{r}, t)$ and $\mathbf{H}(\mathbf{r}, t)$ are the electromagnetic field intensities for arbitrary time dependence.

In the Yee-FDTD method are Maxwell equations (1) discretised taking so called staggered grids [1] on all three spatial axes and in time with equidistant intervals $\{\Delta_x, \Delta_y, \Delta_z, \Delta_t\}$ (denoted by the serial indexes $\{i, j, m, n\}$, i.e.

$$\begin{aligned}
 E_x\left([i+\frac{1}{2}]\Delta_x, j\Delta_y, m\Delta_z, [n+\frac{1}{2}]\Delta_t\right) &= E_x\Big|_{i+\frac{1}{2}, j, m}^{n+\frac{1}{2}}, & H_x\left(i\Delta_x, [j+\frac{1}{2}]\Delta_y, [m+\frac{1}{2}]\Delta_z, n\Delta_t\right) &= H_x\Big|_{i, j+\frac{1}{2}, m+\frac{1}{2}}^n \\
 E_y\left(i\Delta_x, [j+\frac{1}{2}]\Delta_y, m\Delta_z, [n+\frac{1}{2}]\Delta_t\right) &= E_y\Big|_{i, j+\frac{1}{2}, m}^{n+\frac{1}{2}}, & H_y\left([i+\frac{1}{2}]\Delta_x, j\Delta_y, [m+\frac{1}{2}]\Delta_z, n\Delta_t\right) &= H_y\Big|_{i+\frac{1}{2}, j, m+\frac{1}{2}}^n \\
 E_z\left(i\Delta_x, j\Delta_y, [m+\frac{1}{2}]\Delta_z, [n+\frac{1}{2}]\Delta_t\right) &= E_z\Big|_{i, j, m+\frac{1}{2}}^{n+\frac{1}{2}}, & H_z\left([i+\frac{1}{2}]\Delta_x, [j+\frac{1}{2}]\Delta_y, m\Delta_z, n\Delta_t\right) &= H_z\Big|_{i+\frac{1}{2}, j+\frac{1}{2}, m}^n
 \end{aligned} \quad (2)$$

Discretised Maxwell equations (only the E_x and H_x are considered bellow) take the form

$$\varepsilon \frac{E_x\Big|_{i+\frac{1}{2}, j, m}^{n+\frac{1}{2}} - E_x\Big|_{i+\frac{1}{2}, j, m}^{n-\frac{1}{2}}}{\Delta_t} = \frac{H_z\Big|_{i+\frac{1}{2}, j+\frac{1}{2}, m}^n - H_z\Big|_{i+\frac{1}{2}, j-\frac{1}{2}, m}^n}{\Delta_y} - \frac{H_y\Big|_{i+\frac{1}{2}, j, m+\frac{1}{2}}^n - H_y\Big|_{i+\frac{1}{2}, j, m-\frac{1}{2}}^n}{\Delta_z}, \quad (3)$$

$$\mu \frac{H_x\Big|_{i, j+\frac{1}{2}, m+\frac{1}{2}}^{n+1} - H_x\Big|_{i, j+\frac{1}{2}, m+\frac{1}{2}}^n}{\Delta_t} = \frac{E_y\Big|_{i, j+\frac{1}{2}, m+1}^{n+\frac{1}{2}} - E_y\Big|_{i, j+\frac{1}{2}, m}^{n+\frac{1}{2}}}{\Delta_z} - \frac{E_z\Big|_{i, j+1, m+\frac{1}{2}}^{n+\frac{1}{2}} - E_z\Big|_{i, j, m+\frac{1}{2}}^{n+\frac{1}{2}}}{\Delta_y}. \quad (4)$$

Yee-FDTD method as represented by the equations (3) and (4) is the explicit method: the values $E_x\Big|_{i+\frac{1}{2}, j, m}^{n+\frac{1}{2}}$ in (3) in the "new" time layer $n+\frac{1}{2}$ are directly calculated from the "old" known values in layers $n-\frac{1}{2}$ and n . Similar holds for $H_x\Big|_{i, j+\frac{1}{2}, m+\frac{1}{2}}^{n+1}$ in (4). The main drawback of the Yee-FDTD explicit method is its conditional stability. In order to have conserved the wave-power-flow-density in the computational window, the CFL-condition

$$c\Delta_t \sqrt{\Delta_x^{-2} + \Delta_y^{-2} + \Delta_z^{-2}} < 1 \quad (5)$$

where $c = (\mu\varepsilon)^{-1/2}$ is the phase velocity in the lossless medium, has to be met, limiting thus severely the permissible length of the time steps Δ_t .

In the matrix notation (1) reads

$$\varepsilon \frac{\partial}{\partial t} \mathbf{E} = \mathbf{\Delta} \cdot \mathbf{H} \quad -\mu \frac{\partial}{\partial t} \mathbf{H} = \mathbf{\Delta} \cdot \mathbf{E} \quad (6)$$

where $\mathbf{E} = [E_x, E_y, E_z]^T$ and $\mathbf{H} = [H_x, H_y, H_z]^T$ are column vectors of field components and $\mathbf{\Delta}$ is given as

$$\mathbf{\Delta} = \mathbf{\Delta}_1 - \mathbf{\Delta}_2 = \begin{bmatrix} 0 & -\partial/\partial z & \partial/\partial y \\ \partial/\partial z & 0 & -\partial/\partial x \\ -\partial/\partial y & \partial/\partial x & 0 \end{bmatrix}, \quad \mathbf{\Delta}_1 = \begin{bmatrix} 0 & 0 & \partial/\partial y \\ \partial/\partial z & 0 & 0 \\ 0 & \partial/\partial x & 0 \end{bmatrix}, \quad \mathbf{\Delta}_2 = \begin{bmatrix} 0 & \partial/\partial z & 0 \\ 0 & 0 & \partial/\partial x \\ \partial/\partial y & 0 & 0 \end{bmatrix}. \quad (7)$$

Combining \mathbf{E} and \mathbf{H} into one vector \mathbf{F}

$$\mathbf{F} = \begin{bmatrix} \mathbf{E}/\sqrt{Z} \\ \mathbf{H}\sqrt{Z} \end{bmatrix}, \quad (8)$$

where $Z = \sqrt{\mu/\varepsilon}$ is the wave impedance of the lossless medium, one arrives to the equation

$$c^{-1} \frac{\partial}{\partial t} \mathbf{F} = \mathbf{D} \cdot \mathbf{F}, \quad (9)$$

where

$$\mathbf{D} = \begin{bmatrix} \mathbf{0} & \mathbf{\Delta}_1 - \mathbf{\Delta}_2 \\ \mathbf{\Delta}_2 - \mathbf{\Delta}_1 & \mathbf{0} \end{bmatrix}, \quad \mathbf{D} = \mathbf{D}_1 + \mathbf{D}_2 = \mathbf{D}_{12} - \mathbf{D}_{21}, \quad (10)$$

$$\mathbf{D}_1 = \begin{bmatrix} 0 & \mathbf{\Delta}_1 \\ -\mathbf{\Delta}_1 & 0 \end{bmatrix}, \quad \mathbf{D}_2 = \begin{bmatrix} 0 & -\mathbf{\Delta}_2 \\ \mathbf{\Delta}_2 & 0 \end{bmatrix}, \quad \mathbf{D}_{12} = \begin{bmatrix} 0 & \mathbf{\Delta}_1 \\ \mathbf{\Delta}_2 & 0 \end{bmatrix}, \quad \mathbf{D}_{21} = \begin{bmatrix} 0 & \mathbf{\Delta}_2 \\ \mathbf{\Delta}_1 & 0 \end{bmatrix}. \quad (11)$$

Crank-Nicolson formulation of discretisation of differential equation is known to be unconditionally stable. For (9) with respect to the time derivative it yields

$$\frac{\mathbf{F}^{n+1} - \mathbf{F}^n}{c\Delta_t} = \mathbf{D} \cdot \frac{\mathbf{F}^{n+1} + \mathbf{F}^n}{2}, \quad (12)$$

Equation (12) can be put in the following form

$$\left\{ I - \frac{2}{c\Delta_t}(\mathbf{D}_1 + \mathbf{D}_2) \right\} \cdot \mathbf{F}^{n+1} = \left\{ I + \frac{2}{c\Delta_t}(\mathbf{D}_1 + \mathbf{D}_2) \right\} \cdot \mathbf{F}^n, \quad (13)$$

which can after some calculation be re-cast into the following form (see e.g. [7])

$$\begin{aligned} \left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_1 \right\} \cdot \left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_2 \right\} \cdot \mathbf{F}^{n+1} - \frac{4}{c^2 \Delta_t^2} \mathbf{D}_1 \cdot \mathbf{D}_2 \cdot \mathbf{F}^{n+1} = \\ = \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_2 \right\} \cdot \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_1 \right\} \cdot \mathbf{F}^n - \frac{4}{c^2 \Delta_t^2} \mathbf{D}_2 \cdot \mathbf{D}_1 \cdot \mathbf{F}^n. \end{aligned} \quad (14)$$

Solving the full system of implicit equations (13), (14) is far beyond the capabilities of common computational machinery. Therefore after having neglected last terms on the RHS and LHS of (14), one can split the approximate equation

$$\left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_1 \right\} \cdot \left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_2 \right\} \cdot \mathbf{F}^{n+1} = \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_2 \right\} \cdot \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_1 \right\} \cdot \mathbf{F}^n \quad (15)$$

into two subsequent steps

$$\left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_2 \right\} \cdot \mathbf{F}^{n+1/2} = \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_1 \right\} \cdot \mathbf{F}^n, \quad \left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_1 \right\} \cdot \mathbf{F}^{n+1} = \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_2 \right\} \cdot \mathbf{F}^{n+1/2}. \quad (16)$$

where $\mathbf{F}^{n+1/2}$ denotes the intermediate value after the first sub step. This procedure is called Alternating-Directions-Implicit (ADI)-FDTD method. If there are N spatial discretisation points along each axis x , y , and z , then the algorithm for (16) can be organized in such a way that it requires six inversions of the tri-diagonal ($N \times N$) matrices. The original problem (13) requires inversion of the $(6N^3 \times 6N^3)$ sparse matrix. This is already for moderate number of sampling points N an unrealizable task.

Alternatively can (12) be expressed in the following way

$$\left\{ I - \frac{2}{c\Delta_t}(\mathbf{D}_{12} - \mathbf{D}_{21}) \right\} \cdot \mathbf{F}^{n+1} = \left\{ I + \frac{2}{c\Delta_t}(\mathbf{D}_{12} - \mathbf{D}_{21}) \right\} \cdot \mathbf{F}^n \quad (17)$$

and then similarly recast into the form

$$\begin{aligned} \left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_{12} \right\} \cdot \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_{21} \right\} \cdot \mathbf{F}^{n+1} + \frac{4}{c^2 \Delta_t^2} \mathbf{D}_{12} \cdot \mathbf{D}_{21} \cdot \mathbf{F}^{n+1} = \\ = \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_{12} \right\} \cdot \left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_{21} \right\} \cdot \mathbf{F}^n + \frac{4}{c^2 \Delta_t^2} \mathbf{D}_{12} \cdot \mathbf{D}_{21} \cdot \mathbf{F}^n. \end{aligned} \quad (18)$$

After having neglected last terms on RHS and LHS of (18) one again arrives to analogous equation as (15)

$$\left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_{12} \right\} \cdot \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_{21} \right\} \cdot \mathbf{F}^{n+1} = \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_{12} \right\} \cdot \left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_{21} \right\} \cdot \mathbf{F}^n. \quad (19)$$

which can again be splitted into two subsequent sub steps

$$\left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_{21} \right\} \cdot \mathbf{F}^{n+1/2} = \left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_{21} \right\} \cdot \mathbf{F}^n, \quad \left\{ I - \frac{2}{c\Delta_t} \mathbf{D}_{12} \right\} \cdot \mathbf{F}^{n+1} = \left\{ I + \frac{2}{c\Delta_t} \mathbf{D}_{12} \right\} \cdot \mathbf{F}^{n+1/2}. \quad (20)$$

This procedure is called Crank-Nicolson-Split-Step (CNSS)-FDTD method. In both methods are the terms of the second order on the RHS and the LHS of (14) and (18) neglected. Therefore both are in Δ_t second order approximate in comparison with the full Crank-Nicolson formulation (13) or (17).

Numerical dispersion

For the sake of simplicity let us consider the two-dimensional case only. Waves of any temporal and/or spatial shape can be Fourier expanded into the angular spectrum of either TM or TE monochromatic plane waves. Propagation of a spatio-temporal spectral TM component having the vectorial components

$\{E_y, H_x, H_z\}$ in the direction given by the k_x, k_z components of the wave vector \mathbf{k} , $|\mathbf{k}| = k = \sqrt{k_x^2 + k_z^2}$, is described in two dimensions x and z by

$$E_y = E_0 \exp(j\omega t) \exp(-jk_x x) \exp(-jk_z z), \quad (21)$$

where the angular frequency ω is given as $\omega = kc = c\sqrt{k_x^2 + k_z^2}$, and c is the "physical" phase velocity in the given medium.

The FDTD discretisation is performed on the so-called staggered grids [1]. The discretised TM plane wave using (21) is then given by

$$E_y|_{i,m}^n \approx \xi^n \exp(-jk_x \Delta_x i) \exp(-jk_z \Delta_z m), \quad (22)$$

and similarly for $H_x|_{i,m+\frac{1}{2}}^n$ and $H_z|_{i+\frac{1}{2},m}^n$, where $\xi = \exp(j\omega \Delta_t)$ should hold. However, during the numerical simulation of the wave propagation instead of differential equations the difference equations are being solved. Therefore, instead of the above correct terms for ω and c , one obtains different values ω_A and v_p from the formula $\xi = \exp(j\omega_A \Delta_t) = \exp(jk v_p \Delta_t)$, where $v_p = \text{phase}(\xi)/k \Delta_t$ is the numerical phase velocity different from the "physical" phase velocity c due to the numerical dispersion. The numerical dispersion, i.e. the differences between c and v_p are artifacts stemming from the nature of the numerical procedure itself. To avoid aliasing effects for all discretisations the sampling theorem must be fulfilled, i.e.

$$k_x \Delta_x \leq \pi, \quad k_z \Delta_z \leq \pi, \quad \omega_A \Delta_t = \text{phase}(\xi) \leq \pi. \quad (23)$$

For the full Crank Nicolson formulation of the FDTD method using discretised Maxwell equations one obtains the result

$$\xi = \left\{ 1 - A_x^2 - A_z^2 + j2\sqrt{A_x^2 + A_z^2} \right\} / \left(1 + A_x^2 + A_z^2 \right) \quad (24)$$

where

$$A_x = (c\Delta_t/\Delta_x) \sin(k_x \Delta_x/2), \quad A_z = (c\Delta_t/\Delta_z) \sin(k_z \Delta_z/2). \quad (25)$$

For the ADI-FDTD for each of two simulation-half-steps $\Delta_t/2$ the result

$$\sqrt{\xi_{1,2}} = \left\{ 1 + j\sqrt{(1 + A_{x,z}^2)(1 + A_{x,z}^2) - 1} \right\} / (1 + A_{x,z}^2), \quad (26)$$

. For the CNSS-FDTD method one similarly obtains the formula

$$\sqrt{\xi_{1,2}} = (2 - A_{x,z}^2 + j2\sqrt{2}A_{x,z}) / (2 + A_{x,z}^2). \quad (27)$$

The power-flow-density for the full step Δ_t is in all cases unconditionally conserved since either in (24) $|\xi| = 1$, or in (26) and (27) $|\xi| = |\sqrt{\xi_1}||\sqrt{\xi_2}| = 1$, holds. The dispersion characteristics are fully determined by the phase of ξ in the case of full Crank-Nicolson formulation (24)

$$\text{phase}(\xi) = \arctan \frac{2\sqrt{A_x^2 + A_z^2}}{1 - A_x^2 - A_z^2} \quad (28)$$

or by the phase of $\xi = \sqrt{\xi_1} \sqrt{\xi_2}$ using (26) and (27)

$$\text{phase}(\sqrt{\xi_1 \xi_2}) = 2 \arctan \sqrt{(1 + A_x^2)(1 + A_z^2) - 1}, \quad \text{phase}(\sqrt{\xi_1 \xi_2}) = \arctan \frac{2\sqrt{2}A_x}{2 - A_x^2} + \arctan \frac{2\sqrt{2}A_z}{2 - A_z^2}. \quad (29)$$

For the sake of comparison we show the result for the classical explicit Yee-FDTD. Here one obtains

$$\xi = 1 - 2(A_x^2 + A_z^2) \pm j\sqrt{1 - \{1 - 2(A_x^2 + A_z^2)\}^2} \quad (30)$$

In order to have the stability condition fulfilled the term under the square root must be positive, therefore $(A_x^2 + A_z^2) < 1$, or

$$c\Delta_t \left\{ \frac{\sin^2(k_x \Delta_x/2)}{\Delta_x^2} + \frac{\sin^2(k_z \Delta_z/2)}{\Delta_z^2} \right\} < 1 \quad (31)$$

Since the spatial harmonics due to the sampling theorem (Nyquist limit) can have maximum wave numbers equal to $k_x = 2/\Delta_x$, $k_z = 2/\Delta_z$, i.e. the sine functions in (31) are equal to one and the ultimate CFL-limit

$$c\Delta_t \sqrt{\Delta_x^{-2} + \Delta_z^{-2}} < 1 \quad (32)$$

is obtained. Depending on the actual length of Δ_t the formula (32) defines so-called Courant number that cannot be in case of explicit Yee-FDTD larger than one. For the unconditionally stable methods such as CN-FDTD, ADI-FDTD, or CNSS-FDTD can however reach any values larger than one.

Figure 1. Dependence of the normalised frequency $\omega_A \Delta_t \leq \pi$ on the normalised time step $kc\Delta_t$ for $k_x \Delta_x = 3$, $k_z \Delta_z = 3$.

substantial error as compared with the "exact" Crank-Nicolson formulation. As it can be easily seen the condition (23), i.e. $\omega_A \Delta_t \leq \pi$, is fulfilled for CNSS-FDTD only until the normalized time step value reaches $kc\Delta_t \approx 6$. This is a substantial not yet published difference between ADI-FDTD and CNSS-FDTD. Moreover, the possibility of the arbitrarily large Δ_t steps in the ADI-FDTD method does not necessarily mean any advantage, since with growing Δ_t the phase velocity $v_p = \text{phase}(\xi)/k\Delta_t$ decreases, i.e. the simulated spatial propagation path pertaining to increased time step remains effectively the same.

Conclusions

Wave propagation characteristics using the ADI-FDTD and CNSS-FDTD methods are illustrated in Fig.1. For the explicit Yee-FDTD the values can be calculated until the Courant limit is reached. Here the normalized frequency arrives at the Nyquist limit $\omega_A \Delta_t = \pi$. For CN-FDTD and ADI-FDTD it seems that the Nyquist limit $\omega_A \Delta_t = \pi$ is approached asymptotically with increasing Δ_t . Thus, it is inferred that the sampling theorem criteria are fulfilled for any step length for the CN-FDTD and the ADI-FDTD method. As seen from the comparison of curves for CN-FDTD and ADI-FDTD neglecting the second order terms in ADI-FDTD factorization (16) does not cause any

Abstract

A bioplasmatic chiral model of the human head, constructed with 540,000 cubic cells in 54 layers derived of MR images, that allows us to simulate and to evaluate the absorption induced by the radiation microwaves wireless systems between 1 to 100 GHz is presented. The procedure to determine the absorption of microwaves waves emitted by wireless systems consisting of the following three main steps: 1) evaluation of the electromagnetic fields distribution inside the biological target, 2) modeling of human head, and 3) SAR simulation by including chirality effects. The simulations were developed by means of the FDTD technique and the specific absorption coefficient (SAR) was determined for a layer with great concentrations of brain tissue (layer 35). The results show the evolution of SAR coefficient, as function of input power and chiral factor.

1. Introduction

In recent years, there has been a continuing explosion in the growth of microwave and radio frequency communications, particularly a dramatic acceleration in the use of cellular phones and wireless local area networks (WLANs). This has resulted in public concern about the health hazards of microwave electromagnetic fields emitted by these systems. This growth has raised the research on the effects of microwave interaction with biological tissues. Cellular phones use low-speed data transmission (e.g., voice data) over wide geographical areas, while WLANs and wireless Internet are adopted in services requiring high-speed data transmission over small confined areas (e.g., inside a building). It is important to assess the risk, if any, of the wireless revolution and determine if need exists for the establishment of new regulations for evaluation of the mechanisms of interaction between electromagnetic fields and biological systems. [1]

To transmit data, wireless LAN systems use a directive antenna placed at a mobile personal terminal (computer, telephone, camera, etc.) and a wide beam antenna placed at a fixed site (the base station) usually located on the room ceiling. In this arrangement, the user can find him self in close proximity to the radiating mobile antenna, where the EMF assumes its highest values. As a consequence, it is important to consider the possible health hazard due to such systems. Specifically, the heads of many users are exposed to a sequence of microwave fields modulated in substantially different ways [2]. When the cellular phone is close to the head, background levels are sharply distorted, with 40 to 50 percent of radiated phone energy absorbed in the hand and the head of an user [3]. Its emission at the head surface is typically 10,000 times stronger than fields reaching the head of a user standing within 30 m of the base of a typical mobile phone relay transponder mounted on a tower 30m above ground.

In a technical perspective, the carrier wave remains constant in amplitude throughout the transmission epoch, all data information being transmitted in the frequency domain, where systems generally transmit at 900, 1800 MHz and 2.4 GHz. When the antenna is close to the head, background levels are sharply distorted, with 40 to 50 percent of radiated phone energy absorbed in the hand and the head of a user [4].

In this paper, we propose to use a simple chiro-electrodynamical model, which takes into account the main interaction between the bioplasma of the brain neurons and the microwave radiation of mobile phone or wireless systems. To address the problem and on the basis of our previous experience [2][6], our method consists of the following three main steps: (1) modelling of human head through MRI, (2) evaluation of the EM distribution inside the biological target, considering the brain tissue as chiral bioplasmatic media, and (3) SAR simulation to evaluate the thermal effect. A brief explanation of the theoretical base of the technique used and description of the models are given in section 2. Results comparing the computed SAR values in the different models are shown and discussed in section 3. Finally, conclusions are presented.

2. Electrodynamic point of view.

To characterize the microwave absorption by the brain tissue, radiated by cellular phones, it is assumed that the brain tissue media is chiral. This chiral effect is due to a microscopic mechanism where the typical cell membrane of brain is a fluid bilipid layer with a lot big chiral protein molecules embedded in it. Every protein molecule is polar and will tend to align itself with an electric field and often helical rotate in its socket, so any volume of brain tissue must have a lot of cells bearing protein molecules that happen to resonate at its rotation frequency.

Studies on DNA have shown that large electron flows are possible with the stacked base pairs of the double helix and a collective interaction of large ionic ensembles where the electromagnetic field is assumed in aqueous solutions of amino acids. Also when the twisted DNA molecule is a right-handed helix is transcribed into RNA, the DNA molecule can be unwound. And it is possible that signaling inside neurons can have two twists. Here, we propose the hypothesis that all these features can be explained in a unified manner, namely the chiral-electrodynamics model, where the bioplasma is divided into two very thin layers separated by a permeable membrane, having cylindrical microtubules or helical structures. The dimmers α and β can exist in two different geometric configurations which correspond to the electric polarization states of dimmers, whose helicoidal structure can be right (R) or left (L). Then, since the protein medium is chiral, an electromagnetic wave in this medium necessarily will rotate its polarization plane in accordance with the dominant biological structure. Preliminary calculus show that the medium frequencies are between 10 and 20 GHz (microwave radiation). The eigenfrequencies, for typical proteins become between 10 GHz -12 GHz and for cluster DNA molecules the interval is between 1 GHz to 12 GHz. These frequencies are typical for microwave radiation. Accordingly with the above discussion, we consider the brain tissue as a chiral bioplasma immersed in a low magnetic field, characterized by a global chirality factor, T , so the Born-Fedorov constitutive equations are

$$\mathbf{D} = \varepsilon(\mathbf{E} + T\nabla \times \mathbf{E}), \dots \mathbf{B} = \mu(\mathbf{H} + T\nabla \times \mathbf{H}) \quad (1)$$

where ε , μ and T are the permittivity, the permeability and the chiral scalar, respectively. Solving Maxwell's equations for a plane electromagnetic wave of frequency ω ($\omega = k_t v = 2\pi f$, k_t is the tissue wave number and v is the phase velocity) propagating in a chiral medium, it can be shown that the left- and right-hand circularly polarized waves have different wave numbers, $k = k_t / (1 + k_t T)$ and $k = k_t / (1 - k_t T)$, respectively. The chiral parameter T has the dimension of a length. Here, the rotor of polarization plane can be predicted from Maxwell's equations, considering that the \mathbf{P} or \mathbf{M} vector has a proportional additional term to rotor \mathbf{E} or rotor \mathbf{H} , respectively. If it is assumed that the medium is isotropic, non-permeable and non-dispersive, the Cartesian field components are [7]

$$D_{x,y,z} = \varepsilon_0 \varepsilon_r E_{x,y,z} + \varepsilon_0 \varepsilon_r T \left[\frac{\partial E_{z,x,y}}{\partial y, z, x} - \frac{\partial E_{y,z,x}}{\partial z, x, y} \right], \dots B_{x,y,z} = \mu_0 H_{x,y,z} + \mu_0 T \left[\frac{\partial H_{z,x,y}}{\partial y, z, x} - \frac{\partial H_{y,z,x}}{\partial z, x, y} \right] \quad (2)$$

Using the MKS system of units, the following system of scalar equations is the set of Maxwell's equations in the rectangular coordinate system (x, y, z)

$$\frac{\partial H_{x,y}}{\partial t} = \mp \frac{1}{\mu} \frac{\partial E_z}{\partial y, x} \pm T \frac{\partial^2 H_z}{\partial y, x \partial t}, \dots \frac{\partial H_z}{\partial t} = \frac{1}{\mu} \left(\frac{\partial E_x}{\partial y} - \frac{\partial E_y}{\partial x} \right) + T \left(\frac{\partial^2 H_y}{\partial x \partial t} - \frac{\partial^2 H_x}{\partial y \partial t} \right) \quad (3)$$

$$\frac{\partial E_{x,y}}{\partial t} = \pm \frac{1}{\varepsilon} \frac{\partial H_z}{\partial y, x} \pm T \frac{\partial^2 E_z}{\partial y, x \partial t} - \sigma E_{x,y}, \dots \frac{\partial E_z}{\partial t} = \frac{1}{\varepsilon} \left(\frac{\partial H_y}{\partial x} - \frac{\partial H_x}{\partial y} \right) + T \left(\frac{\partial^2 E_y}{\partial x \partial t} - \frac{\partial^2 E_x}{\partial y \partial t} \right) - \sigma E_z \quad (4)$$

where σ ($S m^{-1}$) is the tissue electrical conductivity. After calculation of the induced chiral electric field by the FDTD method, the local specific absorption rate SAR is obtained as

$$SAR_{i,j}(T) = \frac{\sigma_{i,j} E_T^2|_{i,j}}{2\rho_{i,j}} \quad (5)$$

where

$$E_T|_{i,j}(T) = \sqrt{\frac{1}{n} \sum_1^n \left(E_y^2|_{i,j} + E_x^2|_{i,j} + E_z^2|_{i,j} \right)} \quad (6)$$

In these equations, the electric (magnetic) fields depend not only on \mathbf{E} (resp. \mathbf{H}) but also on the transverse components.

3. SAR simulation and analysis of results

For the numerical calculation, the chiral factor is normalized as kT , where k is the wave number in the tissue layer, in some cases it may be $k_t = nk_0$ ($k_0 = \omega/c$ is the vacuum wave number), with $n = 1, 2, 3, \dots$, taking into account the multiphoton absorption when the resonance absorption at macromolecular level becomes important. For the brain, we considered $k = k_b/(1 - k_b T)$ because the clusters of DNA molecules have eigenwaves representing right-hand circularly polarized waves and for the rest of the tissues we considered $kT = k_t T = 0$. Calculation stages of the bioplasmatic model for SAR determination are shown in figure 1. Using the linear FDTD algorithm with chirality, obtained from equations (3)-(6), simulations for microwave spectrum are made. The model of human head was constructed with 540000 cubic cells of 2.5 mm side each. The total number of layers, counted from the bottom of head, used in this model was 54. Here we choose layer 35, because it has a large concentrations of brain tissue. Figure 2 shows these layers in digitalized version (matrix of 100×100), likewise is exhibited the antenna position. Both, the dielectric constant and the conductivity of the brain were obtained from literature. In order to study and isolate the chiral effect, calculations are made for plane wave assumption, powers of 1.25, 12.5 and 125 mW were used, at frequencies of 0.9, 1.8, 2.4, 5.2, 5.8, 30, 60 and 100 GHz, respectively, having the cellular phone antenna an impedance of 180 Ω . Four types of tissues (skin, bone, blood and brain) are considered. Simulations were made in a systematic way, in order to determine the effect that the variation of the chiral coefficient had over the absorption of coefficient SAR, and results, for layer 35, are shown in figures 3-9. Owing to the different electromagnetic properties of the tissues, the power absorption is not a monotonically decreasing function of depth. For $kT = 0$, absorption is highest in the skin, low in the skull, but higher again in the brain. These curves were obtained performing similar simulations and then obtaining a statistical average of the SAR. In all curves, as the wave penetrates the head, it traverses the different parts of which the head model is made and the value of the SAR is attenuated quickly due to the change in medium and the increase of the distance from the emitting source (antenna). It is important to say that the SAR maximum (hot point) is in the outer part (skin). After passing through the bone level, the SAR is much attenuated (between cells 5 and 10) and around cell 10 the SAR increases at brain level. Here, starting from cell 10 approximately it is important to analyze the performance of our bioplasmatic model.

The profile of the SAR for 35th layer, at 0.9 GHz as function of distance for different values of chiral factor kT , is shown in figure 3, where the variation is observed for values of chiral factor $0 < kT \leq 3$. A SAR of 0.032 W kg^{-1} , is observed in the brain region, for a null chiral factor ($kT = 0$). For $kT = 1$, the SAR found was 0.036 W kg^{-1} , an increase of 12.5% with respect to the achiral case ($kT = 0$), and a SAR of 0.043 W kg^{-1} was found for $kT = 3$, with an increase 34%. This increase corresponds to the power absorbed by the head. Figure 4 shows the distribution of the SAR for 35th layer, as a function of distance, for different values of the chiral factor when the work frequency is 1.8 GHz. The maximum SAR found, in the blood-brain region, was 0.08 W kg^{-1} for to $kT = 0$ and 0.116 W kg^{-1} for $kT = 1$, i.e. an increase of 45% with respect to the achiral case. For a high value of chiral factor, $kT = 3$, the maximum SAR found was 0.12 W kg^{-1} with an increase of 50%. Again, this increase corresponds to the power absorbed by the head. Figure 5 shows the distribution of the SAR for 35th layer, as a function of distance, for different values of the chiral factor when the work frequency is 2.4 GHz. The maximum SAR found, in the blood-brain region, was 0.09 W kg^{-1} for to $kT = 0$ and 0.13 W kg^{-1} for $kT = 1$, i.e. an increase of 44% with respect to the achiral case. For a high value of chiral factor, $kT = 3$, the maximum SAR found was 0.16 W kg^{-1} with an increase of 77%.

Figures 6-8 show the distribution of the SAR, for 35th layer as a function of distance, for different values of the chiral factor, when the work frequency is 30, 60 and 100 GHz. The SAR found in the blood-brain region increase when the power get higher also for chiral factor 0, 1, and 2, the SAR is barely increase, for each power simulated. Figure 9 show the distribution of the SAR maximums in the blood-brain region, as a function of frequency, for different powers and chiral factors as summary of all the simulations made it. The consequence of being at such frequency is the fact that the human tissue (especially brain tissue) absorptivity of microwave radiation increase with frequency in this spectrum region. Theses must be verified by using more advanced models. The results of figure 9 are similar to those of Curry [8].

4. Conclusions

A bioplasmatic chiral model of the human head has been presented that allows determination and evaluation of the absorption induced by the radiation of cellular phone and wireless systems. Electromagnetic fields radiated were determined firstly by means of the FDTD technique and then the specific absorption coefficient (SAR). It is shown that the use of a cell model, combined with a real model of the human head, derived from the magnetic resonance of images allows exact determination of the near fields induced in the head when the brain chirality is considered. The simulations are made for the 35th layer. The results also show the evolution of the specific

absorption rate, (SAR coefficient), as function of input power and chiral factor. The more important conclusion of our work are: 1) with the chiral electrodynamics model the head absorption of microwave fields, produced by cellular phones and wireless systems, is bigger than the results obtained for classical models, and 2) the absorption of microwave radiation increases with frequency.

ELECTROMAGNETIC FIELD LEVELS IN THE WORKING ENVIRONMENT IN RADIO AND TV STATIONS. PROGRAM FOR HEALTH PROMOTION

Ivanova, M., V. Zaryabova, Ts. Shalamanova, M. Israel

National Center of Public Health Protection, Sofia, Bulgaria

Abstract

Electromagnetic field sources used for communication always are subject of serious interest. There are many publications concerning exposure and risk assessment of the working in such environment. Results of epidemiological study performed in Bulgaria in 90s (Varna, Proceedings 2001) show exceeding of the maximal permissible values especially in radio stations for the personnel in 24 h working shift.

In the last years the situation is strongly influenced by the development of the technology which leads to changes in equipment in radio and TV stations, using lower power, facilitate the working regime.

Paper presents data of exposure assessment of different professional groups in selected radio and TV stations. Assessment is being performed on basis of EMF parameters values and energetic load calculations according to the national legislation. Data are compared with the results of previous investigation to evaluate the new situation in this branch. Exposure levels are much lower than those in the last study, and lower compared to the exposure limits, as well.

INTRODUCTION

The policy of the World Health Organization (WHO) after its establishment incorporates occupational health issues. Numerous important WHO documents, such as the Constitution, Alma Ata Declaration, "Health for All" Strategy, working programs and certain resolutions of the World Health Assembly underline the necessity to protect and strengthen health and safety at work through prevention and control of workplace hazardous factors and promotion of workers' health and work ability.

The transition during the past two decades experienced by European socioeconomic communities contributed to accelerated changes in labor conditions and market. Many European countries show a tendency to re-orienting the occupational health and safety policy towards improved workers' work ability and significant reduction of increasing social costs for work-related health disorders, injuries and disability. The new global strategy of the EU Commission and International Labor Organization (ILO) is fully focused on improving the activities on health and safety at work (HSW) at enterprise and national level. The developed systems for HSW control are a successful approach to fulfillment of the responsibilities and gaining maximal benefits through their incorporation in company and national policy, moreover, these systems are implemented in many countries, including a number of Bulgarian companies. They are built on the belief that good work management and reduction of workplace risk are based on self-control, self-assessment and adequate measures for improved safety. Such management is much more effective and with better results than just observing the regulations, moreover, ILO methodological guidelines for systems for control of health and safety at work are not mandatory. They are recommendations to the employer on achievement of better prevention level; reduction of risk for work accidents and occupational diseases and following costs and company losses; reduction of occupational risk and hence – improvement of the company image; improved work quality leading to elevated company competence; last, but not least – functional social dialogue.

The employer has to present his HSW policy as a written program, after consultations with the employees and their representatives.

A very interesting professional group exposed to high levels EMF is those of operators working in radio and TV stations. Electromagnetic field sources used for communication always are subject of serious interest. A wide-spread set of communication systems exists in each country and its types and number is ever increasing.

An epidemiological study carried out in Bulgaria in 90 [5] showed exposure to the personnel of such stations above the permissible levels accepted in the country, especially in the cases of 24-hour working shifts. The results showed that the long-term service of emitting systems results in serious health problems for operating staff, charged with broadcasting.

The present study is a continuation of the previous epidemiological study [5] and one of its goals is to assess how the development of the technology which leads to changes in equipment in radio and TV stations, using lower power, facilitation of the working regime affects the exposure of the operators. The investigation

covers a part of previously studied stations, which gives an opportunity for direct comparison of the results for the personnel's exposure.

MATERIAL AND METHODS

Objects of study

This study was performed on radio broadcasting system of short waves (SW), television (TV), and on satellite systems. The study covers the following stations:

- **Radio broadcasting** station on short waves (SW) - from 6 to 25 MHz;
- **TV station 1 with sources emitting EMF with frequencies from** 66 MHz (UHF) to microwaves up to 6 GHz;
- **TV station 2 with sources emitting EMF with frequencies** 101 MHz (UHF) to microwaves up to 6 GHz;
- **TV station 3 with sources emitting EMF with frequencies** UHF и microwaves;
- **Satellite station** – frequencies from 5 GHz to 7 GHz.

We found 5 types of work shifts - A, B, C, D и G as follows:

- A – 5 days a week, 8 h per day – ordinary shift. The rest of the time the personnel is outside the station;
- B – one twenty-four hour period (24 h) in the working environment being followed three subsequent twenty-four hour periods of rest at home;
- C – four subsequent twenty-four hour periods in working environment being followed by three subsequent twenty-four hour periods of rest at home; During its stay in the station the personnel is 10 hours on shift (active working) and 14 h on disposal;
- D – 7 days in the working environment followed by 14 days outside (rest at home). During its stay in the station the personnel 5 days is 12 hours on shift (active working) and 12 h on disposal and the other two days are resting in the station;
- G – two subsequent twenty-four hour periods in working environment being followed by two subsequent twenty-four hour periods of rest at home.

The following jobs were characterized: radio engineer, engineer (both with master degrees), mechanic, technician, fitter, sound-technician, radio technician, power engineer, electric fitter, electrician, electric technician, mast operator. Every station depending on its type, equipment, geographical position, etc. has different professionals. Here, we present the results for the next groups: operator on duty, chief of station, power engineer.

Additionally results for a group “other staff” being not directly engaged in the transmitters’ service is presented. It includes: cleaners (other assistant jobs) and canteen managers.

Measurement equipment

The measurements of the EMF exposures were made using the following equipment:

N F M - 1 (made in Germany):

- measuring values: $E = 2$ to 40 kV/m for $f = 50$ Hz
 $E = 2$ to 1500 V/m for $f = 0.06$ -350 MHz
 $H = 0.1$ to 10 A/m for $f = 0.06$ -10 MHz
- uncertainty: $\sigma = \pm 20 \%$;
- probes - dipole and frame.

RAHAM 495, model 40, “General Microwave Corporation”(USA).

- Frequency range: 200 kHz - 40 GHz;
- Measurement ranges – 0.02, 0.2, 2 and 20 mW/cm²;
- Uncertainty $\pm 20 \%$;
- Minimal measured value – 0.5 μ W/cm²
- Probe – isotropic.

The devices measure the EMF values in a wide frequency range so specific methods for exposure assessment are used.

Measurement procedure

The measurements were made for typical permanent and temporary work places:

In closed premises: transmission's halls, in front of the transmitters, central desks and central control desks, central control rooms, in front of the final cascades of multipliers, near the antenna control boards, etc. All measurements were made on three levels above the ground (floor) - on the levels of head, chest and genitals of the operator, and the hygienic assessment was formed according to the maximum measured value.

On the antennae's field area we measured the field strength both under the feeder lines (feeders) at the same three levels, and along the roots of the antennas, at different depending on the area. In case of TV towers measurements were made on some of the platforms with antennae as well.

In living rooms only the maximum values of EMF measured have been taken for hygienic assessment.

All measurements were made while the transmitters worked at maximum power of radiation.

On the time of measurements the serving operators stayed on minimal distance of 5 to 10 meters behind the measurer.

The hygienic assessment of the measured values of EMF in the living rooms was made according to Ordinance No:9 for exposure to the general population (Table 3) as the personnel staying in this rooms should not be considered as performing its work tasks. The measured values of EMF in living rooms were added to the common assessment for the energetic loading of the organisms of the workers for 24 hours.

	300MHz – 30GHz	-	-	10	-	-	-

Parameters for exposure assessment

For exposure assessment the following parameters were used:

- energetic loading of organism:

$$W_E = \sum_i E_i^2 \cdot t_i, \text{ V}^2 \cdot \text{h}/\text{m}^2; \quad W_S = \sum_i S_i \cdot t_i, \mu\text{W} \cdot \text{h}/\text{cm}^2;$$

Energetic loading of the organism was calculated for the average and maximal measured values on “i” measurement point (place of stay or premise) respectively for electric field strength (V/m) and power density ($\mu\text{W}/\text{cm}^2$), depending on the frequency of emitted EMF;

- Time weighted average (TWA) values of electric field strength and power density, TWA:

$$TWA = \frac{\sum_i E_i \cdot t_i}{T}, \text{ V/m} \quad TWA = \frac{\sum_i S_i \cdot t_i}{T}, \mu\text{W}/\text{cm}^2$$

where E_i and S_i are the measured values on the “i” workplace; t_i is the time duration of exposure on the same

place, $i = 1, \dots, n$; $T = \sum_{i=1}^n t_i$.

For the described stations TWA of electric field strength and power density are calculated for the average and maximal measured value of EMF on the corresponding places of stay of the personnel. Calculations for two averaging periods were made:

- for one working day – 8h, 10 h, 12 h and 24 h corresponding to the work shift duration and work cycle. Here, the real working time, time on disposal, time of rest in the station, time of rest outside the station were taken into account.
- For 120 h (5 twenty-four hour periods – one working week), taking into account the shift type (A, B, C, D и G).

Energetic loading of the organism is considered for zero for the stay outside the station.

Calculated TWA values for SW range (V/m) are presented in units $\mu\text{W}/\text{cm}^2$ “equivalent power density” for plane wave.

The real time of exposure was determined in the following ways:

- "script or scenario" method - an expert method, based on repeated measurements and for long findings of the working process. It was applied for the three groups of personnel (those, working for 24 h in a shift, others working for 8 h - normal shift, and for the "other" workers) at all studied sites, namely radio stations, TV stations and radio relay stations.

- calculating the maximum permissible time duration. The requirements of the Bulgarian National Standards (BNS) were used when determining the limits of the energetic loading of the organism. Maximum permissible time duration of every working place was calculated according to the average values of EMF by using the formulae:

$$T_{\max} = \frac{W_E}{E^2}, \quad T_{\max} = \frac{W_S}{S}$$

where W_E , W_H and W_S are values of the energetic loading of organism for corresponding frequency range according to national legislation (Table 3).

RESULTS AND DISCUSSION

Measured EMF values in relative units compared to the limits for corresponding frequency range are presented in Table No.4.

Table No.4.

Station	Average values	Maximal values
Radio station		
transmission's halls	0.02	0.09
antennae field	0,15	0.95
TV station 1		
transmission's halls	0.003	0.05
antennae field	0.20	0.06
TV station 2		
transmission's halls	0.0075	0.0196
antennae field	0.38	0.085
TV station 3		
transmission's halls	0.0045	0.00305

*The types of shifts are mentioned in brackets

The investigation showed the highest exposure for the personnel in radio station.

The highest values of EMF for every station are measured near the final cascades of the amplifiers, when setting up or repairs are carried out, in the antenna's field (around the irradiating antenna), near the feeders or antenna control board. For these places maximal permissible time of stay was calculated. By professional groups the highest energetic loading of the organism values were found for the professional groups which tasks require prolonged work in antennae field and comutator premises, namely operator on duty and chief of station.

The average values of the energetic loading of the organism in relative units compared to the limit values are between 0.003 и 0.31 depending on the professional group and the working shift type. The calculation for the maximal values (worst case) gives ratio of 3.23 for the SW radio station. In the previous study 3,58 times

exceeding of the energetic loading limit value was established for the 24 h shifts for SW transmitters and up to 0,7 of the limit value for the 24 h shift in the TV stations.

The previous study had shown exceeding of the energetic loading values for 28.1% and 43 % of the working places in the SW stations for 8 h and 24 h shift respectively, exceeding of EMF values was found in 14,3 % of working places in TV stations.

In the present study the exceeding of the maximal permissible values was found only for single cases in antennae field.

There were not measured EMF values above the limits for the general public in the living rooms in stations. Previously, in 67,4% of the studied living rooms EMF values exceeded the limits for the general public.

On the basis of conducted study and estimated exposure to the personnel we propose a risk communication and management program following requirements of WHO and the Precautionary Principle.

Activities concerning risk communication

An acting, addressed towards workers in EMF conditions program demands adhering to WHO requirements for informing the workers, training and limiting the risk to minimal levels. The effectiveness of the program is specified as from the permanent analysis of the taken measures as from the traceability of the actions and from the back link with the management and the group developed the program furthermore.

In this case we recommend outlining the following main actions:

1. Towards EMF levels:
 - adhering to the maximal permissible levels in the current hygienic standards.
 - observing the permissible time duration of stay in sites, where the electric field strength and/or power density exceed the maximal permissible level for corresponding frequency;
2. Control (dosemeters, measurements etc.)
 - regular check of EMF values, considering different powers or changes in the equipment.
 - each station should be equipped with at least one control measuring instrument (dosemeter), especially for performing tasks in antenna field;
3. Prophylaxis (technical, medical)
 - Periodical control of the technical equipment;
 - periodical check up of the health status of the staff including specialized surveillance: cardiovascular, nervous system, analysers, blood cells, germinative functions.
4. Collective and personal means for protection:
 - use and control of the protection measures and equipment
5. Compensations (nutrition, vitamins, etc.)

In cases when other prophylaxis is impossible or insufficient compensations could be applied. This approach is very extreme, and is applied only when all other possibilities are spent.

6. Training

There is necessity for topical courses on the main activities. The staff is well qualified concerning labour safety. The idea is to widen the training in the field of their specialities, work conditions, and the influence of the factors in the working environment.

7. Living conditions; resting rooms

It is clear that this is very important issue, and takes a special place in the risk communication and management. It ensures special attitude in workers.

8. Precautions (labels and fences, briefings, informational sheets and newsletters)

It is necessary precautionary labels, signs and fences (with bright and reflection colours), briefings, informational sheets and newsletters to be developed, and placed on appropriate places to show areas for stay and crossing, to warn for a possible accidents. Boards indicating the limited stay in the antenna field to be placed.

The materials prepared by the management concerning information about the communication program both for activities and results of the control, prophylaxis measures, preventive actions for health protection of the workers, news about the company organization, cases of accidents, etc., should be distributed on appropriate areas (working places, restrooms, dining rooms) aiming to inform the whole personnel.

Special attention should be paid to pregnant women and persons wearing active implants.

Mechanisms for back link

This part is fundamental for realizing the program. This could be performed by the management through an Occupational Health Service, Labour Committee, and Human Resources Department.

CONCLUSIONS

The comparison of results of the two considered studies shows decreasing of EMF exposure to the specific group of operators working in radio and TV stations. This result could be associated with the development of the technology which leads to changes in equipment in radio and TV stations, using lower power, using better shielding in the control rooms, facilitating the working regime.

ABSTRACT

Although recent researches approved that EM waves cause harm to CNS and bone marrow systems [1-6], they are not studied to have health effects on other systems of human body, Nevertheless possible health effects of EM waves on genitalia system is also a question as this system has also dividing cells (like CNS and bone marrow) in males and females. In this case possible effects of E-M waves on infertility is a matter of concern.

This research is done to investigate infertile couples about possession and usage methods of mobile handsets and also to discuss the role of the proximity of housing/occupation to BTSs of GSM (900, 1800) mobile phone network as a means of possible cellular phone exposure and so having possible influence on infertility.

The research has been done by questionnaires and as cross-sectional. Collected data then was analyzed using SPSS software.

The results of the study show that these variables have correlation with infertility:

1. duration which these patients use cellular phone for speech
2. place of holding cellular phone regarding body
3. model of cellular phone
4. Proximity of the handset regarding body

1. INTRODUCTION

Although recent researches have approved that E-M waves may cause harm to CNS and bone marrow systems [1-4], they are not studied to have health effects on other systems of human body. As CNS and bone marrow systems are made of dividing cells in all individuals and are proved to be affected by E-M waves of power lines and Radio frequency which have resulted Brain Cancers and different kinds of Leukemia, this idea is formed that E-M waves may have possible effects on genitalia system also as this system has dividing cells in males and females.

Indeed, a large segment of the world's population is now exposed to RF and microwave radiation. We need a better understanding of the biological effects of RF electromagnetic field so that we can safeguard against possible harms to the general population and increase its beneficial medical uses.

We have chosen the Microwaves used in cellular phone system as a course of study for possible effects on urogenital system. There are many usages of Microwaves in urban lives like satellites, point to point links, and cellular phones. The last one has a higher energy regarding its frequency and also higher amplitude regarding its usage and also is more globally used. Other forms of RF waves do not have remarkable values regarding microwaves used in cellular phone systems. With the widespread use of mobile phones, the question of cellular phone health hazards should be answered. That's why this research is focused mainly on the study of possible effects of cell phone microwaves on infertility.

2. BIOLOGICAL EFFECTS CAUSED BY MICROWAVES

Our knowledge regarding the biological effects of RF radiation have increased for many decades. It has become a focus of attention because of the accelerated use of RF radiation for wireless communication over the past few years. It is fairly well established that at sufficiently high power levels, RF and microwave energy can produce deleterious biological effects. Wireless communication systems use low power modulated forms of RF and microwave radiation that were not investigated extensively in the past.

Nevertheless, available data do not suggest any immediate cause for concern of an impending threat to the health of the population from acute or short term exposure to low level RF radiation. Investigations to answer some of the questions have already begun. Many of them are designed to study the effects of long term exposure. When considering repeated, low level radiation, the possibility of cumulative effects has been raised. While there is presently few confirmed evidence for cumulative effect, there is little information to the contrary.

Large scale epidemiological investigations should also be undertaken among the mobile telecommunication and cellular telephone users who may be exposed to varying levels of RF radiation over time. Better understanding is needed of the mechanisms of interaction between RF and microwave radiation and biological systems, and the significance of any observed effects. Enormous progress has been made in the difficult area of dosimetry. However, measurement of energy distribution in and around a subject for exposure assessment remains a challenge, more so for large numbers of people. This type of quantitative information is also required for extrapolation from animal experimentation to human response.

3. CHARACTERISTICS OF CELLULAR COMMUNICATION SYSTEMS

The research is focused on the health effects of cellular telephones. Cellular telephones operate at frequencies close to 850 and 1900 MHz in GSM¹ systems (these frequencies may vary for different countries.) The cellular phone system mainly consists of Base Transceiver Stations (BTS) and handsets for signal transmission. So studying the radiations of this system should be focused on these two parts.

Handsets transmit at low power levels. 0.6 watts for hand-held units in the first generation mobile telephones which were based on analog technology. Digital communication systems have made digital mobile technology competitive at power consumption as low as 10 mW. But, while in use, are located very close to the user's head. They are also to be used as placed on the belt or heart other locations near body for long hours when are on but not used for speech. They may also be in places near the body while sleeping. This has naturally led to concerns about potential health effects of handset radiations.

Returning to the BTS, the total MW power that could be transmitted from each BTS antenna at a cell site depends on the number of radio channels (transmitters) that have been authorized and the power of each transmitter. Typically, for a cellular base station, a maximum of 21 channels per sector (depending on the system) could be used. Thus, for a typical cell site utilizing sector antennas, each of the three transmitting antennas could be connected to up to 21 transmitters for a total of 63 transmitters per site. When omni directional antennas are used, up to 96 transmitters could be implemented at a cell site, but this would be unusual. While a typical base station could have as many as 63 transmitters, not all of the transmitters would be expected to operate simultaneously thus reducing overall emission levels.

Although an *effective radiated power* (ERP) of up to 500 watts per channel (depending on the tower height) is permitted, the majority of cellular base stations in urban and suburban areas operate at an ERP of 100 watts per channel or less. An ERP of 100 watts corresponds to an *actual* radiated power of about 5-10 watts, depending on the type of antenna used (ERP is not equivalent to the power that is radiated but, rather, is a quantity that takes into consideration transmitter power and antenna directivity). As the capacity of a system is expanded by dividing cells, i.e., adding additional base stations, lower ERPs are normally used. In urban areas, an ERP of 10 watts per channel (corresponding to a radiated power of 0.5 - 1 watt) or less is commonly used.

The signal from a cellular base station antenna is essentially directed toward the horizon in a relatively narrow pattern in the vertical plane. The radiation pattern for an omni-directional antenna might be compared to a thin doughnut or pancake centered around the antenna while the pattern for a sector antenna is fan-shaped, like a wedge cut from a pie. As with all forms of electromagnetic energy, the power density from a cellular or PCS transmitter decreases rapidly (according to an inverse square law) as one moves away from the antenna. Consequently, normal ground-level exposure is much less than exposures that might be encountered if one were very close to the antenna and in its main transmitted beam.

Measurements made near typical cellular installations, especially those with tower-mounted antennas, have shown that ground-level power densities are well below limits recommended by RF/microwave safety standards [7-9]. For example, for a base-station transmitting frequency of 869 MHz the RF exposure guidelines recommend a Maximum Permissible Exposure level for the public ("general population/uncontrolled" exposure) of about 580 microwatts per square centimeter ($\mu\text{W}/\text{cm}^2$).

¹ Global Service Mobile system

This limit is many times greater than MW levels found near the base of typical cellular towers or in the vicinity of lower-powered cellular base station transmitters, such as might be mounted on rooftops or sides of buildings. Measurement data obtained from various sources have consistently indicated that "worst-case" ground-level power densities near typical cellular towers are on the order of $1 \mu\text{W}/\text{cm}^2$ or less (usually significantly less). Calculations corresponding to a "worst-case" situation (all transmitters operating simultaneously and continuously at the maximum licensed power) show that in order to be exposed to levels near limits for cellular frequencies, an individual would essentially have to remain in the main transmitting beam (at the height of the antenna) and within a few feet from the antenna.

This makes it extremely unlikely that a member of the general public could be exposed to MW levels in excess of these guidelines due to cellular base station transmitters. When cellular antennas are mounted at rooftop locations it is possible that ambient MW levels greater than $1 \mu\text{W}/\text{cm}^2$ could be present on the rooftop itself. However, exposures approaching or exceeding the safety guidelines are only likely to be encountered very close to or directly in front of the antennas. For sector-type antennas MW levels to the side and in back of these antennas are insignificant.

Even if MW levels were higher than desirable on a rooftop, appropriate restrictions could be placed on access. Factoring in the time-averaging aspects of safety standards could also be used to reduce potential exposure of workers who might have to access a rooftop for maintenance tasks or other reasons. The fact that rooftop cellular and PCS antennas usually operate at lower power levels than antennas on free-standing towers makes excessive exposure conditions on rooftops unlikely. In addition, the significant signal attenuation of a building's roof minimizes any chance for persons living or working within the building itself to be exposed to RF levels that could approach or exceed applicable safety limits. With this deduction, we have focused mainly on the radiation of the handsets while considering health effects on infertility.

4. MATERIAL AND METHOD

Isfahan is regarded to be Iran's second big city which has a vast cellular phone system. The population of infertile couples in Isfahan is rather high. Isfahan Fertility and Infertility Center (IFIC) is a place for the study of infertility and thus possible effects of microwaves used in cell phones on infertility.

This project is done as a cross-sectional research using questioners. As it was stated before, in lack of quantitative data about the exposure effects of microwave frequency band used in cellular phone system, the questioner based method will be useful to analyze situation. The questioner was designed to gather information about the usage and brand of mobile handsets and also the proximity of housing/occupation to BTSs of cellular phone network. The questioner was to get information of infertile couples that have visited the IFIC in a specific period of time. Our inclusion criteria was (1) visiting the IFIC in the interval of Sep. 2004 – Feb. 2005 (2) Owning a cellular phone.

As to omit the mixture results of Ionizing radiations and power frequencies, our exclusion criteria was (1) proximity of houses to nuclear equipments, (2) occupation in them and (3) occupation and living by power line frequencies sources, (4) power plants, (5) radio stations, and (6) Broadcast, satellite stations, so these cases were omitted of the study set. Data was gathered by interviewing and ask questions to fill the questionnaire. In this period, 209 cases who had the two inclusion criteria and did not have the exclusion criteria included in the study. Table 1 shows some inquiries made by the questioner.

The collected data was then analyzed by SPSS 11.5 and these to summarize data these types of charts used:

- ✓ Pie chart to summarize data of a nominal variable
- ✓ Histogram chart to summarize data of a scale variable

Table 1 shows the most significant inquiries made by the questioner.

Table 1. The inquiries made by the questioner

Personal Information
Name , Home address, Work address, Occupation
Date of infertility notice
Distance between Home and nearest BTS
Distance between work place and nearest BTS
Brand and model of hand set
Hours using handsets a day
Hours having the phone turned on near the body (less than one meter)
Place holding the phone when turned on (by body side)
Place holding the phone when turned on (while speaking)
How long is the phone turned on while sleeping?
How long do you speak with your phone a day
Do you use hands free? Wireless or wired?

5. Results and Findings

The measurement of duration which each case has used cell phone shows that the mean of this time is 4.05 years.

Table 2. Duration which each case has used cell

Duration which each case has used cell	N	Min	Max	Mean	Std. Dev.
Cell Phone Duration	209	1	11	4.05	2.122
Valid N (listwise)	209				

We measured the mean amount of time in which the cell phone is on and in a distance less than one meter regarding the body in each day. 77.9% of them have their cellular within this distance more than 10 hours (including near bed when sleeping).

Table 3. The mean amount of time more is than 10 hours

The mean amount of time more is than 10 hours		Frequency	Percent
Valid answer	yes	163	77.9
	no	45	22.1
Total		209	100.0

The study of cellular phones' model performed and the results below were achieved:

Table 4. Cellular phones' model

Cellular phones' model	Freq.	Valid Percent
Valid		
Samsung	63	30.1
Nokia	101	48.3
Siemens	12	5.7
Sonyericsson	18	8.6
Panasonic	14	6.7
LG	1	0.5
Total	209	100.0

The next Pie chart summarizes data above:

We also studied where each patient holds the cellular phone when it is on but not in use, so the results below achieved:

Table 5. Where does each patient hold the cellular phone?

Where does each patient hold the cellular phone		Frequency	Percent
Valid Answer	Belt	101	48.3
	Shirt pocket	43	20.6
	Slacks pocket	22	10.5
	In bag	17	8.1
	Tied from neck	26	12.4
Total		209	100.0

This Pie chart shows the latter data:

The measurement of the time which each patient calls with cellular phone each day was asked and showed that the mean of this time is 62.61 minutes/day for them. This table shows the data collected:

Table 6. The time each patient calls with cellular phone a day

The time each patient calls with cellular phone a day	N	Range	Min	Max	Mean	Std. Dev.
speech time	209	100	10	110	62.61	7.093
Valid N (listwise)	209					

This graph represents the number of cases which calls with cellular phone in each specific duration:

Figure 1. The number of people (vertical) regarding their speech time a day (horizontal)

The study of relation between the duration which these patients uses cellular phone and the duration of infertility shows a relation with correlation coefficient of $P = 0.345$ ($\rho = 0.037$). This study performed by Bivariate Correlation and usage of Spearman coefficient¹.

¹ In statistics, **Spearman's rank correlation coefficient**, ρ (rho), is a non-parametric measure of correlation, it does not require the assumption that the relationship between the variables is linear,

In principle, ρ is simply a special case of the Pearson product-moment coefficient in which the data are converted to ranks before calculating the coefficient. In practice, however, a simpler procedure is normally used to calculate ρ . The raw scores are converted to ranks, and the differences D between the ranks of each observation on the two variables are calculated. ρ is then given by:

$$\rho = 1 - \frac{6 \sum D^2}{N(N^2 - 1)}$$

where:

D = the difference between the ranks of corresponding values of X and Y , and
 N = the number of pairs of values.

The study of duration of infertility and distance between job/living place and the distance to the closest electric communication antenna shows a relation with correlation coefficient of $P=0.0261$ ($\rho=0.0046$), which shows weak correlation between the two variables. This study performed by Bivariate Correlation and usage of Spearman coefficient.

6. CONCLUSION

In this research, we investigated the possible effect of cellular phone system radiations on infertility. The result of our studies shows possible influences of cell phone handsets on the cases that have been sampled. The study shows that these variables have correlation with infertility:

5. duration which these patients use cellular phone for speech
So that the increase of usage of mobile phone from 10 to 60 minutes a day yields to an increase of infertile couples
6. place of holding cellular phone regarding body
48.3% of the cases hold their handsets on their belts
7. model of cellular phone
48.3% of the cases used Nokia brand
8. Proximity of the handset regarding body
77.9% of the cases had their handsets on and near the body more than 10 hours in 24 hours.

The study of relation between the duration which these patients use cellular phone and the duration of infertility shows a relation with correlation coefficient of $P = 0.345$ ($\rho=0.037$) which shows a slight linear correlation.

The study of duration of infertility and distance between job/living place and the distance to the closest electric communication antenna shows a relation with correlation coefficient of $P = 0.0261$ ($\rho=0.0046$) which shows little correspondence between the two variables so the parameter: Distance between living/job place and the closest electric communication antenna, did not show any meaningful relationship with the infertility date, as was presumed by the discussion presented in section 2.

7. ACKNOWLEDGEMENT

The Authors wish to thank Dr. M. Ahmadi, member of IFIC, for his kindest cooperation in the research. They are also grateful of Mr. E and F. Ahmadi for spreading and gathering up the questioners.

Abstract

Electromagnetic Fields (EMF) can affect biological systems by increasing the amount of free oxygen radicals. Antioxidants are able to reduce the effects of free radicals formed in body. Glutathione (GSH) is one of the important antioxidants in body defense system for free radical. In this study, we examined the effects of 50 Hz magnetic fields on GSH level in kidney. A total of 56 male guinea pigs were used. Forty-nine guinea pigs were exposed to 50 Hz, 1 mT, 2 mT and 3 mT fields with the exposure periods of 4 and 8 hours/day for 5 days. Seven subjects were handled in an identical manner with the exposed animals in the same laboratory. They were used as control without being exposed to any magnetic fields. The GSH levels were determined spectrophotometrically by modified Aykaç et al. method. Increased GSH levels were found in kidneys of guinea pigs exposed to 1 mT magnetic field for the exposure periods of 4 hours. For the magnetic fields of 2 mT and 3 mT applied with the period of 8 hours, increased levels of GSH were also found. It seems that ELF magnetic fields promote the levels of GSH which has a protective role against the oxidative damage.

Introduction

Exposure of human bodies to extremely low frequency electromagnetic fields (ELF EMF) have been increased by growing use of electrical devices, which emit EMF. It has been showed that EMF influence enzymatic activity in biological systems (Noda, 2000). Several studies on effects of EMF have shown that EMF can induce cell proliferation, variations of calcium concentrations, alteration of DNA integrity, changes in transcription of immediate early genes and protein synthesis (Boland, 2002; Ishisaka, 2000; Gold, 1994; Kenneth, 1987; Guler, 1996a; Guler, 1996b; Guler, 1999; Seyhan, 2006; Canseven, 1996; Canseven, 1999; Canseven, 2005a; Canseven, 2005b; Liboff, 1987; Liburdy, 1993) and perturbations of central nervous system (Ilhan, 2004; Jelenkovic, 2006; Jin, 1998; Lai, 1996; Lai, 2004). It is known that ELF magnetic fields (MFs) may cause an increase in free radicals activity in living organisms (Boland, 2002; Kula, 2002; Kula, 2000; Roy, 1995; Khadir, 1999; Simko, 2001; Seyhan, 2006; Guler, 2006). Free radicals are very reactive and unstable molecules that can initiate chain reactions to form new free radicals. Antioxidants are able to reduce the effects of free radicals formed in body. Cells are also equipped with the enzymatic antioxidant mechanisms that play an important role in the elimination of free radicals (Gorenek, 2006; Guler 2006; Ozgur, 2006; Seyhan, 2006) Glutathione (GSH), the most abundant non-enzymatic antioxidant present in the cell, plays an important role in the defense against oxidative-stress-induced cell injury.

It has been showed that exposures of magnetic fields with various frequency and intensity can change the antioxidant activity of human and animal bodies (Harakawa, 2005; Kashalda, 1995; Fiorani, 1997; Ozguner, 2005; Canseven et al., 2005c).

This study was designed to find the effects of exposure to 1 mT, 2 mT and 3 mT of 50 Hz magnetic fields on GSH levels in kidneys of guinea pigs in various exposure periods.

Materials and Methods

Animals

The experimental protocol was reviewed and approved by the Laboratory Animal Care Committee of Gazi University (Report no: 36-7838). A total of 56 male, 250-300 g weighted guinea pigs were used in this experiment. All animals were kept under laboratory conditions and fed standard pellet food.

Magnetic Field Exposure

The system used to generate the magnetic fields was Helmholtz coils' system which was specially designed by Bioelectromagnetic Laboratory at Biophysics Department of Medical Faculty of Gazi University (Canseven, 2005d). This system consisted of two parallel horizontal flat circular coils of 42.75 cm diameter, with a common axis, and separated by 21.375 cm. Each coil has 154 turns and was constructed by insulated copper wire. Sinusoidal current of frequency 50 Hz was generated by the specially designed variable transformer, 2.7 kVA in power. The intensity of MF was modulated by the transformer. The magnetic field generated by the coils is classified as vertical field since the field lines perpendicular to the bottom plane of the animal's cage.

Forty nine guinea pigs were housed in the centre of the Helmholtz coils, 2 per plexiglas cage and were exposed to 50 Hz, 1 mT, 2 mT and 3 mT fields with the exposure period of 4 hours/day or 8 hours/day over 5 days. Seven subjects were handled in an identical manner without being exposed to any magnetic field and studied as controls.

The temperature of laboratory was held constant at 23° C with day and night cycle of 12 hours and ambient geomagnetic field of 30 μ T. To eliminate possible variations due to circadian rhythm, the exposure periods of magnetic fields were chosen as 8:00 - 12:00 a.m for 4 hours of exposure periods and 8:00 a.m - 4:00 p.m for 8 hours of exposure periods.

Following 12 h of starvation, guinea pigs were injected intramuscularly with ketamine (30 mg/kg) and xylazine (2 mg/kg) and 250 IU/kg heparin. Kidneys were sampled immediately. They shocked by liquid nitrogen and stored in deep freezer at -80°C until performing analysis.

Determination of GSH levels

The GSH levels were determined by modified Aykaç et al. (Aykaç, 1985) method. Tissues were homogenized in nine volumes of cold 10% TCA solution and the homogenate was centrifuged for 15 min. at 3000xg at 4°C. The supernatants were transferred to glass test tubes. 0.5 ml of supernatant was added to the 2 ml of 0.3 M $\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O}$ solution. a 0.2 ml solution of dithiobisnitrobenzoate (0.4 mg/ml 1% sodium citrate) was added and absorbance at 412 nm was measured immediately after mixing. The GSH levels were calculated using an extinction coefficient of $13.600 \text{ mol}^{-1} \text{cm}^{-1}$.

All experiments were run in a blind manner.

Statistics

Statistical analyses were carried out using SPSS software (SPSS 11.5 for windows, SPSS Inc., Chicago, USA).

The p value was considered significant at $p < 0.05$.

Mann Whitney-U and Kruskal-Wallis tests were used in statistical analysis. Comparisons between exposed groups and controls were made by using Mann Whitney-U test while magnetic fields of 1mT, 2 mT and 3 mT were compared with Kruskal-Wallis test with respect to exposure periods of 4 hours and 8 hours.

Results

In this study, GSH levels were measured in kidney of guinea pigs, which were exposed to magnetic fields of 1 mT, 2 mT and 3 mT fields with the exposure periods of 4 and 8 hours/day for 5 days. For both of the exposure periods, GSH levels were found increased with respect to controls in kidney of guinea pigs exposed to the 50 Hz magnetic fields of 1 mT, 2 mT and 3 mT, except 1 mT, 8 hours. The increases in GSH levels were found statistically significant for 1 mT, 4 hours ($p=0.000$), 2 mT, 8 hours ($p=0.000$) and 3 mT, 8 hours ($p=0.021$) in kidneys by Mann-Whitney U test.

Field intensities were compared with respect to exposure periods by Kruskal-Wallis test. Significant differences were determined between field intensities of 1 mT, 2 mT and 3 mT in kidney tissues for both of the exposure periods ($p=0.001$ and $p=0.000$ for 4 hours and 8 hours respectively).

Discussion

Glutathione is a major non protein thiol in living organisms. It plays a crucial role in coordinating the body's antioxidant defense process. Several studies have reported the effects of 50 Hz magnetic fields on antioxidant defense system activity or GSH levels (Kashkald, 1995; Harakawa, 2005; Fiorani, 1997; Canseven, 2005d). Fiorani et al. reported that the fields are able to potentiate the cellular damage induced in vitro by oxidizing agents (Fiorani, 1997).

Table 1 . GSH (micromole/g tissue) levels in kidney tissues of 1 mT, 2 mT and 3 mT exposed and control guinea pigs. Exposure periods were 4 hours/day and 8 hours/day for 5 days.

GROUPS	n	GSH Level (micromol/g tissue)
		mean \pm sem
Control	7	3.09 \pm 0.48
1 mT; 4 hours	8	6.44 \pm 0.42
1 mT; 8 hours	10	2.43 \pm 0.17
2 mT; 4 hours	6	3.40 \pm 0.32
2 mT; 8 hours	8	5.93 \pm 0.33
3 mT; 4 hours	9	4.63 \pm 0.41
3 mT; 8 hours	8	5.16 \pm 0.50

To evaluate the effects of magnetic fields on antioxidant defense system, GSH levels were measured on guinea pigs exposed to magnetic fields of 1 mT, 2 mT and 3 mT fields with the exposure periods of 4 hours/day and 8 hours/day for 5 days, in this study. Our data clearly showed that GSH levels increase with respect to controls under the lowest magnetic field intensity with the relatively short exposure period, i.e. 4 hours.

Although statistically significant increased GSH levels were found for the magnetic fields of 1 mT for 4 hours, 2mT and 3 mT for 8 hours in tissues, no matter what the exposure period was, kidney GSH level started to increase at and after 2 mT exposures.

Antioxidants are able to reduce the effects of free radicals formed in body. Our results indicate that chronic exposure to various ELF magnetic fields increase GSH levels, which are free radical scavengers in kidney.

**Figure 1.** GSH levels in kidneys under effects of 50 Hz magnetic fields of 1 mT, 2 mT and 3 mT with the exposure periods of 4 hours and 8 hours.

Abstract

We investigated the effects of continuous and intermittent exposure to extremely low frequency (ELF) electromagnetic fields (EMF) on thiobarbituric acid reactive substances (TBARS) in liver. A total of 18 male, ten-twelve-weeks-old guinea pigs were used. Homogeneous magnetic fields were generated from a specially designed Helmholtz coil system. The subjects were divided into one control and two exposure groups which were exposed continuously (4 hours/day) or intermittently (2 hours on/ 2 hours off / 2 hours on) to 50 Hz magnetic field of 1.5 mT for 4 days. TBARS levels were determined by spectrophotometric method. Mann Whitney-U test was applied for statistical analysis. Increased TBARS levels were found in liver tissues for both of the continuous and intermittent exposures of 1.5 mT. These increases were found to be statistically significant ($p < 0.05$). In conclusion, both types of the exposure to ELF electromagnetic fields (continuous or intermittent) could play a role in lipid peroxidation process.

Introduction

Although the development of technology provides people various facility, each of advanced technological devices are electromagnetic fields (EMF) sources. People are exposed to EMF seriously by wide usage of these devices. Most scientists have thought that EMF have adverse effects on people health. Several studies have been conducted on the effects of EMF as epidemiological and laboratory studies. It has been suggested that there is a link between ELF magnetic field exposure and the increased incidence of certain types of tumor, particularly in leukemia and brain cancer (Kheifets, 1995, 1997, 2004; Lin, 1985; Preston-Martin, 1989; Bastuji-Garin, 1990; Feychting, 1993; Wertheimer, 1979, 1995; Hakansson, 2002; Savitz, 1988). Extremely low frequency (ELF) electric and magnetic field exposure have recently been classified as a possible carcinogen class 3 and 2B respectively (NIEHS, 1998; IARC 2002). Electromagnetic field effects on protein synthesis (Canseven, 2005a; Guler, 1995) gene expression, signal transduction (Liburdy, 1992, 1993), DNA damage (Lai, 2004; Jajte, 2001, 2002), immune system functions (Canseven, 2006), apoptosis induction (Blumenthal, 1997), enzyme regulation (Canseven, 2003a, 2003b, 2004, 2005b; Brocklehurst, 1996; Khadir, 1999), free radical activity (Guler, 2004; Kula, 2000) have been investigated and reported in vivo and/or in vitro experiments. Studies conducted on free radical activities show that EMF Magnetic fields increase the activation of free radicals in tissues (Boland, 2002). The amounts and the activities of free radicals are important for tissue metabolism. Because free radicals are very reactive and unstable molecular species, they can initiate chain reactions to form new free radicals. Increased free radical activity in cellular levels can cause increase in lipid peroxidation which is known as a major factor in formation of the oxidative stress.

To answer the question "Can intermittent or continuous exposures to extremely low frequency magnetic field increase lipid peroxidation in liver?", we examined the effect of continuous or intermittently exposure of 1.5 mT magnetic field in this study. Guinea pigs were exposed to continuous and intermittent magnetic fields with the period of 4 hours/day for 4 days and lipid peroxidation was determined by measuring levels of TBARS in liver.

Materials and Methods

EMF System and Exposure

The experimental protocol was reviewed and approved by the Laboratory Animal Care Committee of Gazi University (Report no : 39-5858). A total of 18 male guinea pigs weighting between 250 and 300g were used in this study. All animals were kept under laboratory conditions and fed standard pellet food.

50 Hz magnetic field was produced by 42.75 cm diameter Helmholtz coil with winding embedded in an open wooden circular frame (Canseven, 2005c). Each coil was constructed by insulated copper wire with 154 turns. Sinusoidal current of frequency 50 Hz was supplied by a specially designed variable transformer (2.7 kilo Volt Amper-kVA) in power to feed the coils. A Hall-Effect Gaussmeter measured the magnetic field at the center of exposure system. Frequency and wave form of the magnetic field was monitored over an ossilloscope. The plexiglas animal cage was put at the center.

Animals were divided into three groups, controls and two magnetic field exposure groups. Exposure groups were exposed to continuously (4 hours/day) or intermittently (2 hours on/ 2 hours off/ 2 hours on) to 50 Hz MF of 1.5 mT with the exposure periods of for 4 days. Controls were handled in an identical manner without being exposed to any magnetic field.

Following 12 h of starvation, guinea pigs were injected intramuscularly with ketamine (30 mg/kg) and xylazine (2 mg/kg) combined with 250 IU/kg heparin. The liver was sampled immediately. They shocked by liquid nitrogen and stored in deep freezer at -80°C until performing analysis.

Determination of Lipid Peroxidation

Lipid peroxidation was quantified by measuring the formation of thiobarbituric acid reactive substances (TBARS). TBARS level of liver tissues was determined according to the Cassini et al.'s spectrophotometric method (Cassini, 1986). Tissues were homogenized in nine volumes of cold 10 % TCA solution and the homogenate was centrifuged for 15 min. At 3000xg at 4°C. The supernatants were transferred to glass test tubes containing 0.375 % (w/v) thiobarbituric acid and 0.02 % (w/v) butylated hydroxytoluene to prevent further peroxidation of lipids during subsequent steps. The samples were then heated for 15 min at 100°C in a boiling water bath, cooled and centrifuged to remove precipitant. The absorbance of each sample was determined at 532 nm. All experiments were run in a blind manner.

Statistics

Statistical analyses were carried out using SPSS software (SPSS 11.5 for windows, SPSS Inc., Chicago, USA). The p value was considered significant at $p < 0.05$. Both comparisons between exposed groups and controls, and comparisons between intermittent and continuous exposed groups were made by using Mann Whitney-U test.

Results

In this study, TBARS level was investigated in liver tissues of guinea pigs which were continuously or intermittently exposed to 50 Hz magnetic field of 1.5 mT with the daily exposure of 4 hours for 4 days. Compared with the control TBARS levels were found significantly increased both continuous ($p=0.009$) and intermittent ($p=0.016$) exposures in liver tissues (Table1-Fig 1). Continuous and intermittent exposures were compared and found that there was no any statistical difference between them ($p=0.093$).

Table 1. Levels of TBARS (nmol/gr) in livers under 50 Hz magnetic field of 1.5 mT

GROUPS	n	TBARS (nmol/g tissue) mean \pm sem
Control	6	79,32 \pm 3,65
Continuous Exposure	6	90,81 \pm 1,16
Intermittent Exposure	6	94,98 \pm 2,79

Discussion

Levels of TBARS were measured in livers to determine the lipid peroxidation which is one of the major factor in formation of oxidative stress.

We found significantly increased liver TBARS levels of guinea pigs which were exposed to 1.5 mT continuous (4 hours/day) and intermittent (2 hours on/ 2 hours off/ 2 hours on) exposures for 4 days compared with the control groups. This was in agreement with our previous studies in MDA (Coskun, 2006). We found statistically significant increases in liver MDA levels under the magnetic fields of 1mT ($p=0.023$) and 2 mT ($p=0.027$) with 4 hours of daily continuous exposure for 5 days. These data reveal that increase of MDA levels as an indicator of lipid peroxidation may give rise to formation of oxidative stress in tissues.

Figure 1. TBARS (nmol/g tissue) levels in liver of 1.5 mT exposed and control guinea pigs. Exposure was continuous or intermittent for 4 days.

Abstract

Reactive oxygen species (ROS) are constantly generated in small amounts during metabolic processes. Recent studies have demonstrated that electromagnetic fields (EMF) can cause increase in ROS formation and resulting oxidative stress. The aim of this study was to investigate the effects of continuous and intermittent exposure to a magnetic field (MF) on NO_x levels in the kidneys in guinea pigs. A total of 18 male guinea pigs weighing 250-300 g were used. The subjects were divided into one control and two exposure groups which were continuously or intermittently exposed to 50 Hz MF of 1.5 mT with 4 hours daily exposure for 4 days. Determinations of NO_x were performed by spectrophotometric methods. The Mann Whitney-U test was used in statistical analysis. Statistically significant increases in NO_x level was found for the intermittent exposure to MF. These findings indicate that increased NO_x levels may reflect formation of reactive nitrogen species following intermittent exposure to 50 Hz MF

Introduction

Recently, the concerns of people about the possible effects of the electromagnetic fields (EMF) on their health have been heightened with the increasing distribution and utilization of electrical machines, electronic equipments, broadcasting and telecommunication systems (Takebe, 1999). For this reason, most scientists have focused on the effects of EMF exposure on people's health and they have conducted several epidemiological and laboratory studies to define the risks of electromagnetic field exposures. Based on the results of these studies, there is growing evidence that electromagnetic fields, the power line frequency (50-60 Hz) and magnetic field (MF), may increase the risk of certain cancers, likely by a tumor-promoting / co – promoting effect. Long-term and as well as short-term electromagnetic field exposure can cause DNA damage and the risk of tumor development. Taking into consideration of the possible adverse effects of extremely low frequency (ELF) electric and magnetic field exposure, they have been recently classified as a possible carcinogens class 3 and 2B respectively, in NIEHS 1998 and IARC 2002 guidelines (Tuncel, 2003; Koifman, 1994; Parola, 1994). Especially, the cellular effects of ELF electric and magnetic field exposure have been investigated intensively. Studies have shown that EMF can induce cell proliferation, variations of calcium concentrations (Canseven, 1996; Canseven, 1999; Canseven, 2005a), alteration of DNA integrity, changes in transcription of immediate early genes and in protein synthesis (Boland, 2002; Ishisaka, 2000; Gold, 1994; Canseven, 2005b) and perturbations of the central nervous system inducing behavioral disturbances in animals (Lai, 1996). In addition, EMF are also able to affect biological systems by increasing the level of free radicals produced by various oxidative stress (Boland, 2002). Oxidative stress is, a physiological condition characterized by an elevated level of oxygen free radical species that cause cellular damage and change vital functions and, is critically important for human health. Oxidative stress occurs due to increased production of reactive oxygen species (ROS) such as, super radical, hydrogen peroxide, and hydroxyl radical at the time of reperfusion, which in turn overwhelm the endogenous antioxidant defense (Narang, 2004). The increase in reactive oxygen species formation can cause the initiation of cumulative damage in the proteins, lipids and nucleic acids' structures. Actually, reactive oxygen species formations are related to the metabolic rate of an organism. In summary, there is a balance between reactive oxygen species formation and antioxidative defense which is important to maintain homeostasis within cells and tissues (Simko, 2004).

In the formation of Reactive Oxygen Species, one of the most important reactants is nitric oxide (NO). Nitric oxide (NO) can undergo numerous reactions as an endogenous mediator of numerous physiological processes. It has an important role in both oxidative stress and nitrosative stress. That is, NO can interact with ROS in many ways resulting in oxidative stress and it can also undergo many reactions that result in the formation of reactive nitrogen species (RNOS) which cause nitrosative stress. NO acts as biological messenger in many physiological processes and plays a role in pathogenesis of many disorders (Jelenkovic et al., 2006). It was suggested that nitric oxide synthase (NOS) activity or NO level could have a prognostic value, which may show the degree of EMF induced tissue damage (Noda et al., 2000; Ilhan et al., 2004; Ozguner et al., 2005). In this study, the effect of continuous and intermittent exposure of 50 Hz, 1.5 mT magnetic field with the exposure period of 4 hours/day for 4 days on NOx levels was investigated.

Materials and Methods

Animals and Magnetic Field Exposure

The experimental protocol was reviewed and approved by the Laboratory Animal Care Committee of Gazi University (Report no : 39-5858). A total of 18 male, 250-300g weighted guinea pigs were used in this study. All animals were kept under laboratory conditions and fed standard pellet food.

Homogenous MF was generated by Helmholtz coils' system. The exposure system developed in our laboratory has been described in detail elsewhere (Canseven, 2005c).

Animals were divided into three groups, controls and two magnetic field exposure groups. Exposure groups were exposed to continuously (4 hours/day) or intermittently (2 hours on/ 2 hours off/ 2 hours on) to 50 Hz MF of 1.5 mT with the exposure periods of for 4 days. Controls were handled in an identical manner without being exposed to any magnetic field.

Following 12 h of starvation, guinea pigs were intramuscularly injected with combinations of ketamine (30 mg/kg), xylazine (2 mg/kg) and 250 IU/kg heparin. The kidney were sampled, shocked by liquid nitrogen and stored at -80°C until performing analysis. All experiments were run in a blinded manner.

Determination of NO Levels

NOx levels - stable end products of nitric oxide- in kidney tissues were measured by the Griess reaction (Green, 1982).

Tissue samples were homogenized in five volumes of phosphate buffer (pH= 7.5) and centrifuged at 2000x g for 5 min. to supernatants (0.5 ml) 0.25 ml of 0.3 M NaOH were added. After incubation for 5 min at room temperature, 0.25 ml of 10% (w/v) ZnSO₄ was added for deproteinization. This mixture was then centrifuged at 14000x g for 5 min and supernatants were used for the Griess assay.

Nitrate levels in tissue homogenates were determined spectrophotometrically, based on the reduction of nitrate to nitrite by VaCl₃ (Miranda, 2001). Nitrite levels were measured by the Griess reaction. Sodium nitrite and nitrate solutions (1, 10, 50, 100 µM) were used as standards.

Statistics

Statistical analyses were carried out using SPSS software (SPSS 11.5 for windows, SPSS Inc., Chicago, USA).

The p value was considered significant at p<0.05. The Mann Whitney-U test was used in statistical analysis.

Both comparisons between exposed groups and controls, and comparisons between intermittent and continuous exposed groups were made by using Mann Whitney-U test.

Results

In this study, guinea pigs were continuously or intermittently exposed to magnetic field of 1.5 mT with 4 hours daily exposure for 4 days and levels of NOx in kidney were determined. An increased level of NOx was found in intermittent exposed animals (385.58± 18.79) with respect to controls (302.42± 6.18). This increase was statistically significant (p=0.009).

Continuous and intermittent exposures were also compared. Significant difference (p=0.016) was determined between continuous and intermittent exposed groups. Although both of the exposures increased the levels of NOx, intermittent exposure was more effective than continuous exposure in this study (Table 1- Figure 1)..

Table 1. NO_x levels (μmol/g) in kidney of guinea pigs under 50 Hz magnetic fields of 1.5 mT

KIDNEY	Total (μmol/gr) mean±sem
Control	30.,42 ± 6.18
Continuous Exposure	314.30 ± 10.71
Intermittent Exposure	385.58 ± 18.79

Discussion

NO (Nitric oxide), one of the primary indicators of ROS (reactive oxygen species) production, may contribute to the pathophysiology of EMF - induced renal impairment. It can also undergo many reactions that result in the formation of reactive nitrogen species (RNOS), which cause nitrosative stress. Nitrogen derived species (RNOS), most notably the ONOO⁻ (peroxynitrite) and peroxynitrous acid (ONOOH) are likely involved in renal damage during oxidative stress in all tissues (Wink, 2000; Ozguner, 2005).

In this study, we found significantly increased NO_x levels in kidneys under intermittent exposure to 50 Hz magnetic field of 1.5 mT.

Our results indicate that, intermittent magnetic field exposure may cause the change in renal functions with the high levels of reactive oxygen species production.

**Figure 1.** NO_x levels (μmol/gr) in kidneys under 50 Hz magnetic fields of 1.5 mT.

Abstract

Interest in researches on the health effects of extremely low frequency electromagnetic fields (ELF EMF) is rapidly growing. ELF EMF has been classified as 2B, possibly carcinogenic to humans, by the International Agency for Research on Cancer. It is believed that ELF EMF prolongs the life of free radicals and can act as a promoter or co-promoter of cancer. It is also known that magnetic fields cause an increase in free radicals activity in living organisms. Free radicals are very reactive and unstable molecular species that can initiate chain reactions to form new free radicals. In the present study, we investigated the effect of various magnetic fields on lung tissue damage resulting from oxidative stress by measuring nitric oxide (NOx) levels. Twenty-three guinea pigs were exposed to 50 Hz, 1 mT and 3 mT fields with the exposure periods of 4 hours/day and 8 hours/day for 5 days. Control subjects (n=9) were handled in an identical manner with the exposed animals in the same laboratory. NOx levels - stable end products of nitric oxide - in lung tissues were determined spectrophotometrically using the Griess reaction. For both of the application periods, increases in NOx level were found by the effect of 3 mT MF whereas increased NOx level was determined only for groups of 1 mT, 4 hours. Nitric oxide (NO) has played an important role related to ELF magnetic fields' exposure in lung tissue.

Introduction

In recent years, scientists have focused on the effects of electromagnetic fields (EMF) on living organisms in cellular levels. These major interests have been born of the overexposure of people to extremely low frequency (ELF) electromagnetic fields (EMF) with the increase of wide use of technological devices in their daily life. In many epidemiological and laboratory studies, it has been suggested that there is a link between ELF magnetic field exposure and the increased incidence of certain types of tumor, particularly in leukemia and brain cancer (Lin, 1985; Preston-Martin, 1989; Bastuji-Garin, 1990; Feychting, 1993; Wertheimer, 1979, 1995; Savitz, 1988;). A variety of EMF effects on biological and biochemical responses such as protein synthesis (Kenneth, 1987; Gold, 1994; Canseven, 2005b), gene expression, signal transduction and DNA damage (Liburdy, 1992, 1993; Jajte, 2001; Lai, 2004), immune system functions (Canseven, 2006; Seyhan, 2006; Waliczek, 1992; De Seze, 1993; Blumenthal, 1997; House, 2000, 1996; Tremblay, 1996), apoptosis induction (Blumenthal, 1997; Jajte, 2002), enzyme regulation (Canseven, 2003a, Canseven, 2003b; Canseven, 2004; Canseven, 2005a, Brocklehurst, 1996), free radical activity (Kula, 2000; Kula, 2002; Roy, 1995; Khadir, 1999; Simko, 2001; Sbozack, 2002; Yokus, 2005; Watanabe, 1997; Fiorani, 1997; Mohtat, 1998; Kashkald, 1995; Jin, 1998) have been described in the reports of many in vivo and/or in vitro experiments. Magnetic fields penetrate the cells and can alter cell membrane potential and the concentration of ions (Canseven, 1999; Canseven, 2005c; Garcia-Sancho, 1994). These alterations may affect free radical processes within the cell. EMF could be also able to affect biological systems by increasing the amount of free radical produced by various oxidative stress (Boland, 2002). ELF EMF has been thought to prolong the life of free radicals and can act as a promoter or co-promoter of cancer (Yokus, 2005). Free radicals, which are known as reactive oxygen species (ROS) are continuously formed in small amounts in biological systems. Depending on the oxygen consumption, the production of ROS increases; however there is a balance between ROS formation and antioxidant defense within cells and tissues. In the case of increase in the formation of ROS, it has been seen the initiation cumulative damage to proteins, lipids and nucleic acids and various physiological conditions, like oxidative stress has been observed. There are many factors, which cause the formation of oxidative stress; among them ROS production is one of the most important.

Nitric oxide (NO) can undergo numerous reactions as an endogenous mediator of numerous physiological

MAGNETIC FIELDS EFFECTS ON NO LEVELS IN LUNG

processes. NO plays an important role in both oxidative stress and nitrosative stress.

Taking into consideration the activation of free radicals in biological systems, the behavior of free radicals was investigated. NOx levels were measured in lung tissues of guinea pigs exposed to 50 Hz, 1 mT and 3 mT fields with the exposure periods of 4 hours/day and 8 hours/day for 5 days to determine the effects of electromagnetic fields on ROS production.

Materials and Methods

Animals

The experimental protocol was reviewed and approved by the Laboratory Animal Care Committee of Gazi University (Report no: 36-7838). A total of 32 male guinea pigs weighing between 250 and 300g were used in this study. All animals were kept under laboratory conditions and fed standard pellet food.

Magnetic Field Exposure

50 Hz magnetic field was produced by 42.75 cm diameter Helmholtz coil with winding embedded in an open wooden circular frame (Canseven, 2005d). Each coil was constructed by insulated copper wire and made of 154 turns. To feed the coils, sinusoidal current of frequency 50 Hz was supplied by a specially designed variable transformer, 2.7 kVA (kilo Volt Amper) in power. Magnetic field at the center of exposure system was measured by a Hall-Effect Gaussmeter. Frequency and wave form of the magnetic field were monitored over an oscilloscope. The animal cage without magnetic material was put at the center.

Twenty-three guinea pigs were exposed to 50 Hz, 1 mT and 3 mT fields with the exposure periods of 4 hours/day and 8 hours/day for 5 days. Control subjects (n=9) were handled in an identical manner with the exposed animals in the same laboratory.

Following 12 h of starvation, guinea pigs were injected intramuscularly with ketamine (30 mg/kg) and xylazine (2 mg/kg) combined with 250 IU/kg heparin. Lungs were sampled immediately. They shocked by liquid nitrogen and stored in deep freezer at -80°C until performing analysis. All experiments were run in a blind manner.

Determination of NO Levels

NOx levels - stable end products of nitric oxide- in lung tissues were determined by the Griess reaction (Green et al., 1982).

Tissue samples were homogenized in five volumes of phosphate buffer (pH= 7.5) and centrifuged at 2000 x g for 5 min. to supernatants (0.5 ml) 0.25 ml of 0.3 M NaOH were added. After incubation for 5 min at room temperature, 0.25 ml of 10% (w/v) ZnSO₄ was added for deproteinization. This mixture was then centrifuged at 14000 x g for 5 min and supernatants were used for the Griess assay.

Nitrate levels in tissue homogenates were determined spectrophotometrically, based on the reduction of nitrate to nitrite by VCl_3 (Miranda et al., 2001). Nitrite levels were measured by the Griess reaction. Sodium nitrite and nitrate solutions (1, 10, 50, 100 μM) were used as standards.

Statistics

Statistical analyses were carried out using SPSS software (SPSS 11.5 for windows, SPSS Inc., Chicago, USA). The p value was considered significant at $p < 0.05$.

Mann Whitney-U and Kruskal-Wallis tests were used in statistical analysis. Comparisons between exposed groups and controls were made by using Mann Whitney-U test while magnetic fields of 1mT and 3 mT were compared with Kruskal-Wallis test with respect to exposure periods of 4 hours and 8 hours.

Results

In this study, the NOx level was investigated in lung tissues of guinea pigs which were exposed to magnetic fields of 1mT and 3 mT with the exposure periods of 4 hours/day and 8 hours/day for 5 days. For both of the application periods, NOx levels were found increased with respect to controls in lung tissues of guinea pigs exposed to both of the magnetic fields (Table 1- Figure 1).

The increases in NOx levels were found statistically significant for 1 mT, 4 hours ($p=0.003$), 3 mT, 4 hours ($p=0.001$) and 3 mT, 8 hours ($p=0.000$) in lung tissues by Mann-Whitney U test.

Field intensities were compared with respect to exposure periods by Kruskal-Wallis test. Significant differences were determined between field intensities of 1 mT and 3 mT in lung tissues for only exposure period of 8 hours ($p=0.004$).

Table 1. Lung NO_x levels of guinea pigs under the effects of 50 Hz magnetic fields of 1 mT and 3 mT with the exposure periods of 4 hours/day and 8 hours/day for 5 days.

GROUPS	n	NO _x Level (μmol/g tissue) (mean ± sem)
Control	9	103.61 ± 3.80
1 mT; 4 hours	4	141.65 ± 3.61
1 mT; 8 hours	4	110.78 ± 1.40
3 mT; 4 hours	7	133.31 ± 4.90
3 mT; 8 hours	8	131.99 ± 3.08

Discussion

For both of the exposure periods, significant increases in NO_x levels were found by the effect of 3 mT magnetic field whereas increased NO_x levels were found only for groups of 1 mT, 4 hours.

TBARS levels in the same tissue for the same exposure conditions were also investigated in our laboratory (Canseven 2005e). The increased NO_x levels in lung for 1 mT, 4 hours and 3 mT, 4 hours was found consistent with the increases of TBARS in these tissues.

Further studies are required to better elucidate the mechanisms of the effect of ELF MFs on lipid peroxidation or oxidative stress in tissues.

**Figure 1.** Lung NO_x levels of 1 mT and 3 mT exposed and control guinea pigs.

A DOUBLE LAYER ARTERIAL WALL MODEL UNDER PULSATING BLOOD PRESSURE

MONA A. EL-NAGGAR

DEPT. OF ENGINEERING PHYSICS, FACULTY OF ENGINEERING,
CAIRO UNIVERSITY, GIZA, EGYPT

Abstract

The behavior of a double layer arterial section of unit length is studied under the effect of radial pressure. The proposed model considers that the radial pressure follows an exponential rise exponential decay biphasic periodic function mathematically represented by a Fourier series. The dependence of the arterial strain response on viscoelastic properties of each layer is studied. The dissipated and stored power per unit length of the vessel, are computed. The stress-strain response is modeled for each layer. Storage and loss moduli are deduced as well.

Introduction

The study of the viscoelastic properties and response of the blood vessels have been one of the most important and biomechanical field of research for quite a while. This study represents an essential step towards controlling the efficiency of the blood pulse propagation process. The blood pulse propagates along the axis of the blood vessels, namely arteries, with a radial component pulsating on the inner wall. This propagation is similar to the propagation of waves in media. The arterial pulse is considered as a pressure wave travelling down the multilayer wall associated with a strain wave. The arterial strain response is the main issue here as it can be considered as an energy storage element that pushes the blood spurts forward down the artery. The rigidity or distensibility of the arteries causes the pressure to be very high during systole and it would fall to low values during diastole. The blood flow as a result of this would be intermittent. Furthermore, the reduced distensibility of the arterial wall has a direct effect on the efficiency of the heart markedly increasing its oxygen consumption making its attack more likely. It is thus extremely important to simulate the pressure wave propagation and its pulsating radial component. The problem is complicated not only because of the non-linearity in blood vessels elasticity, but because of the varying nature of the pulse wave as well. The anisotropic, multilayer and nonlinear viscoelastic properties of the arterial walls lead to certain mathematical complications when the radial dimensions are considered under the effect of pulsating pressure.

Previous work was concerned with mechanical and mathematical simulation to produce stress-strain relation for different soft tissues. Yu Q. et al. [1] evaluated the force-deformation relations for different layers of blood vessels by studying the non axis symmetric deformation of the vessel wall. This was done by imposing bending on the vessel. Young's modulus is given for the intima media and the adventitial layers of the thoracic artery. The circumferential stretch and axial stretch of abdominal arteries are given for different pressure values by Schulz-Bauer et al. [2] for both normal and hypertensive patients. They proposed a method to determine nonlinear constitutive models for human arteries from clinical data using a strain energy function. Mechanical properties are obtained by reliable experimental setups especially for different arterial layers, collagen and body tissues [3]. The degree of nonlinearity and blood vessel elasticity was studied by J. Zhou and Y. C. Fung [4] introducing a pseudo strain energy function and fitting experimental data to produce its parameters. Furthermore the relationship between wall shear stress and intimal thickening for the abdominal aorta was determined by Micheal Bonert et al. [5], who measured experimentally the wall shear stress using the laser photochromic dye tracer technique.

Imaging the mechanical properties of thrombosis, plaques and arterial wall can aid in the characterizing and understanding of the pathogenesis of the cardiovascular disease. Intravascular ultrasound is a widely used method of imaging the coronary arteries. Strain and elasticity images are generated to determine mechanical properties of arterial tissues [6], [7], [8]. Toshiaki Shishido *et al.* developed a new technique by applying minute vibrations at various frequencies to evaluate regional myocardial elastance and Young's moduli at different

regions [9]. Blood flow and pressure in the larger systemic arteries are modelled by structuring a tree attached to the terminal branches in which the root impedance is estimated using an approach based on a linearization of the viscous axisymmetric Navier-Stokes equations[10].

In the present work, periodic pressure pulses are assumed to act in a radial direction on the inner wall of an arterial section. The periodic pulses are represented mathematically by a Fourier series. These pulses are considered to fluctuate between maximum values of a fraction of the mean arterial pressure. They approximately follow the known shape of the arterial pulse. Though the *in vivo* reported arterial pulses show faster rise than decay [11], we assume here that they are symmetric pulses. Biaxial symmetry of the artery is assumed as well. The radial pressure pulses are assumed to follow the heart beats with the same frequency. Some of the reported values concerning mechanical responses of arteries [1], [2], [3], [12] are adopted.

An R-L-C double section series circuit is proposed to simulate the double layer arterial wall. The flow of electric charge in the circuit is analogous to the strain fluctuations, the input voltage to the radial pressure pulses and the current is the pulse velocity. Parameters required to implement the mathematical model at hand are changed in appropriate ranges to show arterial stiffness, pulse damping, variation of the elasticity constant and heat loss.

The Model

A simplified model, introduced earlier [13], simulates the viscoelastic behaviour of a single layer blood vessel in response of the blood pulses acting in a radial direction on its inner wall. The proposed double layer arterial section is modelled as shown in Fig. 1.

Fig.1. Double layer mechanical model

A section of unit length of the artery is assumed to be a double layer viscoelastic cylindrical tube. The inner layer is assumed to be the intima media layer with elasticity modulus, E_1 , while the outer one is the adventitial layer with E_2 . The inner radii of the two layers are R_{01} and R_{02} . The elastic behaviour of the artery segment is represented by that of a spring with spring constants, K_1' and K_2' while its viscous component is represented by a dash pot of friction coefficients B_1' and B_2' for the first and second layers respectively.

The second degree differential equation that governs the strain functions, $\varepsilon_1(t)$ and $\varepsilon_2(t)$ of the interface of the two layers and the inertial forces on them is as follows:

$$\begin{aligned} \frac{d^2 \varepsilon_1(t)}{dt^2} &= F_1(t) - B_1' \frac{d\varepsilon_1(t)}{dt} - K_1' \varepsilon_1(t) \\ \frac{d^2 \varepsilon_2(t)}{dt^2} &= F_2(t) - B_2' \frac{d\varepsilon_2(t)}{dt} - K_2' \varepsilon_2(t) \end{aligned} \quad (1)$$

where $B_1=B_1/\rho_{l1}$, $K_1=K_1/\rho_{l1}$, $B_2=B_2/\rho_{l2}$, $K_2=K_2/\rho_{l2}$, are normalized viscosity and elasticity coefficients to the linear mass densities, ρ_{l1} , ρ_{l2} for inner and outer layers respectively. $F_1(t)$ is defined as the normalized radial component of the force due to blood pressure pulses, $P_1(t)$, pulsating on the inner layer such that:

$$F_1(t) = 2\pi P_1(t) / \rho_{l1} \quad F_2(t) = 2\pi P_2(t) / \rho_{l2} \quad (2)$$

Mathematical Analysis

Firstly, $P_1(t)$ is assumed to take the waveform of a biphasic exponential rise exponential decay periodic function, given below:

$$P_1(t) = \begin{cases} P_0(1 - 2e^{-t\pi/T}) & 0 \leq t \leq T \\ P_0(2e^{-\pi(t-T)/T} - 1) & T \leq t \leq 2T \end{cases} \quad (3)$$

The proposed model assumes the same time interval, T , for the rise and decay pulse components and hence equal decay constants. It is assumed that the pulses fluctuate between equal values $\pm P_0$.

A Fourier series is deduced to represent $P_1(t)$. The coefficients of the Fourier series, produced by integration on the two time intervals given in eq.(3), give a final form of:

$$P_r(t) = \frac{2}{\pi} P_0 \sum_{n=1}^{\infty} \left(\frac{e^{-\pi} (\cos n\pi - 1) - (\cos n\pi + 1)}{n} \cos \frac{n\pi t}{T} + \frac{1}{n} (e^{-\pi} (\cos n\pi - 2) - (\cos n\pi + 1)) \sin \frac{n\pi t}{T} - \frac{1}{n} e^{-\pi} \cos n\pi \right) \quad (4)$$

Fig. 2 shows the pressure periodic waveform. The maximum value P_0 , is assumed to be a 10% of the mean arterial pressure in adults.

Fig. 2. The figure shows a simulation of the rise and fall of the radial pressure in Pa

An equivalent electrical model, introduced as a double R-L-C series circuit, is analogous to the mechanical model above. We give full analogy between the mechanical system and the equivalent electrical circuit in details in appendix 1. We should note that the stress on each layer is the difference in pressures on the lining interfaces. Thus the stress on the inner layer, T_1 , is difference in pressure, $P_1 - P_2$, and the stress, T_2 , on the outer layer is $P_2 - P_3$, where P_1 is the pressure on the inner wall, P_2 on the interface between the two layers and P_3 is that on the outer wall.

Consequently, the strain is calculated as:

$$\begin{aligned} \epsilon_1(t) &= q_1 - q_2 \\ \epsilon_2(t) &= q_2 - q_3 \end{aligned} \quad (5)$$

where q_1 , q_2 and q_3 are related to the respective currents in the equivalent electric circuit as follows:

$$q_1(t) = \int_0^t i_1(t) dt, \quad q_2(t) = \int_0^t i_2(t) dt, \quad q_3(t) = \int_0^t i_3(t) dt \quad (6)$$

Since P_1 , P_2 and P_3 are analogous with V_1 , V_2 and V_3 , thus we can deduce the involved quantities in the s -domain as follows:

$$I_1(s) = Y_{eq}(s) V_1(s) \quad (7)$$

where Y_{eq} represents the total admittance of the two circuit section.

$$V_2(s) = V_1(s) - I_1(s)\left(R_1 + \frac{1}{sc_1}\right)$$

$$V_3(s) = V_2(s) - I_3(s)\left(R_2 + \frac{1}{sc_2}\right)$$
(8)

Results

The stress and the strain waveform for each layer can be produced by eqs.(5-8). Strain pulses follow those of the applied radial pressure having the same frequency with a time delay. They fluctuate between equal values of $\pm e_0$.

Taking the strain response to be the difference between strains of boundary interfaces, results are given for different parameter sets in Table 1. The periodic time for one pressure pulse is 1s.

The first parameter set, is a simulation of normal performance with elasticity constants close to those of intima media and adventitia layers of real arteries.

Fig.3. The stress waveform acting on the inner layer
real and imaginary components in kPa vs. time in s

Fig.4. The strain waveform acting on the inner layer
real and imaginary components vs. time in s

Fig.5. The stress waveform acting on the second layer,
real and imaginary components in kPa vs. time in s

Fig.6. The strain waveform acting on the second layer, real and imaginary components vs. time in s

Figures 3 and 4 show the stress-strain response for the inner layer, intima media; whereas, Figs. 5 and 6 show the stress-strain response for the adventitia, outer layer. They show elastic response of about 3%, which is much higher than the inner layer. This is taken into account by parameters adjustment

Table 1. Normalized Parameter sets used as input for computer runs.

set	K_1 10^6 s^{-2}	K_2 10^6 s^{-2}	ϵ_{01r} $10^{-3}\%$	ϵ_{01i} $10^{-3}\%$	ϵ_{02r} $\%$	ϵ_{02i} $\%$	P_{diss} w/m	P_{str} w/m
1	8	0.05	3	0.03	3	2	83.850	101.640
2	4	0.8	0.5	0.008	0.4	0.4	13.775	19.7611
3	0.4	.02	0.1	8	6	6	1502.75	2486.04

For all sets P_0 and T are kept constant at 1.6 kPa and 0.5s respectively. ρ_{t1}, ρ_{t2} are kept at 25g/m and 12g/m and B_1, B_2 have the values 0.4s^{-1} and 0.417s^{-1} respectively.

Fig. 7 shows the computed power versus time. The real component, P_{diss} , corresponds to the energy loss per second while the imaginary component represents the stored energy per second, P_{str} . The average values of the power dissipated and that stored, measured in w/m, computed over one pressure pulse for each set are given in Table 1.

Fig.7. The power dissipated and that stored in w/m vs. time in s

The storage and loss moduli are computed using the above parameter sets. The average values calculated are shown in Table 2.

Table 2. Storage and loss moduli for a double layer section.

set	E_{loss1} 10^3 kPa	E_{str1} 10^3 kPa	E_{loss2} kPa	E_{str2} kPa
1	432.031	460.852	23.822	46.442
2	3744.905	4024.505	125.022	237.566
3	10.3577	11.0498	0.9822	1.8067

DISCUSSION:

Despite the enormous difficulties studying pulsating flow in an elastic tube of anisotropic material, the elastic analogy offers an adequate tool for approaching this case. The proposed model assumes linear stress-strain relationship and biaxial isotropy of the blood vessel. It offers a new perception towards the understanding of the mechanism of arterial pulsating nature. The elasticity modulus is computed using the stress and the strain complex functions for each layer.

The equivalent resistance, R_{eq} , is the component that is responsible for the dissipated energy per pulse per meter, e_{diss} . Whereas the equivalent reactance, X_{eq} , is the component that is responsible for the stored energy per pulse per meter, e_{st} . These can be deduced as follows:

$$e_{diss}(t) = \frac{1}{T} \int_0^T i_1^2(t) R_{eq} dt, \quad e_{st}(t) = \frac{1}{T} \int_0^T i_1^2(t) X_{eq} dt \quad (9)$$

The results offer an understanding of how energy is stored and dissipated through a cyclic change of the radial pressure. Also the complex nature of the elasticity modulus is illustrated, in the absence of reliable experimental values for many biological constants of blood vessels. This work has to deal with hypothetical set of values that are believed to approach some previously reported values.

Accordingly the stress-strain pattern, the elasticity moduli, as well as the stored and dissipated power are dependant on the chosen set of values. The model proposed is valid to some extent according to reported experimental data. Furthermore, it shows that under all circumstances the strain developed, in both layers, lags the radial pressure and follows the pulsating wave shape. The elasticity, dissipated and stored power per unit length of both layers do as well.

APPENDIX 1

The second order differential equation that governs the electrical charge Q with circuit components and input voltage V_0 is:

$$\frac{d^2 Q(t)}{dt^2} = V_0(t) / L - \frac{R}{L} \frac{dQ(t)}{dt} - \frac{1}{LC} Q(t) \quad (10)$$

By analogy between the two systems, mechanical and electrical, we note that:

$$V_0(t) \leftrightarrow 2\pi P_I(t), \quad R/L \leftrightarrow B, \quad 1/LC \leftrightarrow K, \quad L \leftrightarrow \rho_\ell$$

THE ELECTROMAGNETIC WAVES OF 950 MHz, GSM MOBILE PHONE SYSTEM AND ACQUISITION PHASE OF SPATIAL MEMORY

Abstract

With increasing in mobile communications, exposure to electromagnetic fields due to base station antenna has increased. This study was planned for evaluating the effects of whole-body exposure to 950 MHz GSM electromagnetic field on acquisition phase of spatial memory.

35 naive male Wistar Rats (3 month old, 220 ± 15 g) randomly divided in three groups (control, sham-exposed and exposed) and were trained in a circular Morris water maze (3 days at 2 blocks, with 3 hours interval between blocks) to locate a submerged platform. The exposure program was planned for 10 session (45 min. and Power density = 0.835 mW/cm^2). According to water maze training, exposure was done just before each training session.

Performances of animals were tested 24 hours after the last training, by a 60 second probe test. Evaluation indexes were escape latency at target and opposite quadrants, swim speed and length.

Analysis of the probe data test showed no significant difference between control, sham and 950 MHz exposed groups.

Results of this study provide no evidence indicating that acquisition phase of spatial memory can be affected by the whole-body exposure to 950 MHz electromagnetic field.

Keywords: Electromagnetic field, Base station, Spatial memory, Morris water maze

Introduction

The RF radiations engage the spectrum of electromagnetic waves between 3 KHz - 300 GHz. This field can induce thermal or non-thermal effects on biological medium. Stimulation of excitable tissues will occur readily below 1 MHz, while thermal effects occur at higher frequencies [5].

In the last decade, many researches studied the effects of exposure to electromagnetic fields (EMF) on different nervous system functions such as memory in human and animals. Some of these studies have revealed deficits on memory due to EMF exposure [4; 8-21], whereas other studies did not [2, 3, 6, 7, 26, 31]. Nowadays, with increase in mobile communications, exposure to EMF due to mobile handset and base station antenna has increased. There are concerns about the effects of mobile phone electromagnetic waves on human body functions. These concerns emerge from results of epidemiological studies contributed to effects of mobile phone on human body. For example some of reports indicated that, mobile phone waves not only in regular power density but also in power density less than limited allowed (1 mW/cm^2), can produce headaches, warmth on ear, memory loss and fatigue.

These reports suggest that there is a significant association between calling time/number of calls per day and prevalence of these signs [10, 11, 12, 25, 29]. Although these results are important but in most of these studies the mobile phone handset frequency has been used and the effects of base station antenna waves have been less noticeable.

The GSM mobile phone system that is used in most of the countries has a frequency of either 900 or 1800 MHz (pulsed at 217 Hz, Band width of 200 KHz). The spectrum of 900 MHz has two band areas: 890-915 MHz that is specific for handset and 935-960 MHz that is specific for base station antenna.

To date, a few studies have evaluated the effects of EMF on memory functions in rodents. Studies performed by Wang and Lai [32] and Lai and Carino [18] reported deficits in two spatial learning tasks (Morris water maze and radial maze) after 45-min exposure to 2450 MHz EMF. On the other hand, studies reported by Cassel and colleagues failed to show any impairment of memory performance of rats in a radial maze after 45 min of whole-body exposure to a 2450- MHz EMF [2]. Findings of the last study were confirmed by recent studies showing no effect in spatial memory after daily 45 min of 900-MHz GSM exposure [6, 7]. The above findings indicate that the effects of GSM exposure on memory functions are still controversial. Moreover, to this date, we know no reports regarding the effects of exposure to 950 MHz waves, as a frequency in middle of base station band (935-960 MHz) on the memory function. There fore, the aim of this study was to examine the effects of exposure to 950 MHz waves, emitted by base station antenna, on acquisition phase of spatial memory in a Morris water maze.

Materials and methods

Subjects

35 naive male Wista rats (3 month old, 225 ± 25 g) were divided randomly in to three groups: control (n=12), sham-exposed (n=11) and EMF exposed (n=12). Rats were maintained on a 12-h light-dark cycle and with an ambient temperature of 21°C . They were housed in a maximum of six rats per breeding cage and allowed access to food and water ad libitum. All experiments were performed between 9:00 a.m and 13:00 p.m during the light cycle.

Morris Water Maze training

The behavioral training and testing was conducted in a water maze. The water maze was a blue circular pool (140 cm in diameter and 50 cm high) filled to a 25 cm depth with 22 ± 2 °C water [27]. A circular glass platform (diameter: 11cm) was placed at the center of one quadrant (North-East quadrant) of the maze and submerged 3 cm below the surface of the water. The maze was located in a room containing several visual extra-maze cues.

Each animal was released into the water from the wall of the maze at arbitrarily defined east, south, west, and north points. The sequence of points of release into the water followed a random order. The animal was allowed to find the platform and land on it. If it could not find the platform within 1 minute, it was guided manually to the platform.

After finding the platform, it was allowed to stay there for 45 second before another trial. Performance in the maze was carried out and saved in a computer by an infrared receiver mounted on the roof.

The Morris water maze training program was planned for 3 days at 2 blocks, with 3 hours interval between blocks and 5 trials in each block. Performance of each rat was tested 24 hours after the final training day in a probe trial (60s) during which the platform was removed. Evaluation indexes were time spent in target quadrant, swim speed and total swim length during the probe test.

Electromagnetic field exposure

For whole body exposure to EMF, a 950 MHz GSM simulator (pulsed at 217 Hz and band width of 200 KHz, made by Khaje-Nasir Toosi University, Tehran, Iran) was used. It was connected to a 15 cm rod antenna fixed at the center of a circular plastic chamber (diameter = 30 cm). The animal could freely move inside the chamber. To prevent unknown exposure to reactive area of EMF, some of the near field restricted by a plastic mesh (radius = 5 cm). The power density inside the chamber was measured with RF meter (Narda 8716, USA) in different distances with 5 cm height from the base of antenna. With these records, the average value for power density was 0.835 mW/cm^2 . The exposure program was consisted of ten 45 minute irradiation (as Lai et al., 1994). One day before running maze training, each animal exposed or sham-exposed to 4 sessions of 45 minute EMF with intervals of 1 hour. Subsequently, in 3 days, prior to each training session, animals were exposed to EMF or sham-exposed for 45 minute. The exposure room was adjacent to the experimental room.

Statistical analysis

The training data was analyzed with a one way analysis of variance (ANOVA) with trials as a repeated measure. Probe trial retention measures were analyzed with a two-way ANOVA. Tukey's *posthoc* test was performed to determine the source of detected significances. Values of $P < 0.05$ were considered as significant

Results

All rats learned to locate the platform during training as indicated by decreasing escape latencies as training progressed (Fig.1). A two way ANOVA (group \times block) with block as repeated measures showed significant effects of block ($P < 0.001$), and no significant effects of groups [$F(3, 33) = 1.596$, $p = 0.217$].

Fig.2, illustrates the retention performance as assessed by time spent in the four quadrants. A two way ANOVA (group \times quadrant) showed significant effects of quadrants ($P < 0.001$), and no significant effects of groups [$F(3, 33) = 1.02$, $p = 0.368$].

Fig.3, illustrates the swim path data during the probe test. One- way ANOVA indicated no significant differences among the groups [$F(2, 31) = 2.334$, $p = 0.114$].

Fig. 4 illustrates mean swim speed of rats during probe test. A one way ANOVA showed no significant differences between groups ($p > 0.05$).

Fig. 1: Average escape time (Mean \pm SEM); time to reach the platform after release into the water, during the trials.

Fig 2: Average time spent (Mean + SEM) in three groups for target and opposite areas during probe trials.

Fig. 3: Average swim path (Mean + SEM) in four groups during probe trials of acquisition phase.

Fig. 4: Average swim speed (Mean + SEM) of the rats during probe trials in acquisition phase.

Discussion

The RF radiations engage the spectrum of electromagnetic waves between 3 KHz - 300 GHz. This field can induce thermal or non-thermal effects on biological medium. Stimulation of excitable tissues will occur readily below 1 MHz, while thermal effects occur at higher frequencies [5]. The mobile phones and their base station electromagnetic fields have low specific absorption rate that induce very low rise in brain temperature. Thus, the possible biological effects of mobile phone systems on brain would be expected to be the non-thermal effects [13]. Thus, the aim of this study was to examine the effect of exposure to 950 MHz waves, emitted by base station antenna, on spatial memory.

The findings of the present experiments indicate that acute whole body exposure to 950 MHz waves of GSM mobile phone system (pulsed at 217 Hz) dose not affect acquisition of spatial navigation in rat.

Our finding is in agreement with recent studies showing no effects of electromagnetic field on performance of rat or mice in an 8-arm radial-maze task [2, 17, 31]. Moreover, studies of Dubreuil et al., [6, 7] showed that head only exposure to GSM 900-MHz electromagnetic fields, did not alter rat's memory in spatial (radial maze) and non-spatial tasks. On the other hand the results of studies performed by Wang and Lai [32] and Lai and his colleagues [19] indicated that 45 min exposure to a 2450-MHz electromagnetic fields induced deficits in spatial memory functions in Morris water maze and radial maze tasks.

Lai et al., [18] have shown that low level microwave irradiation could alter the cholinergic transmission in the hippocampus and cortex. Since cholinergic system plays an important role in memory processing, Lai et al., claimed that exposure to 2450-MHz electromagnetic fields alter activity of this system in a way that produces impairment in spatial memory functions [17, 19].

The results of the present study are in contrast with the study of Wang and Lai indicting an impairment of spatial memory in a water maze induced by an acute exposure to electromagnetic fields. This discrepancy may be due to some subtle differences in the training paradigm (two blocks of five trials with a 3 min interval versus two blocks of 6 trials with a 3 h interval), time of probe test (24 h versus 1 h after the last training) or the characteristics of the used electromagnetic fields (950 MHz pulsed with 217 pulses/s, average power density 0.835 mW/cm^2 versus 2450-MHz pulsed with 500 pulses/s, average power density 2 mW/cm^2), and duration of exposure (45 min versus 1 h immediately before each training session). Moreover, previous studies have shown that hyperthermia can induce memory impairment [23], thus it is more likely that impairment reported by Wang and Lai can be due to consequences of a hyperthermia related to the whole body exposure [7].

The epidemiological studies were performed on human cases showed different results like animal experiments. Hocking et al., Oftedal et al. and Sandstrom et al., suggest that there is a direct relationship between the signs and calling time/number of calls per day [10, 11, 12, 25, 29]. In agreement with these results, studies on who lived in areas near the base station antenna showed irritability, depression, memory loss, concentration difficulties, vertigo, headache, sleep disturbances, feelings of discomfort and fatigue [2, 24, 28, 30]. The reported signs depend on duration of exposure, and the distance from antenna, and the antenna characteristics [2].

The results of the present study indicate that exposure to 950 MHz waves emitted by base station antenna had no effect on acquisition of rat's spatial memory in a water maze. Although this study was used as a model for understanding the effect of GSM electromagnetic field on acquisition phase of memory, further studies with a variety of intensities and durations of GSM electromagnetic fields are needed to test their effect on memory processing.

Abstract

Over the last decade, exposure to electromagnetic field due to base station antenna has increased. This in vivo study was planned for evaluating the effects of whole-body exposure to 950 MHz field of GSM mobile phone system on dentate gyrus long-term potentiation.

24 naive male Wistar rats (3 month old, 225 ± 25 g) randomly divided in three groups (sham-exposed, GSM and continuous field exposed).

The exposure program was planned for 10 sessions at 3 days. Animals were exposed to electromagnetic field for 45-min in a circular plastic chamber (mean power density = 0.835 mW/cm^2). Immediately after end exposure, anesthesia was induced for LTP induction. Field potentials were recorded and analyzed using the population spike amplitude and EPSP slope for 60-min.

There were no significant differences in population spike amplitude, EPSP slope and EPSP slope maintenance among the three groups.

This experiment provides no evidence indicating that long-term potentiation can be affected by the whole-body exposure to low-power density of 950 MHz field of GSM mobile phone system.

Keywords: Electromagnetic field, Base station, Long-term Potentiation

Introduction

Nowadays, with increase in mobile communications, exposure to EMF due to mobile handset and base station antenna has increased. The GSM mobile phone system that is used in most of the countries has a frequency of either 900 or 1800 MHz (pulsed at 217 Hz, Band width of 200 KHz). The spectrum of 900 MHz has two band areas: 890-915 MHz that is specific for handset and 935-960 MHz that is specific for base station antenna.

In the last decade, many researches studied the effects of exposure to mobile phone electromagnetic fields (EMF) on different nervous system functions such as memory in human and animals. Some of these studies have revealed deficits on memory due to EMF exposure [5, 8-20, 23, 28], whereas other studies did not [3, 4, 6, 7, 31].

A number of studies have suggested that low frequency EMF may interact with learning and memory processes [18, 24]. Nevertheless, other studies have suggested that much higher frequency fields may also affect spatial memory [16, 18, 33]. Wang and Lai [18, 33] reported deficits in two spatial learning tasks (Morris water maze and radial maze) after 45-min exposure to continuous or pulsed, 2450 MHz EMF.

Since the spatial memory was accepted to have a substantial hippocampal involvement, these studies suggest that EMF may affect hippocampal function. This is supported by a report that exposure to 700 MHz continuous field can change electrical activity in the hippocampus of rat [32].

Long-term potentiation (LTP) is a long-lasting increase in synaptic efficacy resulting from the high-frequency stimulation of afferent fibers [1]. LTP in the hippocampus is thought to be a typical model of synaptic plasticity related to learning and memory [21].

To get insights into the cellular effects that 950 MHz exposure (as a frequency in middle of base station band) could induce on hippocampus, we decided to conduct a general study and investigated the consequences of exposure to continuous and pulsed (GSM) waves of 950 MHz EMF. Thus, the aim of this study was to examine the effects of exposure to 950 MHz fields on dentate gyrus (DG) long-term potentiation.

Materials and methods

Electromagnetic field exposure

For whole body exposure to EMF, a 950 MHz GSM simulator (made by Khaje-Nasir Toosi University, Tehran, Iran) was used to produce 950 MHz fields, in continuous (without any modulation) or GSM (217 Hz modulated and band width of 200 KHz) waveform. It was connected to a 15 cm rod antenna fixed at the center of a circular plastic chamber (diameter = 30 cm). The animal could freely move inside the chamber. To prevent unknown exposure to reactive area of EMF, some of the near field restricted by a plastic mesh (radius = 5 cm). The power density inside the chamber was measured with RF meter (Narda 8716, USA) in different distances with 5 cm height from the base of antenna. With these records, the average value for power density was 0.835 mW/cm^2 . The exposure room was adjacent to the experimental room.

The exposure program was consisted of ten \times 45-min irradiation, delivered at 3 days. In the first and second days, each animal's exposed or sham-exposed to 4 sessions of 45-min irradiation, with 1 hour interval. Subsequently, in the third day, animals had two irradiation sessions. Immediately after the end exposure, anesthesia was delivered for LTP induction.

Animals

24 naive male Wistar rats (3 month old, 225 ± 25 g) randomly divided in three groups: sham-exposed (n=8), GSM (n=8) and continuous field exposed (n=8). Rats were maintained on a 12-h light-dark cycle and with an ambient temperature of 21°C. They were housed in a maximum of 8 rats per breeding cage and allowed access to food and water ad libitum. All experiments were performed between 9:00 a.m and 13:00 p.m during the light cycle.

Surgical method

Animals were food and water deprived for 1 hour prior to surgery. For electrophysiological recording, the rats were anesthetized with Urethane (1.5 g/Kg, i.p., with supplemental injections as required) and stereotaxically implanted with a bipolar Teflon-coated silver electrode (125 μ m diameter) in the perforant pathway (coordinates: AP -6.8 mm, L -4.1 mm, DV -3 mm, from skull surface) and a recording electrode (glass micropipette, 1-3 M Ω , filled with physiological saline) in the dentate gyrus granule cell layer (coordinates: AP -2.8 mm, L -1.8 mm, DV -3 mm, from skull surface).

Electrophysiological recordings

The stimulating and recording electrodes were adjusted to produce maximum field potentials by applying a single pulse stimulus (0.1 Hz, 200 μ s pulse width) and recording field potentials in the DG granule cell layer.

Test stimulus intensity, sufficient to produce population spike (PS) with approximately 50% of maximum amplitude, was selected. After the 15-min base line recording, for LTP induction, two high frequency stimulus (250 Hz, 1s, 30s interval) were delivered to the perforant pathway with test stimulus intensity. The field potentials were recorded at 10, 20, 30, 40, 50 and 60-min after the tetanic stimulations, with 0.1 Hz pulse stimulus. The evoked responses were amplified, filtered (band-pass: 5 Hz – 3 KHz), sampled at a rate of 20 KHz and stored.

Evaluation indexes were PS amplitude, excitatory postsynaptic potentiation (EPSP) slope and EPSP maintenance. The LTP signal parameters were extracted as shown in Fig. 1. For EPSP maintenance, the percent of changes in each recording time calculated as: (Last record value – first record value / first record value) \times 100. Data were statistically analyzed by repeated measures of ANOVA.

Fig.1: EPSP slope and PS amplitude that extracted from LTP signal.

Results

The results of EPSP slope of three groups, during the base line and 60-min recording are shown in fig.2. One-way ANOVA showed no significant differences among the groups.

Fig.3, illustrates the EPSP slope maintenance during the recording time. One-way ANOVA indicated no significant differences among the groups.

Results of the population spike amplitude are presented in fig.4. There were no significant differences between amplitudes of three groups during the base line recording and after LTP induction.

Fig.2: EPSP slope of three experimental groups (Mean \pm SEM). Analysis of the data showed no significant differences between sham, continuous and GSM exposed groups.

Fig.3: EPSP slope maintenance among the groups (Mean \pm SEM). There was no significant difference between maintenance phase of the stimulated and sham exposed groups.

Fig.4: Population spike amplitude (Mean \pm SEM). There were no significant differences between LTP induction and PS amplitude in the sham, continuous and GSM exposed groups.

Discussion

The mobile phones and their base station electromagnetic fields have low specific absorption rate that induce very low rise in brain temperature. Thus, the possible biological effects of mobile phone systems on brain would be expected to be the non-thermal effects [13]. This experiment results showed that exposure to continuous or GSM waves of 950 MHz EMF did not affect the LTP parameters. This is in agreement with recent studies showing that 900MHz EMF, in head-only exposure conditions, can not alter performances of rats in spatial memory and non-spatial memory tasks [7, 8]. Another study shows that 900MHz GSM EMF, dose not alter mice performance in an 8-arm radial-maze experiment [31].

On the other hand, Tattersall [32] indicated that exposure to 700 MHz continuous EMF for 5-15 minute reduced spontaneous epileptiform activity of rat hippocampus. Moreover, the results of Ogiue-Ikeda [26, 27] experiments signified the effect of low frequency magnetic field on EPSP slope of LTP.

Lai and Carino [18] found that low level microwave irradiations can alter the cholinergic functions in the rat hippocampus and cortex. This decrease in cholinergic activity in the brain can impair rat spatial memory [18].

Wang et al. and Lai [18, 33] showed that 45-min exposure to 2.45 GHz microwaves can alter spatial memory. But, Cassel et al. [3] could not access the same results, although their testing protocol was as similar as possible to that of the Lai et al. study.

The memory impairment reported by Lai et al and Wang and Lai [18, 33] can be related to a hyperthermia, because hyperthermia can produce amnesic effects [8].

Results of epidemiologic studies that performed on the effects of EMF, on who lived in areas near the base station antennas, showed that people's complaints (sleep disorders, headaches, concentration difficulties and fatigue) are due to EMF [25, 29]. These signs appeared after exposure and decreased slowly. Santini et al [30] suggest that the signs differ with increase of distance from antenna. In addition to distance, it seems that the antenna characteristics are important factors.

Bornkessel and Stocker-Meier [2] studies on 24 antennas showed that although electrical fields' intensities of these antennas are in standard limit, these results are time dependent and can differ with different antenna traffic along day. Although some of these studies suggest that exposure level is less than allowed level by ICNIRP in areas near the base station antenna, but the probability of long term exposure dangers of these waves for whom live in these areas are not rejected. In agreement with this point, Lai et al [17] showed, intensity and duration of exposure have interactions in effectiveness of the field on memory so that high-intensity/short-duration exposure and lower-intensity/longer-duration exposure have similar effects on frontal cortex and hippocampus cholinergic activity and memory. In addition, it is showed that chronic exposure to EMF can increase plasma corticosterone level [23]. This elevated level of corticosterone can induce time-dependent neuronal damage in hippocampus and impair cognitive function [22].

In the present research, the effect of exposure to 950 MHz waves emitted by base station antenna on electrical activity of hippocampus was investigated via the long-term potentiation. Although, this set of experiment provides no evidence indicating that LTP signal can be affected by the continuous or GSM waveform of 950 MHz EMF, further studies are needed to test other durations and intensities on brain activity. In addition, with

rapid increase of number of mobile phone users in the world and base station antenna in urban area, it seems that the knowledge about the effects of EMF on human body especially human brain is a necessity.

Abstract

Treatment of Red cabbage (*Brassica oleracea* L. CV. Saccata) in vegetative growth phase with a 30 mT static magnetic field (SMF) resulted in altered content of lignin, anthocyanin and wall-bound phenolic compounds, compared with those of non-treated plants.

Exposure of red cabbage to the aforesaid static magnetic field during vegetative phase also induced the growth of the plants. The growth was accompanied by a delayed maturation and a lowered content of lignin in shoot and root system.

Introduction

During the past decade considerable evidence has been accumulated with regard to the biological effects of magnetic fields. Although several studies on bacterial and animal cells have shown that the magnetic fields influence a large variety of cellular functions, the mechanisms of its interaction with the living cells are still unclear and less studies have been conducted on plant cells. So far, many temporal and spatial electric phenomena occur during plant development (Moon 1999). Nevertheless, the magnetic field effects on the appearing of some cancers in human, embryogenesis in animals have been studied, seed germination and ion current and pollen-tube emergence in plants under MF also have been studied. The MF-induced inhibitory or stimulatory effects on the growth of plant tissues have seen to be species-specific, dependent on seasonal biological rhythms, field frequency and daily period of exposure (Moon 1999). In the present investigation the effect of static magnetic field on the growth and the metabolism of certain phenolic compounds of *Brassica oleracea* L. CV. saccata was subjected to study. It is well-known that phenolic compounds have various ecological and physiological roles and their contribution to defense system and UV protection have been studied. Phenolic compounds also inducible by different environmental stress and chemical stimuli (otto et al. 1999).

Brassica oleracea L. CV. saccata seeds were sterilized superficially with NaOCl and soaked in sterile Petri dishes on filter paper moisturized in distilled water. Seedlings were germinated and grown for 5 days at a constant temperature ($25 \pm 2^\circ\text{C}$) in a dark. after germination, the similar and entire seedlings were transferred to flower-pots and kept with a controlled condition at a constant temperature and light ($25 \pm 2^\circ\text{C}$ and 6800 Luxe).

The plants were watered every day with ordinary water and every 15 days they were watered with Hoagland. after one month in the vegetative phase, the intact plants were selected and divided to treated and controlled groups. The treated groups were exposed to a 30 mT static magnetic field during 5 days and 5 hours in every day. The control group were maintained under a same environmental conditions as unexposed control. the samples were harvested in the end of treatment term.

Exposure to MF was performed by a locally designed MF generator. The electrical power was provided using a 220 V AC power supply equipped with variable transformer as well as a single-phase full wave rectifier. The maximum power and passing current were 1 KW and 50 A DC, respectively.

This system was designed to generate MF in range of 0.5 μT -30 mT. it consisted of two coils (each with 3000 turns of mm copper wire) on a U-shaped laminated iron core (to prevent eddy current losses). Using two vertical connectors, the arms of the U-shaped iron core were terminated in four circular iron plates covered with thin

SMF AND PHENOLIC COMPOUNDS

layer of nickel (each 23 mm thickness, 260 cm in diameter). A water circulation system around the coils was employed to avoid the increase of the temperature. Without this system, the temperature of the coils increased, after the apparatus was working for 10 min, from 25 to 40 °C. Applying the water circulation system helped us to use apparatus for long exposures (5 h) as well as to keep the maintenance of the apparatus. The control cells were kept far enough from the MF producing apparatus, to avoid any potential exposure to the MF. Moreover, other electric appliances and laboratory facilities were not working; the control samples were therefore exposed only to the extremely low MF of the earth ($60 \pm 5 \mu\text{T}$), as the treatment groups were too.

PPO was extracted from shoot and root systems, separately, in freshly prepared 200mM k-phosphate buffer (PH 6.8) followed by centrifugation at 12000x g. all these procedures were carried out at 2-4°C. Aliquots of supernatant were added to 200 mM k-phosphate buffer (PH 6.8) and freshly prepared 4-methylcatechol at a final concentration of 0.02 M. Enzyme activity was expressed as a change in absorbance at 410 nm per min per mg protein content of the homogenate. Protein concentration was determined by the method of Bradford (1976), using BSA as standard (Ghanati et al. 2002).

PO was extracted and the activity was determined in two fractions: the soluble PO fraction which is involved in the stress response (Pondolfini et al 1992) and the wall- bound PO fraction which is related to the lignification and suberization of cells (Fukuda and Komamine 1982 and Pando;fini et al 1992). The shoot and root systems, separately, were homogenized in 200 mM k-phosphate buffer (PH6.8) and centrifuged at 12000x g for 15 min at 2°C. the supernatant was used to assay soluble Po. The activity of wall- bound PO was determined in the ionically and covalently bound fractions, in turn. Pellets of the centrifugation were pooled, incubated with 0.2 M CaCl_2 for 2h at room temperature, and centrifuged at was used to measure the activity of ionically wall- bound Po. The pellet was used directly for the assay of the covalently bound enzyme (Fukuda and Komamine 1982). The final reaction mixture (3 ml) was contained 200 mM k- phosphate buffer (PH 6.8), 28 mM guaiacol and 5 mM H_2O_2 . the enzyme activity of soluble and ionically fractions were expressed as the change in absorbance at 470 nm per min per mg protein content. The covalently enzyme activity was determined as the change in absorbance at 470 nm per min per cell wall dry weight (Ghanati et al. 2002).

The shoot and root systems, separately, were homogenized in ice- cold k-borate buffer (0.01 M, PH 8.8) containing 2 mM 2-mercaptoethanol and centrifuged at 16000x g for 10 min at 2°C. The supernatant was used as a crude enzyme solution. The reaction mixture (total 2ml) was composed of 0.5 ml of crude enzyme and 1 ml of extraction buffer (without 2-mercaptoethanol). The reaction started with addition of 0.5ml of 4mM phenylalanine and after 1 h incubation at 37°C, was stopped with 100 μl of 0.5 M HCl. The mixture was extracted three times with EtOAc. The EtOAc extract was air- dried, re- dissolved in 50% MeOH and analyzed by HPLC on an ODS-18 Ts column (15 cm x 6.0) at a flow rate of 0.5 ml min⁻¹ with a linear gradient of 40-80% MeOH containing 0.1% HoAc and detected at 273 nm. The enzyme activity was expressed as the amounts of CA for 1h per mg of protein in the reaction mixture (Ghanati et al. 2002).

The shoot and root systems, separately, were homogenized in water after centrifugation at 1000x g, the pellet was sequentially washed with 10 volumes (v/w) of 0.5 mM CaCl_2 , EtOH, CHCl_3 - MeOH (2:1 v/v) and acetone followed by air- drying. Air-dried materials were desired as wall preparation. Phenolics were liberated from the wall preparations of samples with ammonium oxalate (20 mM, 70°C) and then with 0.1 M NaOH, under N₂ for 24h. After acidification of both fractions to approximately PH 3.0 with HCl, phenolics were extracted three times with EtOAc, air- dried and re- dissolved in 50% MeOH before determination by HPLC as described for the determination of the PAL activity. Phenolics was detected at 280 nm (Ghanati et al. 2002; Liyama and Wallis 1990).

Isolation of cell walls was carried out as described for the determination of wall- bound phenolics. Lignin content was measured via a modified acetyl bromide procedure (Liyama and Wallis 1990). In brief, 6 mg of fine-powdered wall preparation was treated with a mixture (total 2.5 ml) of 25% (w/w) AcBr in HOAc and 0.1 ml of 70% HClO_4 at 70°C for 30 min with shaking at 10 min intervals. After cooling with ice, the digestion mixture was transferred to a 25 ml volumetric flask containing 5 ml of 2 M NaOH and 6 ml HOAc and made up to 25 ml. The lignin content was determined by measuring the absorbance at 273 nm using a specific absorption coefficient of 20.0g⁻¹ L cm⁻¹ (Ghanati et al. 2002; Liyama and Wallis 1990).

The anthocyanin of the shoot system tissues were extracted with cold methanol: water: acetic acid (11: 5: 1). The extraction was spun at 12000x g for 10 min. Anthocyanin concentration was determined by measuring optical absorption at 530 nm (Masakazu et al. 2003).

measurement of total sugar content in shoots and roots was based on phenol- sulfuric method, using glucose as standard (Duboise et al. 1956).

All experiments were repeated at least three times in triplicate. The data shown in the tables and figures are means \pm SD. The significance of differences between treatments was evaluated by student's T- test.

PPO activity in shoot and root system were determined in both control and treatment groups. The activity PPO of root system of treated plants was higher than those of the control groups. The activity of PPO of shoot system of the treated plants was lower than that the control ones (Fig. 1).The activity of Po was measured in three fractions including soluble, ionically- and covalently-bound fractions (Table 1). The activity of three fractions

of PO increased in shoot system of treated plants under static magnetic field compared with those of the control groups. The results from measurement of PO activity in root system showed declining in treated plants in the three fractions relation to control ones. PAL enzyme was extracted from root and shoot system of red cabbage. PAL activity in the shoot and root system of treated plants was lower than those of the control ones (Fig. 2). The content of the phenols esterified to the wall polysaccharides of the shoot and root system under the control conditions and treatment with magnetic field, is shown in table 2. The content of these phenolics of root and shoot system under MF was significantly higher than those of the control ones. The lignin content of MF-treated shoot and root system decreased compared to control ones (Table 2). The results shown that the anthocyanin in shoot system has been increased in treated plants with 30 mT static magnetic field in comparison to the control groups (Fig. 3).

The total sugar were measured based on glucose standard curve in shoot and root system of samples. Compared to the samples under the control conditions, treatment samples significantly decreased total sugar (Fig. 4).

Table. 2. Effect of MF on lignin content and cell wall phenolic compounds of root and shoot system of red cabbage.

Plant tissue	Lignin content (%Lignin/ Cell Wall dry Weight)		Cell Wall Phenolic Compounds (μg phenol/ g Cell Wall dry Weight)	
	Control	Treat	Control	Treat
Root	4.1 \pm 0.5	3.22 \pm 0.7	3665.5 \pm 282.7	7401.67 \pm 2191.54
Shoot	5.04 \pm 0.9	3.04 \pm 0.46	2034.4 \pm 594.8	4144.3 \pm 968.43

Data are means \pm SD, n = 3.

Summary

A magnetic field is an inescapable environmental factor for plants on the earth (Negishi et al. 1999). However, it's impact on plant growth is not well understand(Negishi et al. 1999).In the current studies, contradictory results have been gained by scientists (Negishi et al. 1999). Static magnetic field, sometimes, has been received attention as a stress for beings (Aladjadjiyan 2002) and sometimes, it has been talked the co-operations of static MF with environmental factors, instance nourishing stresses, water deficit and heavy metals.

In the present paper the effect of SMF on the metabolism of certain phenolic compounds was investigated.

PPO is a bi-functional enzyme, that plays roles at both oxidation of phenols and conjugation of phenols to polyphenols. Increase of PPO activity in root system of treated plants can be related to accumulation of phenolic compounds. Also increase of PPO activity has been reported in tobacco cells affected by some nourishing stresses(Ghanati et al. 2002). Also the possibilities that the low PPO activity of the shoot system of treated plants can be due to the presence of an inhibitor, an in-activator or to factors degrading the enzyme (Kahn 1975).

Increased PO activity has been demonstrated to be a metabolic response under various stress conditions, including water stress, air pollution, and heavy metals (Pandolfini et al. 1992). Among the various forms of this enzyme , the wall-bound forms appear to be more efficient at catalyzing bound formation between extension and feruloylated polysaccharides and for the polymerization of phenolic monomers (Ghanati et al. 2002). Also Pandolfini (1992) reported the effects of nickel on peroxidases are always more marked in shoot than roots. Decrease of PO activity in the roots of treatment plants can be leading to stretch ability, wall-loosing and expansion in cell wall. Also, the percent of lignin content in treated roots can be help to this loosing. The lignin synthesis accomplishes from photosynthesis precursors .using of marked glucose showed relation between lignin synthesis and photosynthesis (Kollattukudy 1984). Decrease of lignin synthesis in the MF exposed plants, can be due to disorder in photosynthesis. According to Kazimov et al (1984) the magnetic fields results in decline in contents of photosynthetic pigments, chlorophyll a and b, in kidney bean leaves (Kazimov 1984). Also decrease of total sugar in treated plants with MF can be confirm this subject. it's may be that MF was effected on lignin and sugar content from a common course.

PAL is a one of the main enzymes of metabolism of phenolic compounds that it catalyze changing of phenylalanine to cinnamic acid. The reaction catalyzed by phenylalanine ammonialyase. PAL is commonly regarded as akey step in the biosynthesis of phenols, and is affected by a number of factors (Ruiz et al 1998). This enzyme acts in the initial stages of lignin biosynthesis. rapid induction of the PAL activity (12 to 24 h) was observed during nourish stress and then decrease of PAL activity was reported in the next stages.(Ghanati et al. 2002,2004). In the present investigation, the activity of PAL in treated plants decreased after 10 days. Anthocyanins are another group of phenolic compounds belong to the flavonoids group. Anthocyanins in autumn leaves seem to prevent photo- oxidative irradiation.

The most important environmental cue in anthocyanin synthesis is light, which affects signal transduction and gene expression involved in anthocyanin biosynthesis. Other factors, such as sugar addition, phosphate limitation, and cold stress, can enhance anthocyanin accumulation induced by light. In the present research increase of anthocyanin and wall-bound phenolics may be resulted of phenols changing to anthocyanin and wall-bound phenolics and deviation from the lignin synthesis.

Abstract

With increasing in mobile communications, exposure to electromagnetic fields due to base station antenna has increased. This study was planned for evaluating the effects of short whole-body exposure to 950 MHz GSM electromagnetic field on consolidation phase of spatial memory.

33 naive male wistar rats (200 ± 15 g) were trained (10 trials at 2 blocks, with 3 minutes interval between blocks for one day) to locate a submerged platform in a circular water maze. Immediately after training, animals randomly divided into three groups: control $n=11$, sham-exposed $n=11$ and exposed $n=11$. The last group was exposed to 950 MHz electromagnetic waves (mean power density = 0.835 mW/cm^2) for 45 minutes in a circular plastic chamber. Performances of animals were tested 48 hours later by a 60 second probe test. Evaluation indexes were escape latency at target and opposite quadrants, swim speed and length.

Analysis of the probe data test indicated that, there were no significant difference between control, sham and 950 MHz exposed groups.

Results of this study provide no evidence indicating that consolidation phase of spatial memory can be affected by the 45 min whole-body exposure to 950 MHz electromagnetic waves.

Keywords: Electromagnetic field, Base station, Consolidation, Morris water maze

Introduction

Memory is defined as the capacity of brain to store and retrieve the information. It consists of three phases: encoding or acquisition phase, consolidation or stabilization phase that is a process by which new labile memories convert to more stable long-term memories, and retrieval phase in which memory is expressed.

In the last decade, many researches studied the effects of exposure to electromagnetic fields (EMF) on different nervous system functions such as memory in human and animals. Some of these studies have revealed deficits on memory due to EMF exposure [4; 7-20], whereas other studies did not [2, 3, 5, 6, 28, 33]. Nowadays, with increase in mobile communications, exposure to EMF due to mobile handset and base station antenna has increased. There are concerns about the effects of mobile phone electromagnetic waves on human body functions. These concerns emerge from results of epidemiological studies contributed to effects of mobile phone on human body. For example some of reported data indicated that mobile phone waves not only in regular power density but also in power density less than allowed limit (1 mW/cm^2) can produce headaches, warmth on ear, memory loss and fatigue. These reports suggest that there is a significant association between calling time/number of calls per day and prevalence of these signs [9, 10, 11, 27, 31]. Although these results are important but in most of these studies the mobile phone handset frequency has been used and the effects of base station antenna waves have been less noticeable.

The GSM mobile phone system that is used in most of the countries has a frequency of either 900 or 1800 MHz (pulsed at 217 Hz, Band width of 200 KHz). The spectrum of 900 MHz has two band areas: 890-915 MHz that is specific for handset and 935-960 MHz that is specific for base station antenna.

To date, we know no reports regarding the effects of acute exposure to 950 MHz waves, as a frequency in middle of base station band (935-960 MHz) on the memory processes. On the other hand, most of the experiments contribute to effects of exposure to mobile phone electromagnetic waves on acquisition phase of memory and few experiments are about the effects of these waves on consolidation phase. Thus, the aim of this study was to examine the effects of acute exposure to 950 MHz waves, emitted by base station antenna, on consolidation phase of spatial memory in a Morris water maze.

Materials and methods

Animals

Thirty three naive male Wistar rats (3 month old, 200 ± 15 g) were used in three groups: control ($n=11$), sham-exposed ($n=11$) and EMF exposed ($n=11$). Rats were maintained on a 12-h light-dark cycle and with an ambient temperature of 21°C . They were housed in a maximum of six rats per breeding cage and allowed access to food and water ad libitum. All experiments were performed between 9:00 a.m and 13:00 p.m during the light cycle.

Morris Water Maze training

The water maze was a blue circular pool (diameter: 140 cm, height: 50 cm) filled with water ($22 \pm 2^\circ\text{C}$) to a depth of 25 cm [29]. A circular glass platform (diameter: 11cm) was placed at the center of one quadrant (North-East quadrant) of the maze and submerged 3 cm below the surface of the water. The maze was located in a room containing several visual extra-maze cues. Each animal was released into the water from the wall of the maze at arbitrarily defined east, south, west, and north points. The sequence of points of release into the water

THE EFFECT OF ACUTE EXPOSURE TO 950 MHz AND CONSOLIDATION

followed a random order. The animal was allowed to find the platform and land on it. If it could not find the platform within 1 minute, it was guided manually to the platform.

After finding the platform, it was allowed to stay there for 45 second before another trial. Performance in the maze was carried out and saved in a computer by an infrared receiver mounted on the roof. For spatial training, animals were given 10 trials (one training session) at 2 blocks, with 3 minutes interval between them for one day in Morris Water Maze. **Immediately after the last trial**, Rats were exposed to electromagnetic waves or sham exposed for a 45 minute.

Performance of each rat was tested 48 hours after the training session in a probe trial (60s), during which the platform was removed. Evaluation indexes were time spent in target quadrant, swim speed and total swim length during the probe test.

Electromagnetic field exposure

For whole body exposure to EMF, a 950 MHz GSM simulator (pulsed at 217 Hz and band width of 200 KHz, made by Khaje-Nasir Toosi University, Tehran, Iran) was used. It was connected to a 15 cm rod antenna fixed at the center of a circular plastic chamber (diameter = 30 cm). The animal could freely move inside the chamber. To prevent unknown exposure to reactive area of EMF, some of the near field restricted by a plastic mesh (radius = 5 cm). The power density inside the chamber was measured with RF meter (Narda 8716, USA) in different distances with 5 cm height from the base of antenna. With these records, the average value for power density was 0.835 mW/cm^2 . The exposure room was adjacent to the experimental room.

Data analysis

The training data was analyzed with a one way analysis of variance (ANOVA) with trials as a repeated measure. Probe trial retention measures were analyzed with a two-way ANOVA. Tukey's *posthoc* test was performed to determine the source of detected significances. Values of $P < 0.05$ were considered as significant

Results

The results of escape time during the 10 trials are shown in fig.1. Data analysis showed a significant trial effect (i.e., a significant decrease in escape time with training). There was no significant difference in time during the training session trials between three groups [$F(2, 29) = 0.358$, $p = 0.702$].

Results of the probe trial are presented in fig.2, which shows the average time for the three groups of rats during the 1-minute probe trial period in the platform and opposite quadrants. There was no significant difference in time during the training session trials between three groups [$F(2, 36) = 1.03$, $p = 0.364$].

Fig.3, illustrates the swim path data during the probe test. One- way ANOVA indicated no significant differences among the groups [$F(2, 27) = 1.82$, $p = 0.180$]. Fig. 4, illustrates mean swim speed of rats during probe test. A one way ANOVA showed no significant differences between groups [$F(2, 27) = 1.72$, $p = 0.198$].

Discussion

The mobile phones and their base station electromagnetic fields have low specific absorption rate that induce very low rise in brain temperature, thus, the possible biological effects of mobile phone systems on brain would be expected to be the non-thermal effects [12]. Data from this experiment showed that acute exposure (45 minute) of 950 MHz waves of GSM mobile phone system (pulsed at 217 Hz) does not affect the consolidation phase of rat spatial memory. This is in agreement with recent studies showing electromagnetic field dose not alter performance in an 8-arm radial-maze, either in mice [33] or in rats [16]. In addition, another study shows that 900MHz GSM electromagnetic field, in head-only exposure conditions, can not alter performances of rats in spatial memory and non-spatial memory tasks [5, 6].

On the other hand, Lai and Carino found that low level microwave irradiations can alter the cholinergic functions in the rat hippocampus and cortex [17]. This decrease in cholinergic activity in the brain can impair rat spatial memory [18]. Cassel et al. could not access the same results like the Lai et al findings, although their testing protocol was as similar as possible to that of the Lai et al. study [2]. Sienkiewicz et al. found similar results in radial-arm maze too [33]. But Wang and Lai showed that 45-minute exposure 2.45 GHz microwaves can alter spatial memory in Morris water maze [35]. Because it has showed that hyperthermia can produce amnesic effects, the memory impairment reported by Lai et al and Wang and Lai can be related to a hyperthermia due to the whole-body exposure [6].

McKay et al [23] indicated that exposure to magnetic field can impair memory consolidation of contextual conditioned fear rats. Consolidation is defined as a process by which new labile memories convert to more stable long-term memories. It is showed that consolidation requires RNA and protein synthesis [22, 25]. Sienkiewicz et al [34] suggests that magnetic fields have no effects on the well-established long-term memories.

The epidemiological studies were performed on human cases showed different results like animal experiments. Hocking et al., Oftedal et al. and Sandstrom et al. reported that mobile phone waves can produce dizziness, headaches, discomfort, warmth on ear, memory loss, and fatigue not only in regular power density but also in power density less than allowed limit (1 mW/cm^2). They suggest that there is a direct relationship between these signs and calling time/number of calls per day [9, 10, 11, 27, 31]. In addition to studies performed on effects of waves emitted by phone handset, results of epidemiologic studies were done by Roosli et al and Navarro et al. on persons who lived in areas near the antenna, showed that 74% of people's complaints (sleep disorders, headaches, concentration difficulties and fatigue) are due to antenna. These signs appeared after exposure and decreased slowly [26, 30]. Santini et al suggest that the signs of persons, who live in areas near antenna, differ with increase of distance from antenna [32]. In addition to distance it seems that the antenna characteristics are important factors.

Bornkessel and Stocker-Meier studies on 24 antennas showed that although electrical fields' intensities of these antennas are in standard limit. These results are time dependent and can differ with different antenna traffic along day [1]. Although some of these studies suggest that exposure level is less than allowed level by ICNIRP in areas near the base station antenna, but the probability of long term exposure dangers of these waves for whom live in these areas are not rejected. In agreement with this point, Lai et al showed that intensity and duration of exposure have interactions in effectiveness of the field on memory so that high-intensity/short-duration exposure and lower-intensity/longer-duration exposure have similar effects on frontal cortex and hippocampus cholinergic activity and memory [17]. In addition, it is showed that chronic exposure to EMF can increase plasma corticosterone level [24]. This elevated level of corticosterone can induce time-dependent neuronal damage in hippocampus and impair cognitive function [21].

In the present research, the effect of acute exposure of 950 MHz waves emitted by base station antenna on the consolidation phase of spatial memory was investigated via the Morris water maze. This set of experiment provides no evidence indicating that spatial memory can be affected by the 45 minute whole-body exposure to 950 MHz electromagnetic field. Although this study was used as a model for understanding the effect of GSM electromagnetic field on consolidation phase of memory, further studies are needed to test other durations and intensities on this phase of memory.

Abstract

The health care staff operating MRI devices are exposed to static magnetic field of significant spatial heterogeneity (dB/dx) and high level of flux density – usually existing permanently during the work shift. They can be also exposed to pulses of magnetic field of high rate of rise/fall dB/dt, so-called gradient fields - existing only during examination of patients. The level of the workers' exposure depends both on the type of the magnet and ergonomical design of the particular MRI device.

The paper presents current state of the art on the occupational exposure to static magnetic field health effects, gaps in scientific data, MRI workers' exposure characteristic, research needs and suggestions for the exposure assessment protocol for further investigations.

Keywords: MRI, occupational exposure, electromagnetic fields, exposure assessment

1. Introduction – MRI EMF and exposure results

Electromagnetic fields associated with Magnetic Resonance Imaging

Nuclear magnetic resonance (NMR) is research method which can be used for medical imaging or spectral analysis of chemical structure of samples. The basic physical phenomenon in NMR is resonant absorption and re-emission of radiofrequency (RF) radiation by protons in a strong static magnetic field. In the magnetic resonance imaging (MRI) scanners, magnetic field useful for medical examination is result of summation of 2 components: static field produced constantly by strong magnets (permanent, resistive or superconductive) and pulses of time-varying so-called gradient field produced by gradient coils placed inside the housing of the MRI scanner [10]. The dynamic changes of spatial distribution of field produced in the result enables 3D changes of RF resonating absorption by patients tissues and in consequences the 3D imaging of the internal structure of the patient's body. Diagnostic coils placed at the MRI table or directly on the body of examined patient produce pulses of RF radiation used for such imaging.

Magnets of magnetic flux density of 0.2 - 3 T are currently used as a source of static magnetic field. Higher field's (up to 8 T) MR imaging is under intensive pre-clinical investigations. Workers operating MRI scanners are one of the highest exposed group to static magnetic fields because usually superconductive or permanent magnets generate the field constantly. Only resistive magnets can be switched off when the shift is over. Exposure of workers to RF and gradient fields is not common among MRI workers because during patients' examination medical staff is usually far from the magnet, controlling examination by a computer-console.

Biological and health consequences of electromagnetic fields exposure

Biological and health consequences of RF and gradient fields, associated with thermal effects and electro-sensitive tissues excitations, are relatively well investigated. In contrary, health effects of static magnetic fields are still under question, especially in case of chronic exposure of high level. Recent World Health Organization (WHO) monograph 232 [6] concluded that there is not sufficient scientific data for establishing health risk of static magnetic field exposure.

Physical effects of static magnetic fields (translation and orientation of charged molecules) cause electrodynamic

forces on moving electrolytes, and effects on electron spin states of chemical reaction intermediates [7]. Translation and orientation of molecular and cellular substances such as retinal rods, and some living cells have been experimentally observed in vitro in static fields of high level (above 1 tesla (T)), in various materials - dia- and paramagnetic such as hemoglobin, collagen, fibrin, and also on ferromagnetic particles such as magnetite. Water distribution can be also affected by high-gradient magnetic fields of high flux density (e.g., 8 T, 50 T/m; Ueno and Iwasaka 1994, following [7]), producing the force directly proportional to the square of the magnetic field strength and inversely proportional to the radius of the magnet e.g. force up to 30% the force of gravity in above-mentioned 8 T magnetic field, but only about 1% of gravity in whole-body 4 T magnet.

Static magnetic fields exert electrodynamic forces on moving ions in blood vessels, generating an electric potential across the blood vessels (Hall effect) and theoretically a reduction of blood flow velocity (Tenforde 1992, following [7]) - a 5 and 10% reduction in blood flow in the aorta was predicted to occur in static fields of 10 and 15 T, respectively, due to magneto-hydrodynamic interactions (Kinouchi et al. 1996, following [7]). Related observations included a 0.2–3% change in blood velocity between 1–10 T (Dorfman; Keltner, following [9]). Experimental examination of the scale of biomedical effects associated with electrodynamic and magnetodynamic forces in exposed human body are still under examination, frequently using electrocardiogram (ECG) technique. In addition, vertigo and other sensations, as difficulty with balance, nausea, headaches, numbness and tingling, phosphenes, and unusual taste sensations, were recorded during movement in high field. The other investigated endpoint were: cognitive function, assessed during exposure using standard neuropsychological tests, effects of exposure to fields of up to 8 T on heart rate, respiratory rate, systolic and diastolic blood pressure, finger pulse oxygenation levels, and core body temperature [7]. The exposed volunteers moved very slowly in comparison with normal workers activities in the vicinity of magnets (one or two feet over a few seconds, followed by a 15–30 s pause, taking overall about 3–4 min) into the magnet bore in order to avoid the transient, movement-induced sensations described above. Nevertheless, nine subjects reported sensations of dizziness, and two reported a metallic taste, assumed to be due to electrolysis of metallic chemicals in the subjects' teeth fillings (Schenck et al. 1992, following [7]).

IARC (2002) [12] notes that two somewhat dated studies (Neurath 1968; Ueno et al. 1984) report that exposure to 1 T fields with high spatial gradients (10–1,000 T/m) can adversely effect the development of frogs and toads, but notes that most studies indicate a lack of effect of static field exposure.

With static magnetic fields, reactions under laboratory conditions include a 17% increase in human cardiac cycle length at 2 T (Jehesen et al., following [9]). The authors suggested that the observed effect is probably harmless in healthy subjects, but that its safety in dysrhythmic persons was not certain. Such question is very important in the case of health examination for workers, who are going to start or continue MRI scanners operation.

2. Pattern of occupational exposure during MRI scanners operation

For health care staff (nurses, technicians, radiologists), the static magnetic field from MRI units is of special concern as during the shift the field is permanently on. Inside the MRI's room, the highest exposure occurs in the direct proximity to the magnet's housing. The workers are exposed to the static magnetic field while attending patients before and after examination and also while operating the MRI unit by the console situated on the housing of the magnet. Exposure to gradient and RF pulses is possible only during the examination and affects workers only in special cases, e.g. during so-called dynamic examination, interventional MRI procedure or because of emerging needs (even inside the bore of magnet). During patient's examination, the attendants usually stay in front of the monitor of computer controlling the examination, outside the MRI room (which is usually electromagnetically shielded to screen MRI device from all kinds of outside electromagnetic radiation).

During MRI examination, examined subject (selected part of patient's body) lies at the MRI's table located within the area of static magnetic field of very high spatial distribution's homogeneity in the bore of magnet's housing (in the case of so-called close MRI device) or in the open space between magnet's legs (in the case of so-called open MRI device). Medical staff activities are carried out in the vicinity of magnet housing, in the static field of significant spatial heterogeneity. The standing with the patient before/after examination, usually at the distance of 0.3 - 1.5 m from the housing of the magnet, last in the most cases 2 - 15 minutes [9]. The basic activities are as follows (fig. 1):

- attending at the MRI room during patient's access and lay down on the MRI's table (area A + B)
- positioning of diagnostic's RF coils on the MRI's table or patient's body (area A + B)
- plugging-in/off the RF coils' cables into the supplying socket (area A + B or D or E)

- MRI table positioning for fixing its initial geometrical position and put in/out it into/from the area of uniform field (inside magnet's bore or within open space of open device) (area A + C)
- attending at the room while patient is getting off from the MRI table (area A + B).

In the case of certain types of examination, a patient is dosed with some pharmaceutical components, e.g. contrast, frequently when patient is placed inside the magnet. In the most of cases dosing/injection is made by nurses, even if the use of infusion pumps is technically possible. These activities last 1 - 2 minutes and is frequently the reason of high exposure of the staff within area D at fig. 1.

Cleaners can be also exposed to high level of static magnetic fields inside MRI room or inside the bore of magnet because permanent and superconductive magnets are permanently on.

Fig. 1. Characteristic of the health care staff exposure while MRI examination attending: area A, E, F - whole body exposure; area B - hands exposure or head while worker is leaning towards the patient; C - hands exposure; D - hands or whole body exposure when worker have to approach very close to the area of uniform field (or is leaned against magnet housing) [9]

The exposure of medical staff to static magnetic fields while positioning the patient can be as high as the main field in the system, although locally and for limited periods of time. The trend towards the routine use of high field MRI systems (3–4 T) is increasing concern that exposure of workers and patients can exceed the existing recommended guidelines (tab. 1).

Table 1. Permissible occupational exposure to a static magnetic field.

Recommendations from	Whole body		Limbs		Cardiac stimulators and implanted electronically activated devices
	Whole working day	Ceiling value	Whole working day	Ceiling value	
ICNIRP guidelines, 1994 [7]	200 mT	2 T	not fixed	5 T	0.5 mT
EMF directive, 2004 [4]	200 mT	not fixed	not fixed	not fixed	mentioned but not fixed
IEEE standard, 2002 [8]	500 mT	500 mT	500 mT	500 mT	mentioned but not fixed
ACGIH, 2005 [1]	60 mT	2 T	600 mT	5 T	0.5 mT

Static field exposure levels must be quantified and controlled for medical staff safety. In the near future, ICNIRP is going to review its guidelines on limiting exposure to static magnetic fields [7]. Medical or paramedical staff may be exposed at low magnetic and electromagnetic fields around the device or outside the room for hours daily.

Concerning open or interventional MRI devices with magnetic field strength below 1.0 T, staff operating such devices are not exposed at levels higher than the currently recommended limits for occupational exposure. However, there are only limited data on the exposure of surgeons at open MRI devices.

Medical workers exposure to static fields from 20 various MRI devices of 0.2 - 2 T magnets, used for medical examination of various tissues (with head's examinations carried out the most frequently) presented by Karpowicz and Gryz [9] can be consider as the typical example of medical staff exposure pattern. The level of static magnetic field decreases rapidly with the distance from the magnet housing - app. 100-fold at a distance of about 2 m. In each of the cases, the area of controlled access for persons with cardiac pacemakers ($B > 0.5$ mT) exist, up to the distance no longer than approx. 5 m from magnet. Magnetic fields of $B = 10 - 500$ mT can be found in a distance up to approx. 1.5 m from the magnet. In the case of 0.5 - 2 T MRI units, the area of the high field, where occupational exposure limitations should be consider ($B > 100$ mT) can be found up to approx. 0.5 m from the border of the magnet's bore. The spatial distribution of the field levels are significantly non-isotropic around the bore magnets' housings - in front of and behind them much wider than sidelong. In the case of open MRI units, the spatial distribution of the field is isotropic around the magnet's housing.

Inside MRI rooms, the maximum exposure level in front of the magnet can reach 1 T. Exposure level in the area of workers' routine activities can reach 150 mT (for whole body exposure) and 600 mT (for hands exposure) (tab. 2). In the case of performing professional activities very close or inside the magnet's bore, workers can be exposed to higher fields. Exposure of hands to a static magnetic field up to 1,5 T was found. Exposure of workers outside the MRI room is lower, at a distance of 5 - 10 m, the magnetic field is normally less than 0.5 mT.

Table 2. Static magnetic field in the most possible places where health care staff attending patients before/after MRI examination [9].

Activities types	Health care staff exposure level, mT / MRI unit		
	0.2 T open	0.5 T bore	1.5 T bore
diagnostic RF coils positioning on the MRI table or patient's body - whole body exposure	3-50	5-100	50-150
diagnostic RF coils positioning on the MRI table or patient's body - hands exposure	5-100	20-250	100-600
plugging-in/off the RF coils cables into the supplying socket and console use - hands exposure	60-100	30-40	20-500 up to 1500 ^{*)}
maximum field existing on the accessible for workers cover of magnet	200-270	80-300	250-600

^{*)} - in case of location the supplying socket inside a magnet bore

3. Research needs concerning MRI exposure assessment

No serious adverse health effects from the whole-body exposure of healthy human subjects up to 8 T have been reported in the literature, but also no epidemiological studies have been performed yet to assess possible long term health effects in patients, workers, or volunteers. Only few informative studies have been performed using exposures above 2 T. This fact is very confusing against the growing up, the use of static magnetic fields in medicine, which lead to exposures of patients and workers to very high fields, even significantly exceeding the level of scientifically investigated exposure results (4 to 8 T). The main conclusions from WHO's health risk assessment of static magnetic fields [6], including the analysis of gaps in knowledge about possible health effects, indicated that, research carried out to date has not been systematic and has often been performed without appropriate methodology and exposure information. In consequences, no sufficient knowledge concerning safety conditions are available today for static magnetic fields exposure existing in the vicinity of MRI devices.

This lack of information resulted among others in the EU Directive 2004/40/EC provisions, which does not contain exposure limit value for static magnetic fields. To solve this serious problem for occupational safety and health engineering, further investigations concerning health risk assessments for static magnetic field exposure have been recently identified by international bodies [5, 6, 7, 14] as being of high priority for health risk assessment. The main areas identified for such research include:

- monitoring of occupational exposure, especially above 4 T, suitable to allow epidemiological studies
- epidemiological studies of possible long-term health effects in patients, volunteers, and staff with occupational exposure, particularly those with high levels of cumulative exposure
- epidemiological studies on pregnancy outcome, of high interest for patients as well as pregnant workers

- studies on biological effects of strong static magnetic fields, especially of chronic exposure on reproduction and development.

Further studies should be more systematic and coordinated. Appropriate dosimetry is important for all kind of research. There is a need to investigate the importance of physical parameters of exposure such as:

- field intensity
- exposure duration
- field gradient on biological outcome.

It means in practice the need of the use of investigations protocol, which allow the performance of the analysis of exposure level's distribution during the shift.

Epidemiological studies are of primary importance in health risk assessment [14]. The use of adequate estimates of exposure from all relevant sources and to establish real exposure pattern and it's variability among various countries is essential for quantitative analysis of research results and exposure's risk. High quality epidemiological studies, not executed yet, should focus on workers involved in high exposure areas and address endpoints such as cancer and pregnancy outcomes in occupational situations. Attention should be paid also to the important confounding variables, such as toxic fumes, vibration or other kinds of non-ionizing or ionizing radiation. Highly exposed occupational groups, as medical staff operating MRI scanners should be identified and followed over time with focus on common health outcomes with short latency periods (e.g. effects on CNS functions and cardiovascular effects). A health survey of surgeons, nurses and other workers using interventional MRI would provide useful information as to levels, durations and frequency of exposures of workers to static fields in these systems.

Experience with other frequencies has shown that obtaining reliable estimates of exposure to EMF for use in epidemiological studies can be very difficult, and surrogate measures of exposure, such as job title or distance from a particular source, may not always provide sufficiently accurate assessments. Investigations concerning low frequency exposure shown, that pocket-personal dosimeters would significantly improve exposure assessment for epidemiological studies and risk assessment. Adequate exposure assessment protocol for such method should be focused on:

- magnetic field strength
- magnetic field gradients
- exposure durations
- the rate of change of the magnetic due to motion.

Development of methods and tools for reliable assessment of human body exposure levels taking into account exposure metrics other than average field strength; criteria, improving exposure monitoring strategies both for static magnetic field and time-varying components, for complex and inhomogeneous exposure situations and for personal exposure assessment (personal dosimeters) is included in the high priority research needs [5] crucial for investigations on exposure risk for MRI technology. Numerical and experimental validation of the dosimeters is required and should consider technical properties of dosimeter coming from EMF sensor, its calibration, dynamic and frequency respond, spatial respond, sensitivity to human body, motion speed, sampling, etc. For the possibility of the use of monitoring results for various kind of analysis, it is very important to develop standardized exposure assessment protocol.

Studies in tissues, living cells and cell-free systems play a supporting role in health risk assessments [14]. Long-term and acute studies on experimental animals are needed using endpoints such as life-span, cancer, development, cardiovascular, immune system and CNS responses [5]. In vitro studies should investigate interaction mechanisms such as radical pair reactions and enzymatic activity, as well as effects on gene expression, mutagenicity and cell transformation.

Static magnetic fields may interact with biological systems in a number of ways, although the most likely means of causing health effects are via field-induced effects on charged molecules and alterations in the rate of biochemical reactions. Theoretical and computational studies are needed to investigate the magnitude and direction of induced currents and fields under various magnetic field exposure conditions.

Human laboratory studies on acute transient effects of exposure to static field effects studied in controlled exposure parameters can bring additional knowledge concerning thresholds of particular exposure effects and physical measures of exposure which should be monitored for exposure assessment in real situations. The priorities for such research [14] were identified including studies on field-induced vestibular dysfunction

including vertigo, head and eye coordination in a gradient and static magnetic field. Such investigations are focused on the MRI interventional procedures, when medical staff are in close proximity to patients within a magnet and are consequently exposed to relatively high fields. Further investigation of such mechanisms and intensity is considered of special interest because of the increasing likelihood that medical staff will be performing complicated tasks for extended periods of time within a magnetic field high exposure. Additional attention should be paid on cognitive and behavioral effects of static magnetic fields. Possible investigations could be executed as a battery of cognitive tasks that encompass standard tests of attention, reaction time and memory, as an initial work with exposed volunteers to find topics for further more focused work.

Proper design and interpretation of all types of above mentioned studies are not possible without expert dosimetric support. Computational dosimetry can provide the link between an external static magnetic field and the internal electric fields and induced currents caused by movement of living tissues in the field, taking into consideration specific tissues and organs. Precise investigations can be focused on the electric fields and currents associated with visual phosphenes and vertigo, fields and currents generated by head and eye movements in a static magnetic field, whole-body movement by staff around the interventional MRI system. Such investigations should be performed with the use of a very fine resolution head-and-shoulder phantom and are considered of particular relevance to interventional MRI procedures where reduced head movements of surgeons and other clinical staff may necessitate increased movement of the eyes.

The ability of non-error performing of such work can be of high importance for the patient's safety, and should be also considered within occupational risk assessment.

4. Conclusion

There are many gaps in knowledge of biological effects and interaction mechanisms of MRI-related electromagnetic fields with tissues. High priority research needs cover the studies to fill important gaps in knowledge focused on health risk assessment that are needed to significantly reduce the uncertainty in the current scientific information. In the case of very specific occupational situation of medical staff operating MRI scanners, additional attention should take notice of the occupational risk assessment. Further investigations and exposure assessment should include the safety of patients from non-error work ability of medical staff and safety requirements preventing hazards from "flying metallic objects" (3 mT) and possible destroying of magnetic memories/cards (0.5 mT). Further investigations should provide knowledge for current scientific gaps, but also to allow verification of the protection level from exposure limitations published by various international and national bodies. Such needs indicate that exposure assessment should allow multi-level analysis of exposure pattern, harmonized with exposure limitations mentioned in Table 1. The most important topics for exposure assessment from MRI scanners should include static and gradient fields exposure, exposure results from workers movement in the area of spatially heterogeneous fields, medical staff, technicians, cleaners and other possible exposed workers groups, open and close magnets, low and high field magnets, diagnostic and interventional use, various types of medical procedures, availability of technical staff for the reduction exposure level and duration. In any case of further research, detailed exposure assessment protocol published with the biomedical research results will be of high importance for combined analysis of various studies and determination of the groups of highly exposed or at high risk groups of workers.

Abstract

The aim of this study is to examine the possible synergistic action between the cytotoxic $\text{Ph}_3\text{Sn}(\text{MNA})\text{SnPh}_3$ complex (SNMNA) and its electromagnetic resonance radiofrequencies on proliferation and viability of a cancer cell line. Leiomyosarcoma tumor cells (LMS cells) were isolated from cancer bearing Wistar rats and tested for their proliferation and viability after administration of the SNMNA complex in various concentrations. We used an appropriate system to take the resonance radiofrequencies spectrum of the SNMNA complex. Then the LMS cells were exposed to two groups of frequencies for 45 min every 24h to determinate their proliferation and viability. Lastly we studied the simultaneous administration of the SNMNA complex and exposure to two groups of its radiofrequencies. The data collected reveal that the SNMNA: 1) Is a very cytotoxic and antiproliferative agent against cancer cells and 2) In low concentrations exercises synergistic action with Electromagnetic Resonance Frequencies (ERFs) and promotes obvious cytotoxic and antiproliferative action. In conclusion, SNMNA complex presents a relatively strong anticarcinogenic and cytotoxic activity. The mechanism of SNMNA complex action on the LMS cells seems to be related with the inhibition of the glycolytic metabolism of the cancer cells. Possibly the SNMNA complex acts as an anti-metabolite competing nicotinic acid in energy production metabolic pathways in which it participates as a coenzyme. The cytotoxicity of the SNMNA complex can be modified with the use of electromagnetic fields which can result beneficial for its future therapeutic actions.

Introduction

LMS tumor is a type of cancer which presents great resistance to chemotherapy. Until, cis-platinum is the preferred therapeutic agent [1,2,3,4]. Due to its chemical characteristics and the ability to form bonds between DNA strands, the main intercellular target of cis-platinum is the cell's DNA [5]. The Pt derivatives interpolate between DNA strands and provoke structural deformation to DNA molecules inhibiting the functional rotations around the histones resulting to DNA fragmentation. [5]. It is not really clear if cis-platinum as well as other forms of Pt complexes is metabolically activated by cell's microsomal system in order to react with DNA molecule [6]. Platinum is the preferred element used to construct metal complexes with antitumoral effects. Various Tin complexes are used in the same therapeutic approach as platinum, for cancer experimental therapy [7,8,9,10,11,12,13,14,15,16,17]. A restrict number of experimental studies indicated that Tin complexes may act with a different mechanism of cis-Pt [11,12,13,14,15,16,17]. The present project studies the cytotoxic and antiproliferative effects of SNMNA complex and the synergistic action between the SNMNA complex and its electromagnetic resonance radiofrequencies on cancer cells *in vitro*.

Material and Methods

Tumor cell line development: LMS cells were produced the following way: 3 male and 3 female Wistar rats were selected from a group of syngenic laboratory animals (7th generation). After anaesthetization with ketamine and midazolam, B[a]P was administered using the procedure described by Karkabounas et al [18,19,20,21,22]. 110 to 128 days later, all animals developed tumors. Biopsies were performed after anaesthetization with diethyl ether and a sample of malignant cells was attained using a bioptic needle. Tumors of 4 animals were histological identified as LMS tumors (65%). One of them developed fibromyosarcoma and another rhabdomyosarcoma. Aseptic samples of LMS tumors sizing about 0,5 cm³ were placed into cold Ringer sterile solution. Then they were aseptically cut into smaller pieces (around 1mm³) and placed in a sterilized glass beaker with 20 ml of Trypsin 0,25% solution. Incubation of the pieces was performed by a gently stir and every 15 minutes 20 ml of the supernatant were collected and placed into sterile plastic tubes (falcon) for further process. Before we commence the second round of trypsinisation 10ml of Dulbecco's Modified Eagles Medium (DMEM) were added to protect tumors from the trypsin action. Afterwards 10 ml of DMEM were rejected and 20 ml of trypsin 0,25% solution were added again and the same trypsinization process was repeated until the tumor pieces were dissolved in released tumor cells. In each tube with the collected tumor cells after trypsinization, we added 1 ml of Foetal Bovine Serum (FBS) in order to stop the action of trypsin. The tubes containing the initial trypsinised samples of the tumors centrifuged at 1200 rpm for 5 minutes in order to form a pellet all the remaining cells. Supernatant was rejected, 10ml of Phosphate Buffer Saline (PBS) were added and the cell suspension was gently mixed using pipette before the second centrifugation at 1200 rpm for 5 minutes. Supernatant was again rejected, 10 ml of DMEM with 10% FBS were added, mixed with the cells and a sample of 1 ml suspension was cultured in a Petri dish (9 ml DMEM, 1 ml FBS). Cells incubated at 37°C, 95% O₂, 5% CO₂ and examined once a day by light microscopy. Cells were subcultured in order to obtain large numbers of tumor cells. The confluent tumor cells in each Petri dish washed with 10 ml of PBS to digress the dead cells, added 1 ml of trypsin 0,25% solution in order to be detached and 10 ml of DMEM to stop the trypsin action. The cell suspension from Petri dish transferred into sterilized plastic tubes and centrifuged at 3000 rpm for 5 minutes. The supernatant rejected and the pellet of cells resuspended in a cryopreservation solution of FBS and Dimethyl Sulfoxide (DMSO) at 9:1 ratio, placed in cryotubes (1ml of total volume) and stored in liquid nitrogen in order to be used again when needed. Examination the nature of these cells was performed using two techniques: 1) Classic diagnostic after Giemsa dyeing, 2) Biological testing. We used large numbers of viable tumor cells collected from a recent cell culture as described above. These cells were inoculated into Wistar rats, belonging to a homogenic line, to whom the initial tumor sample was taken (syngenic animals). Before the inoculation the rats anaesthetized with ketamine and midazolam (20mgr+6mgr per Kg BWt) followed by a 2 cm surgical incision performed aseptically on the left shoulder blade. The tissues removed and severed lightly until a small bleeding. 4x10⁶ LMS cells suspended in 1 ml of Hanke's solution and inoculated on the traumatized tissues by a gentle injection. The edges of the wound ascended cut stitched so as the LMS cells to remain in the wound. Tumors were developed after a period of around 10-20 days. Small tumor pieces were cut for histopathological examination. All tumor samples were identified as Leiomyosarcomas. All the inoculated animals developed the characteristics of the neoplastic disease. Tumor's size at death was around 38-45% of the total animal weight.

SNMNA complex cytotoxicity and antiproliferative effects on LMS cells *in vitro*: For these experiments we used LMS cells taken from liquid nitrogen. The LMS cells were cultured in a Petri dish and incubated for 10 days in order to control the proliferation rate and viability. When the LMS cells become confluent, the DMEM rejected, washed with PBS and 1ml of trypsin 0,25% solution added. After five minutes incubation the LMS cells were detached and we added 10 ml of DMEM in Petri dish. We counted the LMS cells on a cymometer Newbauer and seeded in Petri dish containing 24 wells totally (25.000 LMS cells per well, total volume 1 ml). We seeded 3 Petri dishes for 24, 48 and 72 hours. After 24 hours incubation we renewed the DMEM in 12 wells of each Petri (control wells). At the remaining 12 wells of each Petri we rejected the DMEM and added the dissolved in DMEM SNMNA complex in various concentrations (test wells). The total volume was 1 ml per well. We examined the following concentrations of the SNMNA complex: $0,5 \times 10^{-9}$ M, $0,75 \times 10^{-9}$ M, 1×10^{-9} M, 5×10^{-9} M, 20×10^{-9} M, 50×10^{-9} M, 75×10^{-9} M, 100×10^{-9} M, 125×10^{-9} M, 150×10^{-9} M, 200×10^{-9} M, 250×10^{-9} M. After 24 hours incubation we rejected the DMEM, washed with 1 ml of PBS, added 0,25 ml of trypsin 0,25% solution and incubated again for 5 minutes. When the LMS cells were detached we added 0,25 ml of PBS and 0,5 ml of trypan blue 0,4% solution (total volume 1 ml). After 5 minutes we counted the LMS cells of each well on a cymometer Newbauer. The above procedure for 24 hours cell testing was repeated for 48 and 72 hours incubation.

Chemicals: DMEM, DMSO, PBS and Trypan Blue 0,4% were purchased from Sigma; Trypsin 0,25% and FBS were purchased from PAA (Cell culture company); Stereochemical formula of SNMNA complex is shown at photo 1.

Simultaneous administration of the tin complex and its electromagnetic resonance radio frequencies on LMS cells *in vitro*: This experiment included 5 different tests. Cell viability was the comparable parameter in every test. Cell viability was tested by using Trypan Blue 0,4% solution, counting only live cells. For all the 5 different tests, 25.000 LMS cells were cultured in each well of a Petri (24 wells totally), using 6 wells for each count at 24, 48 and 72 hours. Each test was performed as follows:

1st test line (control of the controls): The results of these tests were used to confirm the controls (double blinded) and were characterized as E1 test. Particularly, 24h after cell culture, DMEM was rejected, each well was washed with 1ml PBS and fresh DMEM was added to a final volume of 1ml. Cells were incubated for 24h at 37°C, 95% O₂, 5% CO₂. DMEM was again rejected in the first 6 wells which was washed using 1ml of PBS. 0,25 ml of trypsin solution 0,25%, was then added in each well and cells were incubated for 3 minutes in order to detach. After 3 minutes period 0,25ml of PBS and 0,5ml Trypan Blue (0,4%) solution were added. Following 5 minutes of incubation cell viability was measured using a microscope. This procedure was repeated at 48 and 72h.

2nd test line (control): The results of these experiments were used as controls (blind) and were characterized as E2 tests. LMS cell culture, 24h incubation, dead cell rejection, PBS wash, DMEM renewal was performed as described above. The next step was to let the Petri outside the incubation chamber at RT (25 °C) and normal atmosphere (N₂ 80% and O₂ 20% approximately) under sterilized conditions for 45 minutes. LMS cell viability was measured after 24h incubation (Trypan Blue method described above). The same treatment was repeated at 48 and 72h in order to determinate the LMS cell viability.

3rd test line (substance activity): This line of experiments was characterized as E3 and was conducted the same way as E1 with the exception that before the first 24h incubation the SNMNA complex was dissolved in DMEM (1ml of total volume) and added in each well at various concentrations (1st group: 10^{-12} M, 10^{-15} M, 10^{-18} M and 2nd group: 5×10^{-9} M, 20×10^{-9} M, 50×10^{-9} M). LMS cell viability control was performed at the same time periods using the same methods as described above.

4th test line (electromagnetic field activity): This line of experiments was characterized as E4 and was performed in the same way as E2 with a simultaneous exposure of the Petri at a range EFRs of SNMNA complex for 45 minutes (1st group of exposure included 10 frequencies, 2nd 328 frequencies). LMS cell viability control was determined at the same time periods using the same methods. The conditions of exposure were the same as E2.

5th test line (simultaneous activity of the SNMNA complex and the electromagnetic field): This line of experiments was characterized as E5 and included the simultaneous study of the SNMNA complex actions (2 groups of concentrations) and exposure to its ERFs (2 groups of frequencies) on the LMS cells. Experiments were performed by combining E3 and E4 test lines (addition of the SNMNA complex at known concentrations and exposure at known frequency groups of the LMS cells for 45min/24h). All cell lines experiments were repeated 5 times.

Equipment and used apparatus

Recording-storing-frequency broadcasting system: The used system is called Multi Channel Dynamic Exciter (MCDE) and it is composed of: a) the diagnostic system, b) the storing system and c) the field generator. The diagnostic system is based on Bohm-Aharonov effect, which was discovered by them in 1959 during a study involving experiments of recording beams of electrons (β rays) through a number of various solenoids [23,24]. A substance or a biological sample is put in a determinate part of the diagnostic apparatus in connection with a solenoid and the electromagnetic frequencies generator. The generator is activated and scan a broad spectrum of radiofrequencies from 0,1 Hz to 1 MHz. The frequencies in which observed resonance between electromagnetic radiofrequencies emitted by the sample (substance or biological material) and the generator's radiofrequencies are stored. In this manner is determined a spectrum of resonating radiofrequencies that characterize the chemical substance or the biological material. This spectrum is called as the specific fingerprint of this chemical substance or biological material. This spectrum is registered at the memory of the storing system and transformed at different radiofrequencies by an appropriate algorithm. The transformed radiofrequencies can be used as input in the field generator and emitted back to the target to influence this chemical or biological material. The generator of electromagnetic fields used in the current study produce static electromagnetic fields with the following characteristics: the intensity of the electric field is $1,1-1,11 \pm 0,01$ V/m and $0,0027-0,0029 \pm 0,00005$ A/m for the magnetic field. The radiofrequencies broad ranged from 10Hz to 1MHz. The energy density of the MCDE system generated electromagnetic fields is approximately $100\text{mW}/\text{cm}^3$. The MCDE system [photo 2] was examined for its safety application in animal and humans by the National (Greek) Center for Scientific Research «Demokritos» (Greek Department of the International Committee of Atomic Energy). The MCDE system was found safe for prolonging exposure humans, animals and other living systems. The MCDE system was placed inside a Faraday cage, in order not to be affected by external electromagnetic fields.

Results

Cytotoxicity of SNMNA complex: SNMNA complex is a very cytotoxic agent against LMS cells [figure 1-4]. The Inhibitory Concentration (IC_{50}) for this complex according to these figures is calculated between 5 and 20 nM for 24h, 48h and 72h. Minimal lethal concentration (MLC) of the complex at 24h ranges between 50-75nM, at 48h around 75nM and at 72h between 30-40nM. At all time points (24h, 48h, 72h) there was no significant different between the values of MLC. Thus, LMS cells seem sensitive to the SNMNA complex cytotoxic effects. The SNMNA complex presents a time depending cytotoxic action, and MLC reaches minimum value at 72h. At 48h MLC value is rather steady at 75nM which can be explained as a cell homeostasis adaptation for neutralize the SNMNA complex cytotoxic effects.

Synergistic activity of the complex and its ERFs:

Considering data from test lines E1, E2, E3, E4 and E5 we can conclude that: 1) LMS cell proliferation rate from 24h to 72h shows an increasing rate (control of controls E1). Thus, LMS cells present high viability during incubation without the presence of a substance or electromagnetic field [fig 1,2,3,4], [photo 3], 2) LMS cell proliferation rate (control E2) shows a slight decrease. Cells seem to be affective by stress when they are outside the incubating chamber (45minues/24h) although they continue to proliferate with increasing rates, 3) LMS cell proliferation rate at test line E3 is significantly lower compared with E1 and E2. Proliferation rate drop is smaller at low concentrations (10^{-12} , 10^{-15} , 10^{-18} M) [fig 5,7], [photo 4] and higher at high concentrations (5×10^{-9} , 20×10^{-9} , 50×10^{-9} M) [fig 6,8]. These data imply the strong cytotoxic activity of the SNMNA complex, 4) LMS cell proliferation rate at test line E4 is lower compared with E1 and E2. Thus, even when the SNMNA complex is absent the exposure of the LMS cells to its resonance frequencies provokes the death of the cancer cells. The electromagnetic field exposure is more cytotoxic in comparison with the activity of the SNMNA complex at low concentrations (10^{-12} , 10^{-15} , 10^{-18} M) [fig 5,7]. At higher concentrations (5×10^{-9} , 20×10^{-9} , 50×10^{-9} M) [fig 6,8] the fields shows smaller cytotoxic activity than the SNMNA complex, 5) LMS cell proliferation rate at test line E5 is significantly lower. The decrease of the proliferation rate is the highest among the test lines [fig 5,6,7,8] especially at 48h and 72h. In contrast a small increase is observed at 24h in relation with E2 test line and E1 (smaller than E2), [photo 5]. The decrease of the proliferation rate observed by simultaneous administration of the lowest SNMNA complex concentration (10^{-18} M) and the exposure to its electromagnetic radiofrequencies is the highest among the other low concentrations (10^{-12} , 10^{-15} M) with the presence of the electromagnetic field [Table 1,2]. There is a 54,79% (72h) [Table 1] decrease of the proliferation rate of E5 ($C=10^{-18}$ and 10

radiofrequencies) and 51,35% (72h) [Table 1] decrease of the proliferation rate of E5 ($C=10^{-18}$ and 328 radiofrequencies), in comparison to E2. This result indicates a synergistic effect on LMS cells between the SNMNA complex and its electromagnetic radiofrequencies. The decrease of the LMS cell proliferation rate is related to the exposure time rather than the number of frequencies used in each group.

fig 1: We measure the viability of LMS cells after 24 hours of incubation at increasing concentrations ($0,5 \times 10^{-9}$ M, $0,75 \times 10^{-9}$ M, 1×10^{-9} M, 5×10^{-9} M, 20×10^{-9} M, 50×10^{-9} M, 75×10^{-9} M, 100×10^{-9} M, 125×10^{-9} M, 150×10^{-9} M, 200×10^{-9} M, 250×10^{-9} M) of SNMNA complex.

fig 2: We measure the viability of LMS cells after 48 hours of incubation at increasing concentrations ($0,5 \times 10^{-9}$ M, $0,75 \times 10^{-9}$ M, 1×10^{-9} M, 5×10^{-9} M, 20×10^{-9} M, 50×10^{-9} M, 75×10^{-9} M, 100×10^{-9} M, 125×10^{-9} M, 150×10^{-9} M, 200×10^{-9} M, 250×10^{-9} M) of SNMNA complex

fig 3: We measure the viability of LMS cells after 72 hours of incubation at increasing concentrations ($0,5 \times 10^{-9}$ M, $0,75 \times 10^{-9}$ M, 1×10^{-9} M, 5×10^{-9} M, 20×10^{-9} M, 50×10^{-9} M, 75×10^{-9} M, 100×10^{-9} M, 125×10^{-9} M, 150×10^{-9} M, 200×10^{-9} M, 250×10^{-9} M) of SNMNA complex

fig 4: Wistar rat LMS cells percentage proliferation after 24,48,72 hours of incubation at increasing concentrations ($0,5 \times 10^{-9}$ M, $0,75 \times 10^{-9}$ M, 1×10^{-9} M, 5×10^{-9} M, 20×10^{-9} M, 50×10^{-9} M, 75×10^{-9} M, 100×10^{-9} M, 125×10^{-9} M, 150×10^{-9} M, 200×10^{-9} M, 250×10^{-9} M) of SNMNA complex (collective results)

		(L+10)	
10^{-12} M	28,43	-15,96	-32,33
10^{-15} M	0,90	-31,19	-36,09
10^{-18} M	-5,68	-42,98	-54,79
		(L+328)	
10^{-12} M	18,32	2,99	-8,37
10^{-15} M	48,85	0,69	-50,13
10^{-18} M	1,15	-48,05	-51,35

Table 1: Shows the time dependent declination of LMS cell proliferation in low concentrations (10^{-12} M, 10^{-15} M, 10^{-18} M) of SNMNA complex. The decrease of the LMS cell proliferation is independent to the

number of radiofrequencies. The lowest concentration (10^{-18} M) shows the highest cell proliferation decrease. The table shows the percentage LMS cell proliferation (E5 in comparison with E2 assay).

		(H+10)	
5nM	-22,34	-35,44	-27,55
20nM	-41,08	-43,04	-44,60
50nM	-94,64	-100,00	-100,00
		(H+328)	
5nM	-25,98	-31,30	-27,02
20nM	-36,33	-39,23	-40,15
50nM	-91,63	-100,00	-100,00

Table 2: Shows the time dependent declination of LMS cell proliferation in high concentrations (5×10^{-9} M, 20×10^{-9} M, 50×10^{-9} M) of SNMNA complex. The accumulative decrease (SNMNA complex+electromagnetic field) is minor in comparison with results in table 1. The prevalence of SNMNA complex concentration on the electromagnetic field effects is obvious. The table shows the percentage LMS cell proliferation (E5 in comparison with E2 assay).

Discussion

We have studied the effects of the SNMNA complex on a Wistar rat LMS cancer cell line. We also studied if it is possible to modify the cytotoxicity of the SNMNA complex using electromagnetic fields at radiofrequencies of the complex resonance spectrum. SNMNA complex is a strong cytotoxic agent on LMS cancer cells *in vitro* [11,12,13]. Mercaptonicotinic acid is an essential moiety of the complex and it is possible to act as anti-metabolite. Nicotinic acid participates in coenzymes (NAD^+ , NADP^+), which take place as reduced equivalents carriers in glycolysis pathway and Krebs cycle in cancer cells [25]. Thus, nicotinic acid seems as a very important agent at energy production of tumors energetic metabolism [25]. Mercaptonicotinic acid of the SNMNA complex may compete nicotinic acid coenzymes in the above metabolic energy production pathways. The used LMS cells, such as other cancer cell types, seem to produce energy by glycolytic pathway [26,27,28,29,30,31,32]. This point has been shown by preliminary experiments in which the LMS cells are very sensitive to iodoacetic acid [31,32]. Iodoacetic acid is a strong inhibitor of the glyceraldehyde-3-phosphate dehydrogenase [29]. This enzyme plays a critical role for the whole glycolytic pathway and so the ATP glycolytic production stops by inhibiting this enzyme [33]. The SNMNA complex acts in very low concentrations lower than the iodoacetic acid. On the other hand the SNMNA complex is a strong inhibitor of the 5-lipoxygenase [13,14]. Generally the lipoxygenase, cyclooxygenase 1 and cyclooxygenase 2 inhibitors of synthetic or natural origins are still used as anti-cancer substances with target action [34,35]. It is possible that SNMNA complex acts as a non steroid antinflammation derivative (NSAID) inhibiting 5-lipoxygenase on LMS cells [13,14]. In a recently published work, we find that the SNMNA complex produces free radicals in aquatic solutions [13,14]. This is verified from the EPR spectrums of the SNMNA complex [13,14]. The energy of electromagnetic fields may activate the electrons of the SNMNA complex bonds causing electron excitation. Exposure of SNMNA complex aquatic solutions to UV radiation causes the immediate production of free radicals [13,14]. The chemical reactions can be accelerated when an external electromagnetic field influences a chemical system [36,37,38,39]. For example the Belluzov – Zhabotinsky (BZ) reaction of malic acid catalyzed by $\text{Fe}^{+2} - \text{Fe}^{+3}$ ions (and not Ce) can be accelerated with the use of a low intensity external electromagnetic field (0,1 μT) [37]. Metal complexes such as SNMNA complex can be activated by external electromagnetic fields. The characteristic (fingerprint) resonance radiofrequencies spectrum of a substance can reduce the energy threshold activation of this substance and catalyse its chemical and biological effects.

Abstract

In this study we investigated the effects of low intensity static electromagnetic field (EMF) causing no thermal effects, on leiomyosarcoma cells (LSC), isolated from tumors of Wistar rats. Electromagnetic resonance frequencies measurements and exposure of cells to static EMF's were performed by a device called Multi Channel Dynamic Exciter 100 V1 (MCDE). The tumors were developed in the rats via a 3,4-benzopyrene injection. The LSC were exposed to electromagnetic resonance frequencies (ERF's) between 10 kHz to 120 kHz, for 45 min. During a 24h period, after the exposure of the LSC to ERF's, there was no inhibition of cells proliferation. In contrast, at the end of a 48h incubation period, LSC proliferation dramatically decreased by more than 98%. At that time, the survived LSC were only 2% of the total cell population exposed to ERF's, and under the same culture conditions showed significant decrease of proliferation. These cells were exposed once again to ERF's for 45 min (totally 4 sessions of exposure, of 45 min duration each) and tested using a flow cytometer. It was found that 45% of these double exposed to ERF's, LSC (EMF cells) were apoptotic and only a small percentage 2%, underwent mitosis. In order to determinate their metastatic potential, these EMF cells were also counted and tested by an aggregometer for their ability to aggregate platelets and found to maintain this ability. They showed no difference in comparison to the LSC not exposed to ERF's (control cells). *In conclusion*, exposure of LSC to specific ERF's decreases dramatically their proliferation rate and induces a high rate of cell apoptosis. Also, the LSC that survived after exposed to ERF's, had a lower proliferation rate compared to the LSC controls but did not loose their potential for metastasis. The use of specific ERF's generated from the MCDE electronic device, is safe for humans and animals according to the international safety standards, and appropriate for the experimental treatment of cancer in vitro and in vivo.

Introduction

There are quite a few of data on the effects of electromagnetic field (EMF) on various kinds of malignant cells in experimental animals and in humans, some of them referring to the application of electromagnetic resonance principles [1,2]. The main concepts expressed so far referring to the effects of EMF on malignancies are: the intensity, frequency and duration of application of the electromagnetic waves. The EMF may act as co-carcinogen combined with the primary carcinogen, especially in experimental animals but can also exert anticarcinogenic effects, inhibiting the proliferation of malignant cells in vitro as well as decreasing the size of the experimental tumors in vivo [3-6]. Studies of the EMF pro-carcinogenic effects in experimental animals are not numerous and seem to have many uncertainties [3,4]. On the contrary, studies on the EMF anticancer effects are abundant and their methodology is well documented [7]. It has been also shown, that the cytostatic effects of the EMF on cancer cells are not related to their thermal effects but are temperature-

independent [8-10]. The purpose of the present study is to investigate the effects exerted by low intensity static electromagnetic field on a) the proliferation and the viability of the leiomyosarcoma cells line (LSC) and b) the cell cycle of LSC and c) the platelet's aggregation from a physiological agonist and LSC cells.

Materials and methods

Production of leiomyosarcoma cells (LSC) and smooth muscle cells (SMC): The malignant cells were isolated from selected leiomyosarcoma tumors of Wistar rats. Fifteen (7 male and 8 female) Wistar rats, of the fifth generation of a certain couple, 60 days old, were subcutaneously injected in their right scapula by 1 ml of 3,4-benzopyrene solution (B[a]P) in tricapriline in a dose of 10.08 mg/ml. The rat leiomyosarcomatous tumors B[a]P induced have the following characteristics: a) sensitivity to antioxidant substances and free radical scavengers indicating that their proliferation is related to the release of reactive oxygen species [11-13], b) their proliferation can be inhibited via the administration of cyclooxygenase-2 (COX-2) and 5-lipoxygenase (5-LOX) inhibitors [14] and c) ability to induce leiomyosarcoma tumors when inoculated into Wistar rats. After 110 days (maximum 135 days) of B[a]P injection, all animals developed malignant tumors at the site of injection. All tumors were histologically identified as leiomyosarcomas. The tumors were surgically removed and cut under aseptic conditions into pieces of 0.5 cm³ in volume. Each piece was placed immediately in cold Ringer's solution and sliced down again to smaller pieces (1 mm³). All smaller pieces were inserted for 5 min into 5 ml of cold Dulbecco's modified Eagles medium (DMEM) solution which contained small quantities of trypsin and then these pieces were incubated in the same DMEM solution at 37° C for 4 h, with gentle mixing every 15 min. After incubation the DMEM solutions containing the tumor pieces were centrifuged at 900 rpm for 10 min and the supernatant was rejected. The remaining cells were resuspended in DMEM+10% fetal bovine serum (FBS) solution and seeded in plastic coated dishes of 52 mm in diameter. Tumor cells after been subcultured, were examined histologically and were characterized as leiomyosarcoma cells. In order to verify if these LSC were active and able to induce the same type of malignancy in rats, 4x10⁶ of them were suspended in Hanks salt solution and inoculated into every Wistar rat as follows: the animals were anaesthetized with midazolam and ketamine, and a surgical opening was made in their outer skin layer at the middle of their back. The tissue underneath was traumatized by lancing with a sharp blade in order to bring fresh blood to the surface. LSC were then aseptically infused into the operated area, and the incision was immediately sutured. The animals developed medium-sized malignant tumors approximately 12 cm³ in volume, within the first 10 days after inoculation. Smooth muscle cells (SMC) were isolated from the aorta of Wistar rats and cultured again by the methods described above. The animal experimentation performed according to the European Community Directives and International Legacy for the animal protection. All the in vivo experiments were accomplished according to the European Union Directive for the Protection of Vertebrate Animals Used for Experimental and other Scientific Purposes (86/609/EEC, article 9 §§1,2).

Electromagnetic field equipment: Electromagnetic resonance frequencies measurement and exposure of cells to static EMF's were performed by a device called Multi Channel Dynamic Exciter 100 V1 (MCDE) invented by K. Havelas [17]. The MCDE has been certified by the Greek National Centre for Scientific Research "Democritos" and its Department of International Committee of Atomic Energy for its safe use in humans and animals. This device is consisted of two basic parts: A) an electromagnetic field generator of various intensities. The range intensities for the electrical field are 1.1 to 1.11 ± 0.01 V/m and for the magnetic field are 0.0027 to 0.0029 ± 0.00005 A/m. The radiofrequencies which generate from MCDE system range of 10 Hz to 1 MHz. The power density of the electromagnetic field is 100 mV/cm³ approximately, B) an electron paramagnetic resonance spectrometer with specific characteristics. This spectrometer is a scanner-recorder of the ERF's emitted from biological systems (targets), such as localized tumors in experimental animal, or cultured cancer cells, exposed to EMF. It is well known that the normal function of any biological system produce electromagnetic waves of specific frequencies caused by cell electromagnetic properties (electric membrane potential, transport of ions charges etc). The specific ERF's emitted from an EMF excited biological system, is recorded as an electromagnetic resonance fingerprint of this system. This is due to the electromagnetic resonance taking part between ERF's produced by the generator and ERF's emitted from the biological system. The MCDE is supported by a sophisticated software easy to use (submitted for accreditation). First, it is necessary to record the electromagnetic resonance fingerprints emitted from the biological systems (targets). Then, by selecting the specific MCDE's programs of the software, the appropriate ERF's for the exposure of the target are calculated and then are emitted to the target.

Estimation of leiomyosarcoma cells and smooth muscle cells electromagnetic resonance frequencies: Electromagnetic resonance fingerprints of LSC and SMC were recorded before and after their exposure to EMF (10 Hz-1 MHz). The ERF's of LSC electromagnetic resonance fingerprints are modulated using the software and after that, the cancer cells are exposed to these modulated

electromagnetic fingerprintings for 45 min. The cell proliferation and cell morphology were checked every 24 h. A total of 492 different frequencies emitted from LSC cells were recorded (fig 5).

Method of leiomyosarcoma cells and smooth muscle cells exposure to electromagnetic field

Leiomyosarcoma cells treatment: Twelve Petri dishes with 10 ml growth medium were seeded with 1×10^5 LSC (zero time). The LSC cultures were incubated in 37°C at $95\% \text{O}_2 + 5\% \text{CO}_2$ atmosphere for 48 h. Then the medium was replaced by 10 ml of new DMEM. At 72 h from zero time, six LSC cultures (EMF cells) were placed into a Faraday apparatus at room temperature (RT) and exposed to modulated electromagnetic fingerprints (from 10 kHz to 120 kHz and intensities from 1.1 to 1.11 ± 0.01 V/m for the electric field and 0.0027 to 0.0029 ± 0.00005 A/m for the magnetic field), for 45 min. A total of 492 frequencies were used for LSC exposure to EMF. The used frequencies were derived from a transformation of the 492 frequencies recorded as the LSC electromagnetic fingerprints (Fig 1) by an specific algorithm [$\sum f(r) + f(\text{em}) = c$, $f(r)$ = registrated frequency, $f(\text{em})$ = emitted frequency, c = a constant] The other six LSC cultures (control cells) remained at RT for the same time as EMF cells but without being exposed to EMF. The control and EMF cells were incubated once again at the same conditions as before, for about seven hours. At 79h and 96h from zero time, the cells of each culture were counted, subcultured at about 1×10^5 cells per plate and incubated at the same as above conditions. At 120h from zero time, the EMF cells were re-exposed to EMF as before and 24 h later, both EMF and control cells in each plate were counted and examined microscopically. Then, to examine their proliferation rate in relation to time, both groups (EMF and control cells) were subcultured and incubated at the same described conditions, in order to estimate the time till cell confluence. The cells were then preserved in liquid nitrogen.

Smooth Muscle Cells treatment: The SMC isolated from Wistar rat aorta were subcultured in the same conditions as described above for LSC and exposed to EMF in the same manner and frequencies as rat LSC.

Leiomyosarcoma cells manipulations: The preserved in liquid nitrogen EMF and control cells were defrost and cultured again till cell confluence. Twelve plates were then seeded with the same number of LSC and incubated for 24 h. The EMF cells were again exposed to EMF for 45 min after 24 h and 48 h. Six hours after the last session, cell samples from each plate were taken for testing their cell cycle phases by a flow cytometer Becton Dickinson system.

Estimation of platelet aggregation ability of leiomyosarcoma cells

The potential for metastasis of the LSC was determined from their ability to aggregate platelets before and after their exposure to EMF using the aggregometer CA-500, Cronolog, USA and the Cronolog kit for platelets aggregation. The Cronolog kit was used to verify the normal platelet responses. A total of 120 tests were performed on blood samples taken from six healthy volunteers who abstained from the use of drugs and alcohol for ten days before the tests. The tests were performed in platelet rich plasma (PRP) isolated from the blood samples and prepared according to the manual of the apparatus. The platelet aggregation tests were performed after the suspension of either 5×10^5 EMF cells or of the same number of control cells, in PRP.

Statistics

Student's t-test was used for the statistical evaluation of the results and $P < 0.05$ was considered statistically significant.

Results

Cell proliferation rate: Our results were as follows: a) Twenty-four hours after the first and second session of exposure to the EMF, the proliferation rate of the LSC was slightly decreased, in comparison to the control cells proliferation ($P < 0.05$). Also the microscopic examination showed that the highest percentage of LSC was under stress, showing round-shaped cells with abortive pseudopodia and formation of nuclear membrane blebs. b) The multiplication rate of the EMF exposed LSC after 48 h of incubation was dramatically decreased at a percentage higher than 98%, ($P < 0.0001$ compared to the control cells) and most of the exposed malignant cells were found either dead (mainly apoptotic) or extremely stressed: round shaped cells, formation of blebs in the outer cell membrane, absence of pseudopodia (fig 1) c) The survived LSC after one session of EMF exposure, showed a great difficulty in proliferating according to the time needed till cell confluence (6 days of incubation) in with comparison to the time needed till control cells confluence (3 days), (fig 2). Also, the survived LSC developed a remarkable resistance to EMF, showing only 20% decrease of cell proliferation rate compared to the much higher decrease in proliferation rate of 98%, shown after their first EMF exposure.

Leiomyosarcoma cells distribution in the cell cycle phases: Flow cytometry revealed that after the fourth cell exposure to EMF, 33% of the LSC were found to be in G0/G1, 9% in S phase, 2% in mitosis and 45% were undergoing apoptosis, while the control cells were found to be: 36% in G0/G1, 38% in S phase, 19% in mitosis and 2% undergoing apoptosis (Table 1).

SMC viability after exposure to EMF: The SMC seem not to be affected by electromagnetic fields exposure at 24 and 48 h (fig 3). The exposed SMC have a proliferation rate 10% lower than the non exposed SMC (control). This difference is not statistically significant ($P < 0.04$).

Estimation of sarcoma cells “ potential for metastasis” by platelet aggregation: The aggregation ability of the control as well as of the exposed to EMF cells, was 78%, and almost equal to the ability to aggregate of the ADP (82%). According to the above, LSC exposure to EMF did not affect significantly the “potential for metastasis” of LSC (fig 4).

Estimation of cell electromagnetic resonance – frequencies: Electromagnetic resonance frequencies of the: a) unexposed to EMF LSC were ranging between 10.5 to 120.5 kHz, b) exposed to EMF LSC, between 10 to 120 kHz and c) SMC between 10 to 120 kHz. Spectrum analysis of the above estimations revealed that the electromagnetic resonance frequencies of LSC exposed to EMF showed significant differences as compared to those of the unexposed LSC (control cells) presenting an almost 70% similarity to the electromagnetic resonance frequencies recorded from the SMC (data not shown).

Fig 1. The viability of the EMF exposed LSC after 48 h of incubation was dramatically decreased at a percentage higher than 98%, ($P < 0.0001$ compared to the control cells)

Fig 2. The survived LSC after one session of EMF exposure, showed a significant difficulty in proliferating according to the time needed till cell confluence (6 days of incubation) in with comparison to the time needed till control cells confluence (3 days)

Fig.3 : Viability of Smooth Muscle Cells (SMC) not exposed and exposed to EMF. The non exposed SMC have a rate of growth 10% larger from the exposed ones [$P < 0,4$].

Fig 4. LSC exposure to EMF did not affect significantly the capacity of LSC to aggregate human platelets. PLT : resting platelets, LMC : platelet aggregation LMC induced, EXP-LMC: platelet aggregation induced by exposed LMC, ADP: control of platelet aggregation by ADP as agonist.

Fig 5. The fingerprint spectrum of 492 frequencies emitted from leiomyosarcoma cells of Wistar rat after an accurate registration by the resonating system of the MCDE apparatus

Table 1 : Flow cytometry for non exposed and exposed to EMF sarcoma cells .

The percentage of apoptotic nucleus in the group of control cells is very low (1,79 %) when the percentage of apoptotic nucleus in the group of exposed cells to EMF is much greater (45,34 %) .

Discussion

Our findings indicate that high growth inhibition of LSC of more than 95% can be accomplished by the applying an EMF according to electromagnetic resonance principles. The results of this study reinforce the other authors findings on the proliferation inhibition and on the significant morphological alterations of human melanoma cell lines exposed to low power electromagnetic waves of 50-80 GHz [15] and also on the apoptotic effects of static EMF of 1.95 GHz on human epidermoid cancer cells [16]. In the present study antiproliferative and apoptotic effects have been achieved by exposing LSC to a static EMF of low energy waves and frequencies between 10 kHz to 120 kHz. This field is far lower in frequency and in power than the upper limit of permitted exposure (power: 200m Watt/cm³), being thus, safe for use in animals and humans [17]. It is also evident from the literature, that the EMF effect is dependent on immediate interactions that affect the electronic spin of the atoms or molecules with uncoupled electrons in their external orbit, enhancing electron spin coupling; thus may help the neutralization of free radicals, especially those produced by the activation of arachidonic acid cascades [14,16,18-21]. It is also known that the EMF induce free radicals production that may act as activators of signal transduction pathways [10,19,20]. According to the above, it is possible that the effects of these EMF, could be similar to the effects of antioxidants and free radical scavengers on LSC lines. The high percentage of the exposed LSC found in apoptosis (45%) in comparison to that of the unexposed to EMF, control cells (2%), could be explained as the effect of the EMF's on cellular membranes activating signal transduction pathways leading to genes expression of cell apoptosis [5,7,16,22] or to inactivation of anti-apoptotic genes [15]. The low percentage of cells found in synthesis and in mitosis (9% and 2% respectively) compared to that of the control cells (38% and 19% respectively), indicates that radiofrequency of the EMF can act as cell cycle inhibitor, similarly to the effect of magnetic field on DNA synthesis [23,24,7]. There is also evidence that exposure to the EMF may reduce the immunoreactive p53 expression in tumor bearing mice [19], which has been found increased in BaP-induced leiomyosarcomas in Wistar rats [25]. The lower sensitivity of LSC after their fourth exposure to ERF's, compared to their higher sensitivity after the first exposure, indicates that LSC may have developed some type of resistance to EMF. Our finding, that the electromagnetic resonance fingerprints of LSC changed after their exposure to EMF and resembled to that of the SMC, may indicate that some differentiation in the LSC function has taken place. This differentiation is supported by our -yet unpublished- data indicating that the EMF treated LSC, after being inoculated to Wistar rats, retard the tumor development or even fail to develop tumor, in contrary to inoculated but unexposed to EMF LSC that develop tumors in a 100% of the experimental animals. There are also bibliographic references indicating that the EMF, specific or generalized is able to induce differentiation of cancer and non cancer cells [26,27]. Nevertheless, the LSC exposed to the EMF seem to retain their potential for metastasis as they can still aggregate platelets. It must be emphasized that for the first time a low intensity EMF has been used and it is essential that this EMF is carefully designed on the basis of the emitted electromagnetic frequencies from the target cells, in order to be effective. Also, the intensity of the electric field we used was 75 times lower and the intensity of the magnetic field was more than 1800 times lower than the average of the international safety standards according to the National Centre for Physical Sciences of Greece ("Demokritos", Athens Greece) [17]. Because of that, the use of this electronic device for the treatment of cancer cells seems to be safe. Unpublished data of ours, from the follow up of tumor-bearing animals and cancer patients treated with EMF by the above method, confirm the above. Our data, concerning the changes of LSC electromagnetic resonance fingerprints after repeated exposures to EMF, indicate that, in order to affect the cells functions, it is crucial to make regular readjustments of the electromagnetic resonance fingerprints, in order to differentiate the LSC phenotype to a phenotype with an electromagnetic resonance fingerprinting as close as possible to that of the normal cells (SMC). In this case, the LSC should loose their malignant phenotype, so that their inoculation to Wistar rats could not cause malignant disease. Experiments going on, in our lab, seem to confirm this hypothesis.

Abstract

One of the most used photosensitizer in photodynamic therapy of cancer is the aminolevulinic acid (ALA), a precursor in synthesis of protoporphyrin IX (PpIX). One of the disadvantages using this photosensitizer is the small rate of ALA uptake of the cells. Our work aim was to increase by electroporation the PpIX level in ALA treated cells. Electroinduced pores in membrane would facilitate an enhanced uptake rate of ALA forcing an increased level of PpIX and consequently a better efficiency of ALA photodynamic therapy. B16F10 melanocytes cultures were incubated with 1 mM ALA for 4 h and PpIX level was monitored by the fluorescent emission at 635 nm. The viability of cells was analysed by MTT test. The electroporation of cells in the presence of ALA was done with exponential decay electric pulses in the range of 500-4500 V/cm, 100 μ s, 1-4 pulses. In the control experiment (without electroporation) a rate of PpIX production comparable with results in literature was obtained. Exposing the ALA treated cell cultures to light (633 nm) for various periods the apoptosis or necrosis of cells was triggered. This observation was confirmed by the results of cells viability tests. The electroporation of cells in the presence of ALA did not show significantly increase the cellular PpIX level. In conclusion our *in vitro* preliminary results did not supply evidences that the electroporation of cells can be a way to improve the ALA uptake of the cells and consequently to improve the efficiency of photodynamic therapy with ALA.

Introduction

Photodynamic therapy (PDT) concept is based on a combined effect of the light and chemicals. A photosensitive chemical species incorporated into cell and afterwards exposed to irradiation with light of appropriate wavelength produces very reactive chemical radicals which are able to trigger the apoptosis or necrosis of the cell. This type of therapy was proposed as an alternative to classical surgical techniques. The photosensitive molecules can be an exogenous (an appropriate techniques has to be used to uptake this molecules by the cell) or an endogenous one as protoporphyrin IX (PpIX). 5-aminolevulinic acid being a precursor of PpIX is one of the most used chemical in PDT. ALA is an endogenous precursor of PpIX. In normal conditions the rate of PpIX synthesis is regulated by means of a negative feedback loop limiting in this way the level of endogenous ALA. An enforced uptake of ALA allows overcoming this limiting mechanism resulting in an increased rate of PpIX production by the cells. PpIX absorption spectrum shows a high peak located 635 nm (Ma et al, 2001). Under the light irradiation the PpIX produces several photo-induced products having as final results an unbalanced oxidative status of the cell. As a consequence the cell triggers the apoptosis program. The technique was successfully used in *in vitro* and *in vivo* experiments.

The main disadvantage of this ALA-PDT method is the limiting step of ALA incorporation into the cell. ALA is a hydrophilic molecule and consequently has a very low diffusion coefficient through the membrane lipid bilayer. There are several reports concerning the mechanism of ALA uptake through the cell membrane. Mainly two paths are proposed: (i) the passive diffusion which would be important only during a short period of incubation, till 15 min (Bermudez Moretti et al, 2002) and (ii) an active mechanism mediated by a BETA family transporter (Rud et al, 2000; Bermudez Moretti et al, 2002).

An alternative proposed to improve the rate of ALA influx is the cell electroporation. The action of a short electric pulse of appropriate amplitude is able to produce a reversible permeabilisation of the membrane. During this state the exogenous molecules, for which normally the membrane is not permeable, can pass through the membrane barrier by diffusion. In cancer therapy the technique was successfully used to improve the efficiency of cytostatics (Orlowski, Belehradek et al., 1988). A derived method is the transdermal electroporation. The electric pulses are applied across the dermal layer increasing the diffusion of drugs through it. This method was proposed to improve the efficiency of ALA – PDT when ALA is topically applied (Johnson et al, 2002) and an increase of transdermal transport rate was reached.

In this report we present our preliminary results concerning the possibility to use the electroporation at the cell level in order to increase the uptake of ALA and consequently the production of PpIX.

Materials and Methods

B16F10 murine metastatic melanoma cells were used as biological experimental object. They were cultured in 3 cm Petri dishes, at 37°C, 5% CO₂, in Dulbecco's MEM (Gibco) supplemented with 10% foetal calf serum (Gibco), 100 units/ml of penicillin and 100 µg/ml of streptomycin (BioClone). The B16F10 cell line was kindly provided by Dr. L.M.Mir, Gustave-Roussy Institute (Villejuif), France.

1mM ALA (Sigma) was added in the fresh Dulbecco's MEM medium without foetal calf serum and without phenol red (Gibco) and the cells were incubated with at 37°C for 4 hours. A longer ALA incubation period did not increase the PpIX production (data not shown). After this incubation the ALA-treated cells were harvested by mild trypsination and the level of PpIX was measured by fluorescence. The PpIX excited at 510 nm has two emission peaks at 635 and 706 nm (Orenstein et al, 1997). The emission spectrum in the range of 600 – 750 nm was recorded in a SPEX spectrofluorometer. The intensity at 635 nm was considered as a measure of PpIX production.

In order to produce the photo-degradation of PpIX the cells attached to Petri dishes and incubated with ALA, were exposed to red He-Ne laser beam (power at the level of the dish surface was 16 mw) expanded by a simple lens system to cover the all dish surface. After different exposure durations (4-35 min) the cells were harvested by mild trypsination and the fluorescence spectrum recorded.

The level of toxic photo-induced products was evaluated using the MTT cell viability test after exposure to laser beam. The cells were seeded at appropriate concentration on a 96wells plate for 24h, than incubated for 4 h, at 37°C, with 0.5mg/ml thiazolyl blue tetrazolium bromide (TBTB, Sigma). The viable cells are transforming the TBTB into coloured formazan precipitate. The production of formazan was quantified using a spectrophotometer plate reader (Awareness).

The cell suspension electroporation was done using an Eppendorf electroporator. The suspension medium was the same as Eppendorf recommended. An exponential electric pulse (time constant of 100 µs) was applied between the electrodes of an electroporation cuvette (BioRad) where the cell suspension was introduced. The electric field intensity ranged from 0.5 to 6 kV/cm. In order to evaluate the efficiency of electroporation the uptake of a membrane impermeable molecule (ethidium bromide, EB) was followed. The dye was added to the cell suspension just before the electroporation. The labelled cells were counted under a fluorescence microscope (Zeiss Axiovert 200) equipped with an appropriate filter set and the percentage of the coloured cells was calculated. To evaluate the cells 'death' (at high electric field intensity a large number of cells die) the EB was added to the electroporated cell suspension after 10 min. It was considered that during this period the permeability membrane of surviving cells was recovered and only the irreversible permeabilized cells will uptake the dye.

Figure 1. Fluorescence spectra of cells incubated with ALA, 1 mM, 4 hours (ALA) and without ALA (Control). $\lambda_{ex} = 510$ nm

Results and Discussions

The cells incubated with ALA, 1 mM, 4 hours, had a strongly increase of PpIX production (fig. 1). The spectrum is very similar with other reported results (Orenstein et al, 1997; Dysart and Patterson, 2006) and two peaks can be observed at 635 nm, the main one, and at 706 nm. In contrast, the control cells (without ALA) did not present observable levels of PpIX.

The effect of light irradiation on cells incubated with ALA was revealed by means of decrease of PpIX level in cells after irradiation (fig. 2). The PpIX level decreases with irradiation time confirming other results reported in the literature (Orenstein et al, 1997). Plotting the maximal intensity at 635 nm against irradiation time a linear decrease of PpIX level in irradiated cells can be observed (fig 3). Over 35 min of irradiation the fluorescence intensity at 635 decrease much slowly suggesting a saturation of the process (data not shown).

Figure 2. Fluorescence spectra of cells incubated with ALA, 1 mM, 4 hours (ALA) and irradiated with red laser light (633 nm) for different periods. $\lambda_{\text{ex}} = 510 \text{ nm}$.

Figure 3. Fluorescence intensity at 635 nm ($\lambda_{\text{ex}} = 510 \text{ nm}$) of cells incubated with ALA, 1 mM, 4 hours and irradiated with red laser light (633 nm) for different periods.

In order to check the effects of irradiation on the viability of the cells the MTT test was applied. Four variant of cell cultures were tested: a control consisting in cells without ALA, a second control without ALA but irradiated at 633 nm, a non-irradiated but ALA incubated culture cells and a culture cells incubated with ALA and irradiated with 633 nm laser light. The period of irradiation was 30 min. ALA incubation was performed as above. The results are in presented in Figure 4. The red light irradiation and ALA incubation did not affect the viability of cells with respect to the controls. Only the cells incubated with ALA and irradiated with red light show more than two times smaller viability. This experiment actually proves the fact that our experimental conditions are appropriate for an *in vitro* experiments revealing the presence of photo-induced products in ALA incubated cells and irradiated with red light.

Figure 4. Viability of the cells evaluated by MTT test: C – control, C-I – control cells irradiated with red light, ALA – ALA incubated cells, ALA-I – ALA incubated cells and irradiated with red light.

In order to find out the optimal conditions for the electroporation a range from 0.5 to 6 kV/cm was used. One exponential pulse (time constant of 100 μ s) was applied to the cell suspension with or without EB. The results are in Figure 5. At low level of electric field intensity a rapid increase of porated cells percentage is observed reaching a plateau for higher values of electric field. On the other hand, at low field intensity the viability of cells is very close to maximum (100%) and decreases when the electric field increases. For medium values of the field intensity (between 2 and 4 kV/cm) the cells have simultaneously a maximal level of poration and of viability. Considering the conditions of minimal stress for the cells we used in our experimental trials to increase the uptake of ALA in the cells by electroporation the following electric conditions: one exponential pulse of 2 kV/cm and 100 μ s time constant.

After all these preparatory experiments which allow us to have proper conditions to reveal the photosensitizer effect and to have optimal electroporation parameters we performed experiments trying to find out an increase of PpIX production in cells electroporated in presence of ALA. The following conditions were used: ALA 1mM, one exponential pulse of 2 kV/cm and 100 μ s time constant. 15 min after electroporation the cells were incubated in a fresh culture medium without ALA and after 1 h the cells PpIX level was recorded. For control cells the same experimental conditions were used without electroporation step but with a 4h incubation with ALA.

An unexpected result was obtained. In the electroporated cells no PpIX was revealed. The spectrum was very similar to the spectrum of control cells without ALA (data not shown).

In order to check if the electroporation step disturb or not the metabolism of cells a further control experiment was performed. Cells electroporated without ALA were incubated immediately after the electroporation in fresh medium with 1mM ALA for 4 hours. The level of PpIX was recorded by fluorescence spectrum and the PpIX value was similar to the control cells incubated with ALA for 4 h, without electroporation. This is an evidence for the fact that electroporated cells were able to develop the biochemical processes needed for PpIX synthesis.

Figure 5. The electroporation yield and the viability of electroporated cells.

Summary

In this paper we report our preliminary results concerning the possibility to improve the efficiency of ALA – PDT method by electroporation. Our *in vitro* trials did not supply evidences that the electroporation of cells in suspension can be a way to increase the rate of ALA uptake of the cells. These results are apparently in contradiction with reports of other authors which successfully increase the transdermal transport rate of ALA and the level of PpIX production in *in vivo* experiments on mice (Johnson et al, 2002).

REGULATORY COMPLIANCE OF MOBILE PHONE BASE STATIONS IN AUSTRALIA

**TANYA STOIANOFF BAgrEc MPS
EXECUTIVE DIRECTOR, MOBILE CARRIERS FORUM
L6, 46 MARKET STREET, SYDNEY 2000**

Abstract

Mobile phone base stations in Australia are governed by a mix of regulatory and self-regulatory instruments ranging from how base stations are built, through to cumulative EME compliance on existing shared sites.

This paper explores various levels of regulatory compliance required of Australia's mobile phone carriers when it comes to siting, designing and operating mobile phone infrastructure.

The regulatory and self-regulatory mix aims to address both the science underlying human exposure safety and the public perception of health risks from mobile phone infrastructure - so there is a mix of both the ICNIRP standard for human exposure as well as the adoption of precautionary behaviours when carriers build base stations in Australia.

The ACIF Code for the Deployment of Mobile Phone Networks is the key instrument which has adopted precautionary behaviours requiring carriers to:

- Have written procedures for site selection;
- Improve notification and community consultation procedures;
- Design and operate base stations with the objective of minimizing electromagnetic emissions; and
- Provide electromagnetic radiation emission reports, or Environmental Reports for every site, as per the Federal Department of Health's requirements.

Australia's Mobile Carriers Forum (MCF) has played an important role in this regulatory/self-regulatory mix. It is an industry forum comprised of the four mobile phone carriers building networks in Australia, and was formed in 2000 to address a number of issues in the area of wireless infrastructure network operations and mobile base station deployment. Of particular relevance was responding to issues of community concern and improving inter-carrier cooperation.

The MCF has either contributed to the creation of the various regulatory and self-regulatory instruments discussed in this paper, or has developed operational programs and systems for the carriers to use in practice to ensure regulatory compliance. While it does not claim to be a complete analysis, this paper explores the main instruments and initiatives.

Introduction to the Australian Scene

Mobile phones have become an integral part of day to day life for individuals, businesses and the community at large. According to Credit Suisse First Boston 2005, the Australian mobile telecommunications industry today has approximately 19 million subscribers with various mobile technologies being used by about 95% of the Australian population. Although it may seem surprising, a penetration rate exceeding 100% has been achieved in a number of countries and research suggests that it will be achieved in Australia by the end of 2008.

The Allen Consulting Group states in its publication *Australian Mobile Telecommunications Industry – Economic Significance (2005)* that the mobile telecommunications industry is a high revenue, high cost industry that makes a substantial and growing contribution to the wider telecommunications industry and the Australian economy. Industry gross product for the financial year 2004/05 was \$6.1 billion, up

from \$5.3 billion in the previous year. Since 1997, capital expenditure by the industry on new networks has exceeded \$10 billion. Revenue from the mobiles sector of the telecommunications industry was \$9.9 billion in 2004/05 according to Credit Suisse First Boston 2005. Australia's mobile phone networks reach over 98 percent of the population and cover just over 20 percent of the Australian land mass.

Data such as industry gross product, mobiles revenue and capital expenditure figures are important in demonstrating the economic contribution of Australia's mobile phone industry, however those measures do not convey the many ways in which mobile telephony contributes to improvements in the quality of people's lives and increases in social equity.

For many people, mobile telecommunications is more than a tool to make voice calls; instead, the extensive coverage, array of services and information available mean that the mobile phone can "make life mobile". The accessibility and freedom for people on the move to maintain contact with other people is a significant benefit. From an emergency perspective, a third of all calls to emergency services in Australia are made from mobile phones. Furthermore, emerging technology such as 3G and video phones will help to increase social equity by expanding access to groups such as the hearing impaired. Mobile telephony is increasingly more affordable in Australia particularly through low-cost and capped plans, allowing more people to benefit from the connectivity of mobile telecommunications services.

The MCF found in its publication *Third Generation Mobile Networks in Australia, Broadband For Your Mobile Phone (2005)*, that 3G applications in the Australian business sector are also growing, ranging from video-calling to location based mobile data services and telecommuting for employees.

Regulatory Environment

In Australia, telecommunications facilities are primarily regulated under Commonwealth law. This is largely due to Section 51(V) of the Australian Constitution which reads:

"The Parliament shall, subject to this Constitution, have power to make laws for the peace, order and good government of the Commonwealth with respect to:...(V) postal, telephonic and other like services:..."

In 1991 the Commonwealth Parliament enacted the *Telecommunications Act 1991*. The *Telecommunications Act 1991* and subsequent Carrier licences obligated Carriers to provide mobile telecommunications services to a large percentage of the Australian population. To assist Carriers meet these obligations the *Telecommunications Act 1991* also provided broad ranging powers to Carriers to install all types of mobile telecommunications facilities by granting exemptions from State and Territory environmental planning laws. These exemptions allowed Carriers to build quite substantial structures such as, for example, 30-metre towers without regard to State and Territory planning law.

However in 1997 the telecommunications regulatory environment was reshaped with the introduction of the *Telecommunications Act 1997*. This Act significantly curtailed the carriers' powers to install telecommunications facilities by limiting those exemptions from State and Local planning laws. Carriers must now comply with State and Territory planning and environmental assessment laws in relation to the installation of certain types of telecommunications facilities.

The Australian Government recognised however, that there are some telecommunications facilities and activities that are "unlikely to cause significant community disruption or significant environmental disturbance". These are exempt from certain State and Territory laws. These new telecommunications facilities and activities are described in the *Telecommunications Act 1997 (as amended)*, (referred to as "the Act") and in a Ministerial determination made under the Act – the *Telecommunications (Low-impact Facilities) Determination 1997* (referred to as the "Low-impact Determination") as amended.

The Act and the Low-impact Determination define what low-impact installation activities may be undertaken in certain areas without reference to particular State and Territory laws. Low-impact facilities are those which are considered essential to maintaining telecommunications that cause minimal detrimental visual impacts. Common examples of low-impact facilities are smaller scale structures such as panel antennas on light poles, building facades and rooftop installations. The

Determination sets out performance criteria for certain types of facilities based on the proposed location (an area classification criteria) of the facility and the dimensions of the proposed facility (a dimension criteria).

Facilities that do not meet the performance criteria outlined in the Determination cannot be defined as low-impact facilities. Those activities which are not exempt require consent from the local council as they are subject to State planning laws which vary in each of the States of Australia. For the purposes of brevity, this paper will not outline each State's planning regime.

Mix of Regulation and Self-Regulation

The Australian Communications and Media Authority, the ACMA, (formerly known as the Australian Communications Authority) is the regulator of the Australian communications industry. Since 1997 it has regulated telecommunications consumer and technical matters, and manages radio-communications. Specifically, the ACMA is responsible for the issuing of carrier licenses, the regulation of service providers, the registration and enforcement of industry (including consumer, operations and technical) codes of practice and the setting of industry standards, to name a few of its responsibilities.

The issue of electro-magnetic radiation (EMR) is an important issue for consideration in the deployment of telecommunications infrastructure. Some members of the public perceive that exposure to this type of radiation from mobile telephony could be harmful to human health. For the purposes of this paper it is necessary to outline that in Australia, exposure to EMR is regulated by the ACMA. The applicable standard is the "Radiation Protection Standard – Maximum Exposure Levels to Radiofrequency Fields – 3kHz to 300 GHz. The standard prescribes "fundamental limits designed to ensure that known health effects do not arise from exposure to radio frequency fields".

The Australian Radiation Protection and Nuclear Safety Agency (ARPANSA) is an Australian Government agency under the Department of Health, charged with responsibility for protecting the health and safety of people, and the environment, from the harmful effects of ionizing and non-ionizing radiation. ARPANSA builds and maintains expertise in the measurement of radiation and assessment of health impacts, it advises Government and provides information to the public, on issues related to radiation protection and nuclear safety, and it leads in the development of standards, codes of practice, guidelines and other relevant material to support radiation protection and nuclear safety throughout Australia. For example, the ACMA changed its Radio-communications (Electromagnetic Radiation) Human Exposure Standard 2001 to incorporate the limits of the new radiation protection standard recommended by ARPANSA – harmonising Australia with the ICNIRP guidelines a few years ago.

The considered scientific opinion from ARPANSA about possible health effects from this type of infrastructure is that "the weight of national and international scientific opinion is that there is no substantiated evidence that RF emissions associated with living near a mobile phone base station of telecommunications tower poses a health risk". The Australian Government and its regulatory bodies commonly refer to the World Health Organisation's position on this issue. Comprehensive reviews of over 2200 research publications, including more than 410 studies specifically on mobile phones and base stations, by governments and health authorities continue, without exception, to find there is no substantiated scientific evidence of health effects.

The World Health Organisation (WHO) in May 2006 updated their fact sheet entitled "Electromagnetic Fields and Public Health – Base Stations and Wireless Technologies", saying:

"Considering the very low exposure levels and research results collected to date, there is no convincing scientific evidence that the weak RF signals from base stations and wireless networks cause adverse health effects"

Only recently the WHO said that despite the feeling of some people that more research needs to be done, scientific knowledge in this area is now more extensive than for most chemicals.

The Australian Communications Industry Forum (ACIF) is an industry owned, resourced and operated company established by the telecommunications industry in 1997 to help implement and manage

communication self-regulation within Australia. ACIF develops Standards and Codes to support competition and protect consumers, and administer technical and operating arrangements.

ACIF developed an *Industry Code for the Deployment of Radio-communications Infrastructure* (referred to as “the Code”) which was registered by the ACMA in 2002. The Code applies the precautionary approach to the siting, design and operation of mobile phone base station infrastructure in Australia. It requires carriers to:

- Have written procedures for site selection;
- Improve notification and community consultation procedures for low-impact sites;
- Design and operate base stations with the objective of minimizing electromagnetic emissions; and
- Provide electromagnetic radiation emission reports upon request, as per the Federal Department of Health’s ARPANSA requirements.

The Code was developed in response to calls for greater council and community involvement and more information when mobile phone base stations are installed. It was developed and agreed to by carriers, local government, unions, community groups and the ACMA.

It is important to note that the Code was developed to increase the transparency and accountability of carriers and increase consultation with the community when low-impact mobile phone base stations are built. The Australian community now has rights of access to information about any proposed base station in their area.

Self-Regulatory Aspects to Code Implementation – Industry Activity

As the industry approached the introduction of the above mentioned Code, the MCF recognised that the industry needed to be well prepared for the significant changes the Code would make to Australia’s traditional deployment processes. The Code introduced new notification and consultation requirements for low-impact sites that were not required previously by law. It requires carriers to provide certain EME information about all sites across the country and it requires carriers to demonstrate that they had investigated possible co-location opportunities in the first instance.

In order for the Code to succeed, the carriers needed an implementation program of proforma documentation and flowcharts which guided carrier staff to ensure industry compliance with the Code. The MCF created such documentation with the input and ownership of each carrier on the Code drafting committee. The implementation process was then transferred into an interactive web based system which each carrier utilises. The program has provided some industry consistency in what could have become a myriad of interpretations which may have resulted in poorer compliance and would have made it even more difficult for the regulator, the ACMA, to monitor. The ACMA records all legitimate complaints made to it about a carrier’s compliance or lack of compliance with the Code and assesses whether in fact the Code has been breached. Fines of up to \$250,000 per breach may be charged by the regulator.

Other countries have introduced similar industry policies to the Code, but none have been supported by industry-consistent implementation documentation and processes which provide a paper trail demonstrating industry compliance with such a regime.

As part of the implementation program it was important to engage with the key stakeholders in the Code. The MCF organised a series of National Workshops in partnership with each State Local Government Association (LGA), the ACA and ARPANSA, to improve council awareness of the new Code. The MCF also produced an Information Kit for councils, distributed via LGA channels.

One particular Council in Sydney even made a specific report to its full council on the MCF’s Code Information Kit and Workshop and stated that “the Code appears to be a genuine attempt by the Carriers to gain some community and Council trust”. This feedback was an important message confirming to the industry that its efforts had not gone unnoticed.

In addition to this work, the MCF embarked upon a project with State Local Government Associations in Australia, which resulted in the creation of *Guidelines for Local Government on the ACIF Code* in

2006. The Guidelines were created with extensive consultation with local councils and they provide a useful toolkit for local council staff to monitor carrier compliance with the Code, despite the fact that low-impact sites do not require local council consent.

Demonstrably, the MCF's promotional and operational activities have been world leading in that the adoption of the code was strengthened with the development of an implementation program for demonstrating industry compliance and process, as well as providing local government with enhanced awareness of required carrier processes. This has reinforced Australia's self-regulatory regime for telecommunications.

Coordinated Strategy for On-site Regulatory Compliance

The MCF has facilitated the creation of a regulatory compliance strategy for carriers to assist them in managing their cumulative EME exposure obligations at both carrier and non-carrier owned sites. This strategy involves inter-carrier data exchange as well as liaison with third party property owners and radio licensees.

The strategy, which is now known as the MCF EME Regulatory Compliance Strategy (MERCS) was first tested via a national trial of fifty rooftop sites each containing two or more carrier facilities. A process for inter-carrier information exchange, cumulative radio hazard assessment by accredited specialists and communicating compliance to the property owner through a standard form Radio-communications Site Management Book (RCSMB) was developed and tested. This strategy is now being used by the industry across the country.

The MCF Rooftop Trial, as it was known, was also transferred into an electronic repository or database of carrier sites by one of the MCF's members, Telstra. It is now being populated by all carriers. This database, known as the National Site Archive (NSA), facilitates an electronic information exchange amongst carriers. Each carrier site, as it is built, is uploaded onto the NSA and the public are provided access to each site's environmental EME report (ARPANSA report) and compliance certificate as part of the industry's objective of transparency and accountability.

During the Trial, a National Antenna Database (NAD) was developed as the centralised database of mobile carrier antenna data. The NAD is an essential system to ensure that consistent and standard antenna data is available to carriers for EME software applications. The NAD is also critical to further automation of the NSA e.g. producing automatic environmental reports from STAD tables.

The MCF Rooftop Trial created a system for ensuring cumulative assessment of EME at shared sites given the regulatory requirements placed on the carriers by the ACMA and ARPANSA which included occupational health and safety (OH&S) obligations for workers who would access such rooftop sites. It is not an overstatement to say that the MCF Rooftop Trial revolutionized how carriers ensured compliance with cumulative exposure standards and OH&S laws on non-carrier owned sites.

The resulting NSA is also linked to an electronic system for managing the afore mentioned ACIF Code. Australia's largest (majority Government owned) carrier, Telstra assisted the industry by taking the MCF's Code implementation documentation and transferring it into an electronic system for compliance, linked to the NSA. Carriers in Australia can now upload site data onto the NSA, record the required compliance documentation, upload the required site management book, and document the completion of their ACIF Code requirements through a linked MCF web based electronic system.

The efficiencies and benefits to the industry from these initiatives are significant. The MCF's ability to facilitate such a consistent industry owned and used system is laudable and is testimony to the growing maturity of the MCF's members - the Australian mobile telecommunications carriers.

Visual Impact of Mobile Phone Base Stations

As was outlined by Stoianoff (2004), when communities convey concerns over base station deployment, it usually arises in three areas, not in any particular order – firstly, EMR emissions and health, secondly, visual amenity concerns about infrastructure and thirdly, a perceived lack of community empowerment when base stations are being built.

In Australia, the third concern has somewhat been addressed via the previously described ACIF Code, however, this instrument, nor any other similar instrument, can ever fully satisfy every community member's desire to control development in their area.

The first concern in relation to emissions and health is a world-wide phenomenon and can only be managed with the assistance of ongoing replicated research and the communication of information and education to the community from independent expert bodies such as the World Health Organization and local authorities such as ARPANSA in Australia.

The second concern, visual amenity is a somewhat different issue in that it is influenced by a number of factors such as cost, technical RF requirements, topography and vegetation and land owner requirements. Given the varying range of issues, the most aesthetic design is not always an available option when building base stations, however, industry needed to make an effort wherever possible.

Early on in the MCF's formation, a set of Guidelines were created incorporating urban design principles with the requirements of the infrastructure regulatory regime in Australia. The *Guidelines for Better Visual Outcomes – Low-impact Mobile Facilities* book was published by the MCF in 2001. It was well received by planners, government and local councils. Some local councils even sought permission to extract sections of the Guidelines to insert into local government policies and planning schemes. A second edition of the Guidelines was produced in 2004 to include the ACIF Code in the chapter which outlines Australia's telecommunications regulatory regime.

More recently, with the imprimatur of the Australian Government, the MCF has convened a *Design and Innovation Taskforce* inviting key stakeholders to participate including the property sector, structural designers and engineers, local government, town planners and telecommunications industry representatives. This group of stakeholders was identified as those who are best placed to make either a technical contribution to the Taskforce or those who have a direct involvement in the siting and design component of mobile phone base station deployment.

The Taskforce's key objectives are to:

- help investigate the national and international scene for improving the visual amenity of infrastructure – what designs are in use globally,
- gain a better understanding of the real life impediments to the adoption of “aesthetic design options” in Australia; and
- identify practical methods or opportunities to improve the visual amenity of facilities in Australia - providing recommendations within the context of the Australian marketplace.

The MCF Taskforce intends to generate a technical paper drafted by a specialist planner which should focus on the above key objectives. The Technical paper will also focus on typical types of telecommunications sites including: building rooftops, base stations in parks and recreational space, and on telegraph/electricity poles and other utility structures.

Summary

This paper has outlined the main regulatory instruments which govern mobile phone base station deployment in Australia. It is clear to see that a balanced mix of regulatory and self-regulatory mechanisms are at play ranging from legislation and Codes of Practice through to industry initiatives geared towards ensuring compliance with regulatory expectations from Government and the community's perspective.

This paper has also outlined a summary of MCF initiatives from devising regulatory compliance programs to creating publications which assist in industry performance and stakeholder appreciation of the limitations in network deployment options. Each of the MCF's initiatives may assist other country's organisations in addressing similar issues of concern.

While the telecommunications industry is governed by a largely self regulatory regime, the industry must take a proactive and responsible approach to deployment in order to honour such a regime.

Abstract

For the past two decades, researchers have actively been studying the effects of time-varying magnetic fields (MF) on humans, principally examining the potential for the field to have acute effects on human physiology, neurophysiology and behaviour. The more consistent results reported in recent literature seem to show an increase in occipital alpha rhythm of resting electroencephalographic activity (EEG) with exposure (Cook et al., 2004; Ghione et al. 2005). Interestingly, other studies have demonstrated that human motor behavior can be modulated by exposure to an Extremely Low Frequency (ELF) MF, showing a reduction in anteroposterior standing balance oscillations (Thomas et al., 2001) and a decrease in physiological tremor intensity (Legros et al, 2006). However, to establish a connection between these observations would require a project that, in one procedure, investigates physiological, neurophysiological and behavioural parameters. Therefore, subject testing has begun, in a project approved by the University of Western Ontario (Health Sciences Research Ethics Board # 11956E), to investigate the effects of a 60 Hz, 1800 μ T MF on heart rate (frequency and variability), peripheral blood perfusion, brain electrical activity (EEG), postural oscillations, voluntary motor functions, and physiological tremor. Preliminary results will be presented and should provide reliable information concerning human exposure to power-line frequency MF.

Introduction

Domestic electrical appliances, distribution and transport power-lines, and residential wiring are some of the numerous sources of magnetic field (MF) in our everyday environment. Over the past several years, studies have been conducted with the aim of characterizing the effects of Extremely Low Frequency (ELF, below 300Hz) MF on human health and performance. Despite the amount of work that has been done in this area, there remains no consensus as to the effects of ELF MF on humans.

From brain electrical activity to motor behaviour, a number of aspects of human physiology and behaviour have been examined in scientific literature in response to acute exposure to ELF MF. Among the potential effects, many studies detected neuropsychological changes induced by the exposure (Keetley *et al.* 2001; Preece *et al.* 1998). That these studies are still relatively rare, and often have conflicting findings prevents the confident characterization of the field's effects. Further, exposure protocol and neuropsychological evaluating tools differ between studies, and reported effects are tenuous or even absent. Nevertheless, the examination of these studies shows that any notable cognitive effects generally appear to affect high level cognitive processes such as attention mechanisms, learning and memory; and executive functions such as working memory, flexibility, categorization, deduction and problem solving (see Kazantzis *et al.* 1998; Podd *et al.* 2002; Preece *et al.* 1998; Stollery 1986). Moreover, authors have found that the changes influence the quality and the precision of high level cognitive mechanisms rather than the velocity of execution.

If such neuropsychological functions are effectively modulated by the exposure to ELF MF, effects should be detectable at a neurophysiological level. Several studies have shown effects of MF exposure on human electroencephalogram (EEG) or evoked potentials (Bell *et al.* 1992; Bell *et al.* 1994a; Bell *et al.* 1994b; Cook *et al.* 2005; Cook *et al.* 2004; Ghione *et al.* 2005; Heusser *et al.* 1997; Lyskov *et al.* 1993a; Lyskov *et al.* 1993b; Marino *et al.* 2004). Still, no consensus exists on the direction of these effects, though the most conspicuous results seem to suggest a higher resting EEG in the alpha rhythm after exposure (8-13 Hz, see for example Cook *et al.* 2004; Ghione *et al.* 2005).

Other studies analyzing the interaction between heart rate (HR) behavior and MF have shown that electrophysiological rhythms can also be modified at the peripheral level and that the exposure to 60 Hz MF could induce a slowing of the HR that may or may not be associated with changes in HR variability (Cook *et al.* 1992; Graham *et al.* 2000a; Maresch *et al.* 1988; Sastre *et al.* 1998; Sastre *et al.* 2000). Again, other works did not detect any exposure effect on HR (Graham *et al.* 2000b; Graham *et al.* 2000c; Kurokawa *et al.* 2003). For a better understanding of the mechanisms underlying observed changes in HR, electrophysiological data should be completed by the monitoring of hemodynamic parameters such as blood flow.

Another way to investigate the effects of MF on the human body in its entirety is to evaluate human motricity. A few studies have demonstrated an effect on human motor control resulting from exposure to time-varying MF. Thomas *et al.* 2001a, for example, explored human postural oscillations and reported significant decrease in anteroposterior balance using a pulsed MF at 200 μ T. Legros *et al.* explored human physiological tremor (Legros and Beuter 2005; Legros and Beuter 2006; Legros *et al.* 2006). They did not report any significant effect of a 50 Hz, 1000 μ T MF on physiological tremor occurring during a goal directed task. However, the analysis of tremor occurring during a postural task of the index finger suggested a relaxing effect induced by the exposure, decreasing tremor size. Interestingly, Cook *et al.* who, in 2004, showed an effect of a pulsed 200 μ T MF on EEG alpha activity, also underlined the link between resting posterior alpha activity and the state of relaxed wakefulness (Niedermeyer 1999).

Reported results are subtle and often not replicated. These discrepancies defining the effect of an ELF MF on humans can be attributed to the heterogeneity in intensity, shape and frequency of the MF used, as well as the differences in exposure duration. Furthermore, results differ with continuous versus intermittent exposure, and depending on whether the testing of the subjects is performed during or after the exposure.

Objective

The main objective of this study is to evaluate subtle effects of a 60 Hz MF exposure up to 1800 μ T on human physiology, neurophysiology and motor functions in a single procedure. This intensity has been chosen because the International Commission on Non-Ionizing Radiation Protection (ICNIRP) guidelines establishes that current density induced by MF occupational exposure "should be limited to fields that induce current densities less than 10mA/m²" (ICNIRP 1998), and this corresponds to computed MF value which can reach 1800 μ T (Stuchly and Dawson 2002, http://www.emfs.info/sci_Numerical.asp). This global approach will then establish a better understanding of the effects of high intensity MF on these functions. Conclusions will be drawn from the examination of human blood perfusion, HR (frequency and variability), brain electrical activity (EEG), posturo-kinetic activity as postural sway, voluntary motor functions as rapidly alternating movements and involuntary movements through the measurement of postural tremor.

HUMAN ACUTE EXPOSURE TO A 60 HZ, 1800 μ T MAGNETIC FIELD

Based on results in the literature, we hypothesize that MF exposure will (1) not affect ECG or blood flow, (2) increase EEG power in alpha band activity, especially in the posterior regions of the brain, (3) decrease the quantity and the variability of anteroposterior displacements of postural sway, (4) increase the rapid voluntary movements' maximum frequency, and (5) decrease postural tremor amplitude. Effects should appear after several minutes of exposure. The results could be useful in the development of public policy regarding the safety of MF exposure.

Methods

This is a currently ongoing study. To date, 8 subjects have completed at least 1 of the 2 sessions of testing. All participants give their informed consent before participating (University of Western Ontario Health Sciences Research Ethics Board # 11956E). At term, 70 healthy adults between 18 and 55 years of age will have completed the full protocol consisting of 2 counterbalanced exposure sessions given on 2 separate days (with at least 2 days in between): 1 active exposure condition (real) and 1 control exposure condition (sham) as detailed in Figure 1a. None of the participants have ever experienced an epileptic seizure; have motor limitation; suffer from chronic illness (e.g., diabetes, severe psychiatric, cardiovascular or neurological diseases); or have a cardiac or cerebral pacemaker. They have no history of head, eye or thorax injury involving metal fragments; they do not wear metal braces on their teeth. Finally, women cannot be pregnant, nor have an intrauterine device. A double blind computer driven procedure controlling for variables is used such that neither the participant nor the experimenter know when the real or sham condition occurs. Each session lasts 1 hour and 45 minutes and is composed of four 15 minute blocks of testing with 15 minutes rest in between. 1 hour of MF exposure is given from minute 15 to minute 75 of the real exposure session. There is no MF exposure in the sham session.

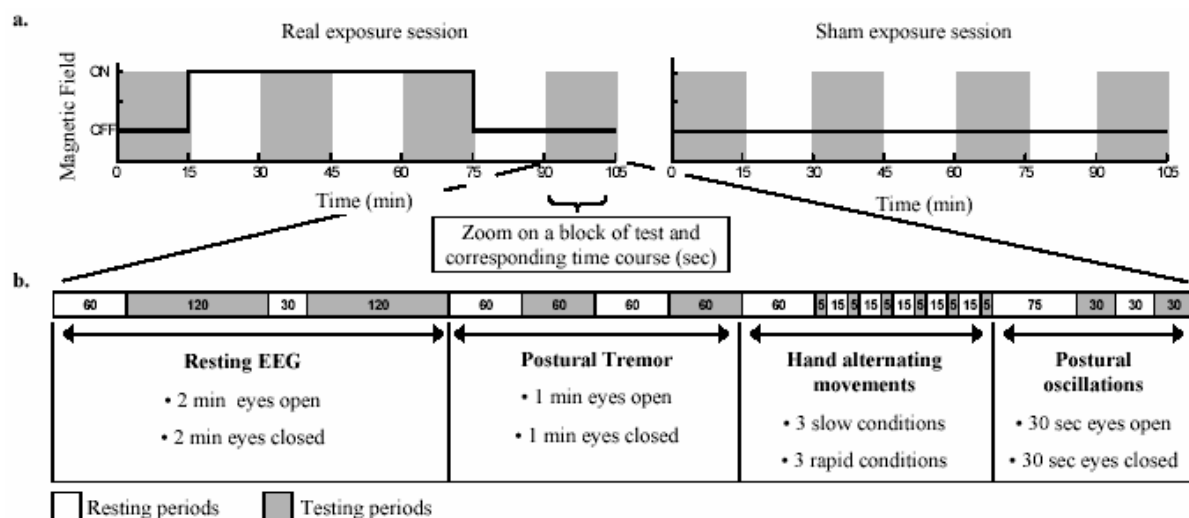

Figure 1: a. Time course of the 2 exposure sessions (real and sham). The horizontal black line represents the MF status (OFF when down, ON when up). Note that during the sham exposure session, the MF is never ON. Vertical grey bands represent the four 15-minute blocks of testing. **b.** Zoom on the time course of a block of testing (the same for each block). White cells represent resting periods and grey cells represent testing periods (duration is displayed in seconds inside the cells). The table below indicates the tests to which these periods correspond.

Each subject is equipped with the recording devices and his handedness is determined with the Oldfield questionnaire (Oldfield 1971). For the experiment, he is seated in an armchair in the exposure facility. The exposure system generating the MF has been designed for this experiment. It is composed of 2 octagonal coils, 1.6 meters in diameter, running parallel to each other 1.2 meters apart. Each coil contains 80 turns of AWG-10 wire mounted with a nonconductive cooling/heating tubing system. The system is configured to generate a homogenous 60 Hz field, up to 1800 μ T, centred at the level of the head.

Prior to testing, the subject receives written directions, and is shown an audio-video demonstration of each task through a LCD screen and speakers, both positioned 1 meter in front of him. The room temperature is maintained at 23 °C. From the beginning of the testing session, both the subject and experimenter wear ear plugs to make it impossible to detect the subtle noise produced by the coils when the field is generated. The time course of the testing, as well as the MF generation and data acquisition, are entirely automated and computer driven (Labview 8.0 and Data acquisition card NI PCI-6289, National Instrument Inc., USA); except for recording of EEG, ECG and blood flow data. Automatic audio directions are given to the subject throughout the

duration of the experiment. He obtains visual information about the timing of the experiment through the screen in front of him.

Each of the 4 blocks of testing in each session follows the same time course (Figure 1b). The subject first relaxes for 1 min. Then his resting eyes-open-EEG is recorded for 2 min. After 30 sec of inactivity, his resting eyes-close-EEG is recorded for another 2 min. Baseline local blood perfusion (recorded at the tip of the non dominant index finger, PF 5010 Laser Doppler Perfusion Monitoring unit and probe 407-1, Perimed, Sweden) and ECG are recorded simultaneously. EEG and ECG are recorded at 512 Hz with a 32 channels ambulatory unit (Siesta unit, Compumedics Inc., USA). During the real exposure session, the MF is switched OFF during the second minute of both EEG recordings (eyes open and eyes closed) to keep 1 minute free of MF artefact in the data.

The subject is then asked to open his eyes, and after a resting period of 1 minute, his eyes-open postural tremor is recorded at the extremity of his dominant index finger for 1 minute. A Class II laser diode pointing toward the ground (Micro laser sensor LM10, series ARN11, Matsushita Electronic Work, Ltd., Osaka, Japan) and located 8 cm above the piece of white cardboard fixed on nail of the index finger enables 1000 Hz vertical displacement recording. A target horizontal line gives feedback about the index finger's vertical position, and is also displayed on the LCD screen. In this test, the subject must point the index finger (in extension at the level of the metacarpophalangeal joint) to keep the target line centred in the middle of the screen for 1 minute at the "zero position". After another 1 minute rest, he performs the same test with his eyes closed and therefore, with no visual feedback.

After another 1 min period, the subject is asked to extend his arms in front of him, parallel to the floor, and then to bend them to a 90 degree angle at the elbow, with hands open, palms facing each other. From this starting position, he has to execute alternating hand movements that involve rotating the hands at the wrist axis: (1) with the right hand at a natural rhythm; (2) with the left hand, natural rhythm; (3) with both hands, natural rhythm; (4) with the right hand at a higher frequency; (5) with the left hand, higher frequency; and (6) both hands, higher frequency. For the higher frequency condition, the subject is asked to rotate his hands "as fast and as far as possible". Recordings last 5 sec each, with a 15 sec rest between any two. Recordings are done with the liberty system (Polhemus inc., USA), with 2 transducers fixed like watches on the dorsal side of the wrists, allowing recording of movement kinematics with 6 degrees of freedom at 200 Hz in the used configuration (3D and 3 angles of rotation, accuracy of 0.03 RMS for X, Y, Z position and 0.15° RMS for orientation). The Liberty system is an electromagnetic tracking system and therefore, during MF exposure session, the field has to be turned OFF during each 5 sec recording periods so as not to affect data.

Finally, the subject has 75 sec to step onto a force plate (standardized socks, feet parallel, 1 cm apart) and to relax before his postural sway is recorded during 30 sec eyes open, and 30 sec eyes closed, with a 30 sec period in between. The 3-D force plate used in previous works (Thomas *et al.* 2001a; Thomas *et al.* 2001b, OR6-7-1000, AMTI, Watertown MA) is mounted on the floor in the centre of the MF exposure system, and measures the force and momentum applied by the subject's feet at a sampling rate of 1000 Hz. These measurements can be converted to centre of pressure (COP) values, i.e. the perpendicular projection of the centre of gravity through the force plate. Postural sway is then the change the COP over time.

As detailed in the Figure 1b, this block of testing is given 4 times over a session. During a real exposure session, this would mean that the testing begins: 15 minutes before the beginning of the exposure period, 15 minutes after the beginning of the MF exposure, 45 minutes after the beginning of the MF exposure, and 15 minutes after the end of the MF exposure. Skin temperature is monitored throughout the experiment. After each block, the subject has to answer the Field Status Questionnaire (FSQ, Cook *et al.* 1992) to assess his ability to detect the presence of the field.

Data processing and Analysis

As an ongoing study, data are still being collected and analysed. Therefore, given the advancement of the study and in a concern of clarity of the purpose, it has been chosen to focus here on a limited set of data, including EEG in the occipital region of the brain (O1, O2), postural tremor data, and postural sway data.

First, the ambulatory EEG data are recorded on a flash memory card, and then an averaged reference montage is used to import data in Matlab for processing (The MathWorks Inc., Natick, USA). Fast Fourier Transform (FFT) and inverse Fast Fourier Transform (iFFT) are used to extract time series in the theta (4-7 Hz), alpha (8-13 Hz), and beta (14-35 Hz) frequency bands. The average amplitude in each band is then computed for each electrode (O1, O2 here, see example in Figure 2).

Secondly, the laser system records vertical displacement with a resolution of 13 μm (i.e. 2σ , where σ is the standard deviation of a recording on a stationary target) which is effectively reduced to 5 μm after filtering out high frequencies (above 25 Hz, FFT, iFFT). Data are transferred to Matlab for A/D conversion to mm given a calibration constant (-3.97). Position and velocity data (obtained by differentiation of the raw displacement data) are used for indexes computation in time and frequency domains (Beuter and Edwards 1999; Edwards and

Beuter 2000) allowing the characterization and the examination of temporal, frequential and morphological components of the signals (see also Legros and Beuter 2005; Legros and Beuter 2006). Here, amplitude, drift, median frequency and frequency concentration are computed (see Appendix 1 for index definitions and Figure 3 for an example).

Figure 2: From the top to the bottom: 10 sec of O1 EEG trace and corresponding theta, alpha, beta and gamma components respectively extracted using FFT and iFFT. Averaged amplitude for this sample are: Theta = 3.909 μ V, alpha = 2.485 μ V, beta = 1.757 μ V; gamma = 0.641 μ V.

Figure 3: Position data (top), velocity data (middle) and corresponding power spectrum (bottom) for 10 sec of recording during MF exposure with eyes open (block 3). The computed values on this sample are: Amplitude = 0.032 mm; drift = 0.106 mm, median frequency = 7.04 Hz; and frequency concentration = 6.31 Hz.

Third, postural sway data are exported under Matlab and converted from volts to COP trajectories (in meters) using a calibration matrix. Through the inclusion of two dimensional trajectories (X vs. Y), the following validated characteristics have been computed (Despres *et al.* 2000; Thomas *et al.* 2001a): Mean sway, sway, velocity and sway area (see Appendix 1 for index definition and Figure 4 for an example).

Figure 4: 30 sec of postural sway recording during MF exposure (block 3) with the eyes are closed. The smallest polygon including the entire trajectory is also displayed. The computed characteristics on this sample are: Mean sway = 0.53 cm; sway velocity = 1.62 cm/sec, sway area = 3.41 cm^2 .

Preliminary results

For 3 of the 8 subjects who have completed at least 1 of the 2 sessions of testing, the first session was a real exposure condition. Therefore 3 subjects who have completed the sham session first have been chosen to afford a control group (i.e. the sham condition), which allowed providing a preliminary assessment of the exposure effects on their behaviour. According to the small sample size available at this step, a simplified statistical procedure has been chosen, focusing on the data acquired in the block 1 (before exposure) and the block 3 (during exposure, and after a 45 min period of continuous exposure, see Figure 1). A within-subject ANOVA including a between-subject factor (sham vs. real) have been conducted on each of the above

mentioned indexes: ANOVA 2 (eyes open vs. eyes closed) x 2 (block1 vs. block3) x 2 (sham vs. real). The level of significance has been set at $p < .05$ and no adjustment for multiple comparisons has been applied.

No Block main significant effect has been found either for EEG, postural tremor or postural sway recordings. However, with eyes closed, subjects had significantly higher EEG alpha activity in the occipital region (O1: $F = 24.85$, $p < .01$, $\eta^2 = .86$; O2: $F = 20.54$, $p < .05$, $\eta^2 = .83$), larger and faster postural oscillations (mean sway: $F = 17.38$, $p < .05$, $\eta^2 = .81$; sway velocity: $F = 51.47$, $p < .005$, $\eta^2 = .92$; sway area: $F = 35.14$, $p < .005$, $\eta^2 = .89$), and higher index finger drift ($F = 12.19$, $p < .05$, $\eta^2 = .75$) with eyes closed than with eyes open. No interaction effect was found.

Discussion-Conclusion

Preliminary results confirm that this experimental protocol is adapted to detect subtle changes in the neurophysiological characteristics investigated, despite the small number of subjects tested at this point. Indeed, as expected we observed significant differences between open and closed eyes conditions in EEG, tremor and postural sway. However due to the small number of subjects tested we did not detect a significant effect due to the presence of MF. This is why we performed a sample size analysis.

The sample size calculation for 2 independent samples with common variance was done on the sway velocity characteristic because this is the lowest p value for the interaction block x sham/real ($F = .509$, $p = .51$, $\eta^2 = .113$). In the present configuration, the decrease of .072 cm/sec observed for the real exposure group would be significant with two groups of 34 subjects (p fixed at .05, power = .80). We have planned to test a sample of $n = 70$ subjects which should be sufficient to detect the MF effects on the characteristics examined. We have to keep in mind that, at this stage of the study, 2 groups of subjects were evaluated. However in the final study all participants will have been tested under both MF conditions with a counterbalanced protocol. This should contribute to make the protocol more sensitive to subtle effects (reducing the impact of the between-subjects variability).

The results presented in this paper are only partial results on selected tests recorded. They will be completed by heart rate frequency and variability, blood flow perfusion, alternating movement performance. Finally data acquisition will be completed in 2007.

Appendix 1

Postural tremor characteristics:

Amplitude: Root Mean Square (RMS) of position time series centered on their mean (highpass and lowpass filtered, between 2 and 25 Hz).

Drift: RMS of the low frequency component of the time series (below .01 Hz), quantifying slow movements of the finger.

Median frequency: Determines the value at which 50% of the power spectrum is below this frequency, and 50% is above. It is computed on the power spectrum between 2 and 25 Hz.

Frequency concentration: Quantifies the degree of organization of tremor by computing the width of the interval containing 68% of the power of the spectrum between 2 and 25 Hz.

Postural sway characteristics:

Mean Sway: Average distance between the geometric center of all recorded forces and each point visited by the Center of Pressure (COP) during a test.

Sway Velocity: Average velocity of the COP displacements.

Sway Area: Area of the smallest polygon including the entire trajectory of the COP.

ELECTROMAGNETIC FIELDS EFFECTS ON WITHDRAWAL SYNDROME SIGNS OF MORPHINE (WSSM)

2. Department of pharmacology, Qazvin University of Medical Sciences.
3. Department of Biostatistics, Qazvin University of Medical Sciences.

Abstract:

Background: Many studies have showed that electromagnetic field decreased WSSM.

Objectives: Effect of electromagnetic fields on WSSM investigated on rats.

Materials and methods: In this study 102 male rats with weight (225 ± 25) gr were classified in 17 groups ($n = 6$). They were addicted by morphine injection according to Pinelli Method. 16 groups of them exposed to electromagnetic fields with 25, 50, 75 and 100 Hz frequency and with magnetic field 0.5, 1.5, 2.5 and 3.5 G intensity. One group was chosen as control. WSSM jumping, climbing, rearing, diarrhea, weight loss, ptosis and yawning by naloxone injection in pretoon (5mg/kg) at all animals were investigated.

Findings: WSSM were obtained by counting the jumoling, wawing, alimbing, rearing and the ptosis, diarrhea were scrod from +1 to +4. Also weight losses were measured in all groups.

Results: This study showed that magnetic fields caused the significant decreased on waving, ptosis, weight loss and diarrhea at all of the exposure groups ($P < 0.001$). Rearing and climbing decrease significantly in groups that exposed to electromagnetic fields and this fields with 25 Hz frequency and 0.5 G intensity have minimum and with 100 and 75 Hz frequency 3.5 G intensity have maximum effects on WSSM.

Keywords: Electromagnetic field, Withdrawal syndrome signs, Morphine, Rat.

Introduction:

About the role of electricity for curing addiction, some studies have been performed as bellow that about the laboratorial addicted animal has been used so that two metal electrodes have been touched around the two sides of its body, so that it would be done under special condition, and this action must be done daily for several times. This action is called Transcutaneous Electrical Nerve Stimulation or TENS. And according to the Frequency and Voltage that is given two kinds of TENS can be done so that the low TENS and high TENS would have electrical changes in the epidictic system in this case this currency of addiction would be activated and then released. So if TENS be given to an addicted animal to morphine many of the signs in this field would be removed (1,2). In the recent years, the electromagnetic fields (EMF) in the medical sciences have many usages and they have indicated that the resulted energy from this field for curing the wound, reduction of all the kinds of pain can be effective, in a way that today the electromagnetic fields have found an important place as the alternative medicine and then they are mentioned like that.

Naturally the electromagnetic waves by high TENS would have some effects to the talent and focusing point and they would reduce the memory. Anyway in the animal tests it has been shown that the actions of electromagnetic fields in the addicted mice to morphine would cause the reduction of the signs of Syndrome especially for pain (3). The electromagnetic waves have some effects to the channels in the brain and also the environmental tissues would cause some changes in the physiological operation and the operation of these hormones, neurotransmitters, and some other medicine effects that strongly are related to the tissue of mind (4).

According to the last information of National Center for Complementary Alternative Medicine(NCCAM) National Institute of Health(NIH) the subsistent, electrical, magnetic, methods and electromagnetic fields and the electrical stimulations the nervous stimulation methods have been replaced(5). Some of the researchers about the role of electromagnetic in the addiction to morphine have provided some reports that would reduce the signs of dependency role,. They believe that the serotonin and triptophan surfaces and Hydroxide indol astic acid during the electromagnetism would be increased and following it some changes in some of the channels that are calcium in the brain (3). Some reports have been available that during electromagnetic therapy beta endorphins were increased. And this action will prevent the occurrence of syndrome in the body (3). It is possible that the increase of endorphin system and the increase of chemical materials in the brain be released (3). The last research of Magnet Therapy has caused the reduction of pain in the Post-Polio patients and this kind of therapy has little third effects (6). One of the usages of electromagnets is during the time of intensified pain. In the northern America the expenditures more than 10 to 15 thousands dollars for the reduction of pain for each person is used. 17 % of the population over 15 suffer from the pain that they get from the daily activities and in the United States of America about 93 millions dollars daily and more than 5 milliards dollars per year would be wasted for this purpose(7). Some evaluations would be done in the static and some channels that are similar to each other. Many researches about Pulsed Electromagnetic Filed have been done for reduction of pain and the provided results indicate the following effects:

1. Increase of pain field
2. Activation of anti-contagious system
3. Stimulation of producing aphetic points
4. Betterment of blood currency and the resulted effects of it including the increase of oxygen transferring and etc.
5. Improvement of blood thickness
6. Betterment of metabolism in the brain
7. Improvement of the movement of blood in body and brain

Pain is the important parameter that caused to become addicted patients. Some of researches showed that nerve systems affected by PEME curing (8).

Materials and methods

In this study 102 rat with 200-250g weight were divided in 17 group (n=6). That each group contains 6 muse. And these groups were Group one considers as the control group and the groups 2-17 as study groups that were expose to magnetic field as below detail.

Group2 (B= 0.5G, F = 100Hz), Group 3(B= 1.5G, F = 100Hz), group 4(B= 2.5G. F = 100Hz)

Group 5(B= 3.5G, F = 100Hz), Group 6 (B= 0.5G, F=75Hz), Group 7(B=1.5G.F= 75Hz)

Group 8(B=2.5G, F=75Hz), Group9 (B= 3.5G, F = 75Hz), Group 10 (B= 0.5G, F = 50Hz)

Group11 (B= 1.5G, F=50Hz), Group12 (B=2.5G, F = 50Hz), Group13 (B=3.5G, F = 50Hz)

Group14 (B= 0.5G, F = 25Hz), Group15 (B=1.5G, F=25Hz), Group16 (B=2.5G, F= 25Hz), Group 17 (B= 3.5G. F = 25Hz)

The animals were addicted according to Poinelli Method, and then animals of 16 groups as mention above condition were exposed to magnetic field for 30 minutes.

The syndrome signs of morphine stop were studied after Naloxone injection in pretoon. Jumping, Rearing, Climbing, yawning, diarrhea and ptosis, as syndrome signs were studied in this research after 2 hour naloxone injection. In this research we used the analyze variance, Dunnet and crouscal valis for data analyzing.

Findings

Seven signs for the stopping point of morphine in all the groups were considered. The most important sign was jumping, the number of Jumping in the groups 17, 16, 15, 12, 11 and 10 not only was not reduced but also ratio to other groups were more. In the groups 2, 6, 8, 13 and 14 the number of jumping was reduced but this reduction was not so much. In the groups 3, 4, 5, 7 and 9 the reduction of jumping was observed and it was so much in a way that in the groups 5 and 9 $P < 0.001$ was observed. In the groups 4th and 7th $P < 0.01$ and in the 3rd group $P < 0.05$ was seen. Except the group 14 and 15 which the reduction was so much. In the 9th group more than other groups the reduction could be seen and it was as $p < 0.001$. In all the groups the magnetic field except the group 4th has an important

Electromagnetic fields effects on withdrawal syndrome signs of morphine (WSSM)

reduction which was $P < 0.001$. In the groups 9 and 12 the reduction was more than other groups. In the group 10, 14 and 15 there was not so much reduction but in the other 13 groups the reduction was so much. In way that other 14 groups had the weight reduction by $p < 0.001$. The little weight for reduction in the second and fourth groups is shown in the diagram 2. Generally it can be stated that the lesser response was in the groups 5th and 9th which had the best operation and the response would be provided.

Discussion

Present study showed that magnetic field with various intensity and frequency have affected on syndrome signs of morphine stop in rat magnetic field decrease jumping in exposure groups (3.4, 5, 7, 9) and also decreases rearing in exposure groups (2-13, 16, 17) significantly ($P < 0.05$). This study showed the magnetic field with various condition cause to reduce syndrome signs of morphine stop in rat such as climbing, yawning, Ptosis, diarrhea and weight significantly ($P < 0.05$). The magnetic field affected on the number of jumping depend on intensity, frequency and time exposure.

Morphine is an alkaline material and ionizes in body. The ionized form of morphine can't pass the Blood Brain Barrier (B.B.B), the magnetic field caused to ionizing the acidic and alkaline drug (9) for this reason the magnetic field can reduce the syndrome signs of morphine stop. The result of this study showed that the magnetic field with high frequency and high intensity reduce the syndrome signs of morphine in rat. This reduction can explain by this reason.

- 1- Increase the polarity of Naloxone
- 2- Alteration of receptors instruction
- 3- Reduction of morphine in brain cells

This study showed that rearing and climbing reduced significant in exposed groups ($P < 0.05$). We think that these reduction is because of increase the induction and releasing the androgen peptides opiate and alteration of nerve mediator induction and releasing such as dopamine, glutamate, serotonin, Spantant. This nerve mediator affected to jumping, another study showed that Spantant system can increase the jumping in rat (10). Also other researcher showed that the electromagnetic field caused to induction and releasing the acetylcholine in animals cells (11). In this study we showed that magnetic field didn't have any effect on weight loss and this finding accompany with our result of previous study (1). The magnetic field with high frequency and high intensity decrease diarrhea but acetylcholine and piocarpin increase diarrhea (12). By considering the results of this study, we obtained that magnetic field reduce the cholinergic system and acetylcholine in brain cells and also other reports indicated dopamine has affected on climbing and yawning (13, 14, 15). According to results of others study we can guess the electromagnetic field increase serotonin and dinorphine and decrease dopamine and acetylcholine.

LEGISLATIVE NEEDS FOR COMPUTATIONAL EMF EXPOSURE ASSESSMENT THE EUROPEAN DIRECTIVE 2004/40/CE

PAOLO ROSSI, ROSARIA FALSAPERLA

National Institute of Occupational Safety and Prevention (ISPESL) – Rome – Italy
paolo.rossi@ispesl.it, rosaria.falsaperla@ispesl.it

Abstract

The European directive 2004/40/CE on the minimum health and safety requirements regarding the exposure of workers to the risks arising from electromagnetic fields, based on ICNIRP guidelines for occupational exposure, is presented and commented. The resulting needs for computational assessment of workers' exposure in terms of dosimetric quantities is considered and discussed.

I. The European Directive 2004/40/CE

The directive 2004/40/CE [1], on the minimum health and safety requirements regarding the exposure of workers to the risks arising from electromagnetic fields, has been issued in the European Official Journal on May 25, 2004, as the 18th individual directive within the meaning of framework directive on health and safety at work (391/89/EEC). The EMF directive follows the publication of directives on other physical agents, namely 2002/44/CE on vibration and 2003/10/CE on noise. The aim of the directive is the protection from established adverse effects caused by induced currents and by energy absorption, as well as by contact currents. Suggested long-term effects are not addressed, due to the lack of conclusive scientific evidence. The directive lays down minimum requirements giving EU member states the option of maintaining or adopting more favourable provisions for the protection of workers. Like in the previous directives on physical agents, the framework is based on the definition of "exposure limit values" and "action values". The exposure limit values can never be exceeded, whereas the action values are levels at which the employer must undertake technical or organizational measures to reduce exposure. The numerical definition of such values is based, respectively, on basic restrictions (dosimetric quantities) and reference levels (unperturbed fields) established for the workers in the relevant guidelines of the International Commission on Non-Ionizing Radiation Protection (ICNIRP) [2]. The directive claims the employer to give particular attention to any indirect effects, such as interference with medical devices like cardiac pacemakers, and adapt risk assessment and mitigation measures for workers at particular risk. Member states have to transpose the directive into national law within April 2008.

Directive 2004/40 CE claims the employer to a specific risk assessment, and to verify the respect of limits of exposure that are expressed in terms of dosimetric quantities, induction of current and Specific Absorption Rate (SAR). Such evaluation is achievable only by means of simulation computational methods, and in fact the directive often refers to calculations. Moreover, the directive shall be taken into account in the definition of product standards for special families of equipment emitting EMFs, to be used at the workplace. Compliance verification of the basic limits by calculations calls for the use of proper numerical methods able to solve Maxwell's equations, in combination with high resolution models of worker's body, and satisfactory representation of sources and workplace environment.

II. Computational exposure assessment for workers – Critical points

As information technology, numerical methods are increasing and developing very rapidly. Application to more and more complex problems is expectable, like multiple sources and complex environments, but the reliability of results critically depends on the representation of the real problem; any obtainable result refers in fact to the representation scenario and not to the actual problem, otherwise than *in situ* field measurements.

Many of the available numerical methods, that are listed in [3], are implemented on commercial SW packages mostly developed by research teams, provided with digital human body models and CAD tools able to realistically represent sources and environment. A lot of scientific work and applications have been developed, mostly addressed to relatively simply exposure evaluations, like in the case of mobile phones (head) or base

stations and broadcasting (whole body), and specific standards for calculations have been issued by CENELEC and IEC, but extensive application to more complex occupational exposures has not been carried out yet, due to lower public and authority concern.

All simulation packages and components are affected by limitations, advantages and disadvantages, so that the proper choice in a given situation may not be easy. The duration of calculation is one aspect to be considered in relation with the efficiency of the representation. Concerning human body models, the knowledge of dielectric properties of human tissues is still affected by gaps especially at low and intermediate frequencies range, and the available models only refer to very simple postures (erect), even if in occupational exposures the posture of the workers may be very complex. Methods have been introduced for scaling and obtain different body postures but results need to be carefully validated in a wide number of conditions.

III. Needs for computational exposure assessment - Discussion

The provisions from Directive 2004/40/CE pose the need to answer to some basic questions, and identify a logical pathway in order to manage the dosimetry problem. A basic question is to address when numerical dosimetry must be invoked in EMF occupational risk assessment. The first case is a condition where reference/action levels are exceeded, but basic/exposure limits are probably not. Such condition may occur for instance in the case of RF fields strictly confined close to the source, similarly to head exposure from a mobile phone. A second case, to be carefully considered, deals with compliance with local basic restrictions. Guidelines of ICNIRP [2] clearly states that: *"the reference levels are intended to be spatially averaged values over the entire body of the exposed individual, but with the important proviso that the basic restrictions on localized exposure are not exceeded"*. In other words, reference/action levels are able to guarantee compliance with body averaged SAR but don't assure compliance with restrictions on local SAR, which is however crucial when the source is very close to the worker and directly coupled to the body. In the frequency range 10 MHz - 110 MHz, where the electromagnetic energy is mostly absorbed inside legs and limbs, ICNIRP Guidelines [2] and Directive 2004/40/CE provide a reference/action level for feet current that is helpful in order to verify compliance with local SAR limits in the limbs. On the opposite hand, in the "hot spot" frequency range (400 MHz - 3 GHz) localized peaks of energy absorption may concern internal organs, and in such condition the assessment of local SAR by means of numerical dosimetry should be recommended even when the exposure levels (as spatially averaged values over the body) approach the reference/action levels.

Another critical point to be addressed is the accuracy, or approximation, of the representation of the exposure problem. This point needs consideration on sources characteristics, human model, but the surrounding work-place must be taken into account too, especially in the case of presence of metal objects or structures. The choice of proper resolution of the human model is crucial again; too low resolution could lead to unreliable results, but too high one could overload computational time and HW resources.

As a matter of fact occupational exposure assessments based on numerical methods are very complicated and require high level education, to-date available only in research centres or institutes. The possibility of practical use of numerical modeling by the employers for real cases in working environment seems to be very limited, in contrast to the relatively effective use of such technique for large scale manufacturing in standardized condition, bearing in mind however that occupational exposure patterns are much more complicated than general public ones (e.g. SAR in the head with mobile phones), and standardization bodies should carefully consider it.

Simplified models could be useful for performing rough assessment on occupational EMF sources and workers' exposure levels. Worst-case models could be used as intermediate step between field measurements and refined dosimetry. To such aim, extensive comparisons of standard case-studies should be carried out, analyzing the performance of simplified models compared to more sophisticated ones.

EXISTING ELF, IF AND HF ELECTRICAL APPLIANCES AND TECHNOLOGIES PRODUCING HIGH EMF EXPOSURE

MONICA SANDSTRÖM, JONNA WILÉN, KJELL HANSSON MILD

NATIONAL INSTITUTE FOR WORKING LIFE, UMEÅ, SWEDEN

The new EU directive, 2004/40/EU, issued on occupational exposure to electromagnetic fields (EMF), calls for occupational risk assessment and implementation in the EU states national occupational safety and health regulations before April 2008. Commonly, workers are exposed to EMF with a mixture of different frequencies. In most cases the exposure levels are low and not in conflict with the new directive. However, some work situations or occupations need special attention due to risk of high exposure. Following the protocol in the directive, workers exposure to EMFs should be estimated, measured or calculated depending on type of workplace and possible risk of over exposure. One of the assigned issues in the EMF-NET MT2 group is to identify work situations that might be in conflict with the new EU directive. In this review, a number of work situations where there is a risk of high EMF levels will be presented and a few examples are listed below.

At electrolytic processes static magnetic field levels at the operator's location can be about 8-15 mT with an AC rectification's component about 30 %. The fundamental frequency is usually 50-300 Hz.

Magnetic resonance imaging systems use magnets typically from 0.05 T to about 3 T. In addition to static magnetic fields, RF fields (10-100 MHz) and rapidly changing gradient magnetic fields occur in pulse sequences within MRI equipment. The time derivatives of gradient fields (dB/dt) affecting patients vary typically from 1-3 T/s, and exposure of staff to EMF can be significant inside treatment rooms surrounding MRI equipment. The maximum exposure level is about 1 T in front of the magnet, and nurses/technicians staying with patients can be exposed to magnetic flux densities up to 0.2 T, approaching the protection guideline. In the case of performing professional activities very close or inside the magnet's tube, workers can be exposed to higher fields (up to 1-2 T), e.g. during adjutancy or plugging in RF cables of treatment coils, or device cleaning.

Transcranial magnetic stimulation or repetitive transcranial magnetic stimulation (TMS/rTMS) is currently being used in treatments of the central nervous system diseases, for instance, depressive states. During the treatment the therapeutic staff is exposed to a pulsed 100 kHz magnetic field that might exceed the reference values in the EU directive. The time derivative, in some of the measured tests, was in the order of kT/s!

Operators of induction furnaces and heaters are highly exposed to magnetic fields. At a distance of 1 meter from a 1-10 kHz heating equipment, flux densities typically range from 0.03 to 0.5 mT, and may reach 5 mT at 10 cm. Measurements of devices operating at 50 Hz, have shown that at a distance of 20 cm the flux density of the field might exceed 5 mT. At a distance of several meters 0.1 mT have been measured. The reference values in the EU directive (30.7 μ T for 1-10 kHz and 500 μ T for 50 Hz) are exceeded during work procedures close to furnaces.

Welders are one of the occupations that are highly exposed to EMF and thereby in conflict with the new EU directive. Arc welding uses high electric currents up to several hundreds of Amperes. The current, provided by the welding power source, flow through the torch-cable and torch to the welding arc, and into the workpiece and back to the power source via the ground cable. This provides a source for magnetic field to which the worker is exposed during the welding process as the cable can touch the welder or even be wrapped around the shoulder of the welder. Magnetic flux densities are about 1 mT at the surface of the welding cable and power supply, exposing the welders to strong ELF fields. (ref)

Glue dryers in the wood industry and plastic welders are using RF energi by applying a strong RF current between metal electrodes. The output powers range from 1 to 200 kW at the ISMfrequencies of 13.56, 27.12 or 40.68 MHz. Most plastic sealers are operated manually and require the presence of the operator close to the RF electrodes. In some applications, pieces of plastic materials to be heated must be held by hand, so that the operator's hands will be highly exposed to RF fields. Electric field strengths range in areas of operators typically from 1 to 300 V/m, and magnetic fields from 0.1 to 20 A/m, respectively.

Broadcast stations are using high RF energy intentionally radiated into the air. Typical maximum radio and TV transmitting powers fed to the antennas are about 500 kW for LF, MF and HF antennas and 10-50 kW for VHF and UHF antennas. Since the antennas are mounted near the top of a mast at the height of over 200 m, the exposure levels at the ground level are very low, but the occupational exposure can, however, be high during maintenance and installing work inside a mast, and special precautionary actions has to be taken.

A mobile phone base station emit RF fields in the range 450-2200 MHz. With a maximal output power of let say 50 W the EU directive might be exceed within a couple of dm in front of the antenna. In other positions or at a longer distance from the antenna there is no conflict with the directive.

THE FUNDAMENTALS OF OCCUPATIONAL EXPOSURE ASSESSMENT IN REAL LOW AND INTERMEDIATE FREQUENCY EMF ENVIRONMENT

JOLANTA KARPOWICZ, KRZYSZTOF GRYZ

*CENTRAL INSTITUTE FOR LABOUR PROTECTION – NATIONAL RESEARCH
INSTITUTE, LABORATORY OF ELECTROMAGNETIC HAZARDS
WARSAWA, POLAND, e-mail: jokar@ciop.pl*

Abstract

The presentation is based on analysis of the fundamental problems defined for the use of numerical calculations for workers exposure assessment in real occupational situations. The examples of data from workplaces in the vicinity of LF or IF sources will be presented, focusing: space distribution of EMF, complex characteristics of the frequency content, workers activities/moving in the workplace, field impedance, etc., as well as discussion concerning situations when the use of calculations is required.

Keywords: EMF exposure, exposure assessment, numerical calculations, low frequency, intermediate frequency

1. Introduction

Electromagnetic field's (EMF's) exposure assessment adequate to the real exposure level is the crucial step towards appropriate risk assessment for occupational safety and health (OSH) engineering, epidemiological studies of EMF-exposed groups, environmental monitoring. The highest requirements concerning detailed EMF exposure assessment come from the legislations concerning mandatory control of occupational or environmental EMF exposure, e.g. European Directive on workers EMF exposure limitation.

The provisions of the Directive 2004/40/EC permit the employer to use exposure level (external measures of exposure like electric and magnetic field strength, E and H) or dosimetric quantities (internal measures of exposure results like induced current, J , and Specific Absorption Rate, SAR) for the mandatory risk assessment. In the case of EMF of low and intermediate frequencies (LF and IF) the basic internal measure used for exposure assessment is induced current density in head and torso. IEEE standards offer also the use of E field induced in exposed tissues. Both parameters can be used till low MHz frequencies. The use of internal measures require numerical calculations and detailed analysis and interpretation of data obtained from modeling.

EMF from LF and IF range, affecting workers are usually so-called near fields. The impedance of such fields (the ratio of electric fields strength to magnetic field strength) is defined by the technical properties of the EMF-source-worker-body system. Electric voltages and currents in the electric device, producing EMF play important role, but in many cases also the direct coupling between workers body and EMF source modify the exposure conditions. The sources of high level of EMF exposure to time-varying LF or IF fields are basically: high voltages power distribution systems, welding devices, industrial induction heating devices, electro surgery devices. In consequences the most important external measure of exposure is magnetic field strength (or magnetic flux density) assessed following the frequency-dependent exposure limitation in the case of very huge number of welding and induction heating devices. Significant exposure to electric component can be found in practice in the vicinity of high voltage electricity distribution systems. The most complicated situation can be found, when both components (E and H) should be consider, especially when the field impedance can varying significantly during the application, as in the case of electro surgery use.

For the practical EMF exposure assessment at workplace, first of all it should be discussed when it is acceptable to make the EMF exposure assessment by spot measurements with a broad-band RMS meter (i.e. the most convenient and less expensive method). For the other situations, it should be decided the use of more complicated (and more expensive) exposure assessment method: more detailed measurements or dosimetrical calculations.

2. Method

Professional activities of authors is focused on the detailed analysis of occupational EMF exposure characteristics in various enterprises and application of EMF measurements and/or numerical calculations

technique for workers exposure assessment. The presentation is based on analysis of the fundamental problems defined for the use of numerical calculations for workers exposure assessment in real occupational situations.

3. Results

Electromagnetic field (EMF) in the workplace has often very specific characteristics in comparison with the fields from general environment. In working conditions not only the locations of the EMF source and worker's body, but also the geometry of the source, frequency and level of produced EMF in its vicinity, can change significantly, exposure level can be high, even exceeding international safety guidelines.

The analysis of detailed data obtained from various work place and experience with the numerical calculations modeling realistic exposure scenarios for the assessment of the exposure following the internal measures' limitations have shown a number of practical problems, identified for the worker's exposure assessment.

In the most of cases of high level exposure of workers to LF or IF EMF, their professional activities need hand operation of the EMF sources. For the exposure assessment of such cases the modeling of realistic posture of worker's body and possible simplifications of it to reduce the complication and costs of exposure assessment process is of high priority. Important question is on the exposure assessment of hands, especially while hand-operating of EMF sources of high level. The use of calculations for exposure assessment in LF and IF band is more difficult, that RF (with huge experience obtained from mobile phones research) because of:

- the lack of models, transferable from one software to other one, representing realistic EMF occupational sources, already verified by reference data from workplaces and taken as standardized models
- the lack of well verified data on electrical properties of various elements of workplace, as shoes, floor cover, furniture's, etc.
- relatively small number of the scientific data concerning human body models, electrical properties of tissues, numerical calculations procedures, etc. for the assessment of IF fields.

For the wider use of numerical calculations for the assessment of workers EMF exposure, it is of high priority to obtained well verified scientific data concerning

- the possibility to use simplified numerical models of working places and EMF exposure conditions
- the uncertainty of exposure assessment for checking the compliance with the Directive
- the role of frequency components within the exposure assessment procedures
- the assessment of pulsed fields, especially in the case of hand-operated devices, when the repetition time of pulses is not fixed.

The practical use of numerical calculations for the EMF exposure assessment is also problematic because it was not defined when various software packages can be use, and non of currently available software is specialized for workers exposure. Additionally, a few commercial human body models are applicable for selected specialized software only. Separate problem is the calculations of induced and contacts currents, which can be also measured.

4. Conclusion

The use of internal measures of exposure results for risk evaluation is possible only by simulation computational methods, with the use of adequate representation of the workplace environment and worker's body models. Such calculations for particular exposure situations require highly skilled professionals and specialized software. The modeling of real exposure scenario, validation of calculations result and interpretation of obtained data is usually very time-consuming and currently achievable by research centers only. These are reasons why, the possibility of practical use of numerical modeling by the particular employers, especially from SMEs is very limited in contrast to the relatively effective use of such technique for large series manufacturing (e.g. common use electrical devices, like mobile phones handsets). In this respect, the question arises if more simple models are powerful enough for performing roughly assessment of the occupational EMF sources and workers exposure level, while every day's occupational safety and health practice.

ISSUES IN ACTUAL RF ENVIRONMENT OCCUPATIONAL EXPOSURE ASSESSMENT

DINA SIMUNIC

*UNIVERSITY OF ZAGREB, FACULTY OF ELECTRICAL ENGINEERING AND
COMPUTING, UNSKA 3, HR-10000 ZAGREB, CROATIA*

Introduction

Exposure assessment of electromagnetic fields is a topic that gets more importance every day, especially related to Directive 2004/40/EC and EC Recommendation 1999/519. The complexity of interaction between electromagnetic fields and human body makes any kind of analysis (theoretical-analytical, numerical, experimental) difficult. In an actual multi-source radiofrequency environment situation is even worse, due to a consequent complex distribution of electromagnetic fields.

Method

Issues related to actual RF environment, specifically related to multi-frequency, multi-source environment require sound analysis. The number of issues is even bigger in the indoor environment, where a building structure influences the electromagnetic field distribution. In such environment a number of reflections exist, which forms a complex environment of standing waves. Thus, it is necessary to perform a detailed analysis of the field distribution.

The field distribution is the first step in performing exposimetry analysis, as well as dosimetry analysis.

Results

The results of exposimetry and dosimetry analysis indicate the issues addressed by the process, especially related to uncertainty of the analysis. The concerned sources are wireless communications devices, i.e., mobile telephony, Bluetooth and wireless LAN devices, which are located in the indoor and outdoor space. The devices in the outdoor space are treated by analytical methods, whereas in the indoor space, it is impossible to perform even exposimetry analysis without a numerical tool.

Conclusion

The complete dosimetric and exposimetric analysis of the human body in electromagnetic fields can be performed only by a numerical analysis. The needs and necessary requirements of the analysis for a full application for existing legislative acts, especially for Directive, are related to the complex electromagnetic environment which makes albeit difficult dosimetric analysis more complex.

NUMERICAL CODE VALIDATION WITH EMPIRICAL DATA

Dr. PETER GAJŠEK

INSTITUTE OF NON-IONIZING RADIATION, LJUBLJANA, SLOVENIA

Abstract

The development of mathematical dosimetry modeling techniques and powerful computer hardware has resulted in dosimetry modeling as a principle tool in determining EMF exposure. The results of any anatomical model are questionable if the model has not been validated with empirical data obtained from *in vivo* or *in vitro* experiments. Validation of the theoretical with empirical results and the subsequent refining of a model are essential in order to earn the credibility when using these models to establish or revise exposure standards. The increasing acceptance and use of FDTD modeling within the EMF community make it imperative that predictions be compared, and validated against experimental data. With the development of the Finite-Difference Time-Domain (FDTD) code, it is possible to predict whole body and localized SAR values under a wide range of exposure conditions in phantoms and laboratory animals, as well as humans.

In the past, FDTD predictions have been validated mainly for very simplistic geometric models. For far-field sources, simulation results have been compared with analytical results for square [Umashakar and Taflove, 1982], cylinders [Furse et al., 1990], spheres [Gandhi et al., 1992; Gandhi et al., 1999], and plates [Taflove et al., 1985]. Calculations of currents induced in a standing human have compared well with empirical data [Furse et al., 1997]. For near-field sources, simulation results have been compared with analytical, measured or method of moment results for dipole antennas in front of layered half-spaces, layered boxes and homogeneous spheres [Furse and Gandhi, 1998]. In addition, the FDTD method has been validated for near-field testing of realistic cellular telephones next to the human head [Dimbylow and Mann, 1994; Gandhi and Chen, 1995]. Agreement between FDTD code and experimental results (e.g. E-field measurements on simplistic canonical geometries such as box or sphere filled with tissue equivalent material) was excellent and generally within $\pm 20\%$ (± 1 dB) [Gandhi et al., 1999]. However, little direct comparison of empirical data obtained by actual type of organism with SAR values predicted by FDTD modeling exists in the published literature [Walters et al., 2000; Mason et al., 2000].

In this paper, we report on the use of the convergent technologies to validate the use of computational codes to predict SAR values in both, simplistic models (spheres) and actual biological organisms. Since experimental validation requires the implantation of thermal or e-field probes, it is not feasible to perform such studies in human subjects, therefore laboratory animals and phantoms were used. The brain of the rat offers an ideal organ for comparison, due to the reliability of stereotaxic probe placement, as well as the ability to easily confirm probe placements in tissue sections following experimentation [Walters et al., 1998].

Our predicted SAR values obtained by computer models based on FDTD code of spheres and Sprague-Dawley rat were compared to temperature measurements made with implanted probes and infrared thermography model [Gajsek et al., 2001].

ASSESSMENT OF LF AND IF EMF OCCUPATIONAL EXPOSURE

The SAR values were determined thermally. Irradiation was performed at a high exposure level (above 700 mW/cm²) and short exposure duration (30 seconds) to produce a measurable linear temperature rise. This was done to allow accurate quantification of the rate of temperature rise in the absence of any significant thermoregulatory effects. Good correlation between the predicted and empirical phantom and animal data would provide increased confidence in the results predicted by the man model [Mason et al., 2000].

SIMULATION OF ELECTROMAGNETIC FIELDS INCLUDING BIOLOGICAL MODELS WITH CST STUDIO SUITE

MONIKA BALK

CST – COMPUTER SIMULATION TECHNOLOGY

In our modern society technology and simultaneously electronics play an important role. It is almost impossible to avoid electromagnetic field exposure. When evaluating the human body field exposure the always occurring problem is: How to measure it. Most of the time it can't be measured in vivo. Thus, the interaction of electromagnetic fields and biological tissues is a topic of intense research. Therefore, 3D numerical EM simulations have been established as a tool to analyse the effect of the electromagnetic fields caused by the environment on human beings. This effect is usually described by the Specific Absorption Rate (SAR).

The software package CST STUDIO SUITE™ is a specialised tool for evaluating 3D electromagnetic fields, which is based on the Finite Integration Technique (FIT). The software package offers the possibility to import data obtained by medical imaging. With this voxel import the characteristics of the biological tissues are translated into material information used by the simulation software to evaluate the electric and magnetic fields. Based on the electric and magnetic field, the specific absorption rate can be calculated using a mass averaging approach compliant to the IEEE C95.3 standard. Alternatively, own procedures are offered that show improved consistency for structure rotations.

In this talk first of all the Finite Integration Technique fundamentals are described. Furthermore the simulation work flow within the software package is shown. Finally several examples concerning SAR calculations are shown.

BIOLOGICAL EFFECTS OF EXTREMELY LOW FREQUENCY ELECTRIC AND MAGNETIC FIELDS

AHMAD YOONESSI, ARASH MIRHASHEMI

KHAJE NASIR TOOSI UNIVERSITY OF TECHNOLOGY, TEHRAN, IRAN
AMIRKABIR UNIVERSITY OF TECHNOLOGY, TEHRAN, IRAN

Abstract- There has been numerous evidence that exposure to extremely low frequency magnetic and electric fields can produce biological effects. Many of these effects are not clearly understood so far. Most of these researches emphasize on power frequency (50 or 60Hz) and the biological effects at these frequencies. The following paper attempts to describe the current researches toward emphasizing the effects in the Extremely Low Frequency (ELF) range. Lab experiments regarding biological effects of ELF fields have been shown in various organs and the results have been discussed. There is presently no clear and convincing evidence from animal or cellular studies that demonstrates harmful effects of EMF. There are, however, some studies that are suggestive of potential health impacts. From the perspective of laboratory studies, this presentation will discuss biological responses to extremely low frequency electric and magnetic field exposures.

Introduction

With the ongoing advancement in electrical and electronic devices the odds of exposure to electrical and magnetic fields have raised dramatically. More and more people are exposed to electrical and magnetic fields daily. Therefore the need to understanding the effect that these fields have on the human body is significantly important. One of the areas that are often neglected is in the Extremely low Frequency Range (up to 300Hz). At the frequencies this low, the wavelength in air is very long (6000km at 50 Hz and 5000Km at 60Hz) The only area within this range that is on the main focus is the power frequency (50Hz or 60Hz) Since it is the widely found frequency in the environment. This paper tries to summarize the effect on the ELF range without focusing on any special frequency.

Biological effects may sometimes lead to adverse health effects. Biological effect is when exposure to an electromagnetic field produces a noticeable or detectable change in a biological system. An adverse health effect occurs when the biological effect is outside the normal range for the body to compensate and thus leads to some detrimental health conditions. [1], [9], [13]

The primary mechanism of interaction between elf fields and biological system is in the induction of electrical charge and current.

ELF electric fields exist whenever a voltage is present regardless of the current flowing. Almost none of the electric field penetrates into the human body. On the other hand ELF magnetic fields exist whenever a current is flowing. They can easily penetrate into the human body. [1], [9]

Circulatory System

Heart

There have been some studies suggesting that exposure to ELF electric and magnetic fields decreases heart rate [3]. While this studies report this incident, they often characterize it as temporary and within the normal physiological variation. The boundary for this effect is reported as low as $0.1\mu\text{A}/\text{cm}^2$. [3] There have been reports of effect on the blood pressure, Heart rate and electrocardiograph waveform but these studies are limited by uncertainties regarding exposure duration and subsequent control group. [3], [4], [5].

Endocrine system

Melatonin

Some studies suggest that exposure to ELF fields may suppress secretion of melatonin, a hormone related to human day-night rhythm [1], [6]. It has been suggested that melatonin is effective in the prevention of breast cancer and therefore suppressing it will result in an increased incident of breast cancer. Although there is some evidence in laboratory animals, human volunteer studies have not confirmed this report. [1], [7], [8]

Musculoskeletal System

Bone growth and fracture repair

Electrical and magnetic stimulation have been known to have effect on bone fracture repair since 1970. The mechanism which enables these fields to increase new bone formation is still not known. Effect of pulsed EMF on fracture healing have been proven in numerous clinical studies on human and animal subjects.[10],[11] However the mechanism that this interaction takes place is not clearly known so far. Some studies suggest that EMF can increase the secretion of growth hormone IGF-I and IGF-II and therefore increase the healing rate. [12], [14], [15]

Nervous System

Behavior

Many studies have been done to demonstrate the effect of elf magnetic and electric field on human and animal behavior Since nervous system plays a major role in function of all the body and since many of the nervous signals communicate in a form of electrical signal it can be predicted that the elf could alter the behavior.

There has been numerous studies showing the effect of E field on animals such as rats, mice, pigs and birds.[16] Most animals try to avoid exposure to E fields over 50-75kV/m. The exposure to B field shows little evidence on animal behavior in general. [13], [14]

In humans a phenomena known as phosphene is reported in the B fields as low as 20 mT. [13], [19]

Reproductive System

It is known that the developing system is more prone to various environmental hazards. Therefore it is assumed that a developing system is more sensitive in response to electrical and magnetic fields. Studies have been done mostly on animals such as chicken, rats and rabbits. Few studies have been done on human growing organisms such as hair follicles. [13], [16], [17]

Immune System

Cancer and Mutation

The EMF effects on promoting cancer have been studied more than anything else. However few life long studies have been reported. There have been some studies on the effect of 50 or 60 Hz B field on the male and female rats which showed that although the B field can increase the carcinogenic activity it is not effect is not significant.

Evidence of effect of ELF B and E fields on the DNA breaking and tumor initiation has been minimal. Since these frequencies do not possess enough energy to break bonds between molecules and damage DNA. [14], [15]

Summary

The health effects of extremely low frequency EMF still remains a controversial subject as the mechanism of interaction is not yet known. The biggest issue in various experiments regarding these fields is the lack of reproducibility of different outcomes. This will be the case until the clear mechanism of interaction between living systems and electric and magnetic fields
